CHILD SEXUAL ABUSE

Reports suggest that 26% of girls and 5% of boys have experienced some form of sexual abuse by the age of 17 years.[45] When there is concern for possible sexual abuse, determine the best ED method for evaluation; decide when to refer to other professionals and child protection authorities; and decide how to counsel the parents. The child's ED visit may be

triggered by a broad spectrum of issues including anogenital bleeding, vaginal/urethral discharge, dysuria, urinary tract infection, sexualized behaviors, suicidality, or as commonly happens, a recent disclosure of sexual abuse without any specific physical symptoms. The sexual abuse may be either recent or remote relative to the time of presentation and may have involved numerous contacts over a period of time. The offender is typically well known to the child and, indeed, is often a parent or family member.[45-47] As a result, the child's caregivers typically present in emotional crisis, even though the child may not be suffering any physical trauma. The family requires a patient, supportive individual to listen to their concerns and provide appropriate guidance and reassurance.

First begin by assessing the urgency of the situation and determining when and where the full assessment should most appropriately be performed. In some jurisdictions, **sexual assault nurse examiners** or child abuse pediatricians are available. Emergency evaluation with collection of forensic evidence is indicated if the abuse has been recent, the child has genital bleeding or concerns of acute trauma, or there are other concerns for occult trauma. As yet, there is no consensus on the outside limit for the timing of forensic evidence collection in the pediatric patient. Research suggests that physical examination should be performed as soon as possible after an assault, yet evidence collection is unlikely to produce positive results in child victims outside the first 24-hour period.[48] Whether or not forensic evidence is collected, an immediate physical examination is recommended for all children disclosing sexual abuse within 72 hours of the last event.[49,50] Physicians should be aware of the policies for the timing of forensic evidence collection within their own jurisdiction.

CLINICAL FEATURES

There are numerous factors that make conclusive evaluation of alleged child sexual assault challenging:

- **The medical diagnosis of sexual abuse is heavily reliant on the history provided by the child.**[47,51] A proper forensic interview should be conducted by trained child protection investigators.
- **The absence of physical findings does not exclude abuse.**[47,51-54] Many sexually abusive activities leave no physical marks on the child, and in the rare instances where traumatic injuries do occur, they often heal well, with no obvious evidence of prior injury.
- **Forensic evidence is most often lacking in child sexual abuse.**[47-49,55] Forensic evidence may include blood, seminal fluid, sperm, saliva, or other foreign debris. The likelihood of obtaining forensic evidence from the prepubertal child is low, and the majority of evidence will be found on linens or clothing.[47,48,55]

History Obtain the initial historical details from ancillary personnel (parents, guardians, police, or social workers) without the child present. Often the most compelling evidence for criminal prosecution is the detailed, forensic interview of the child performed by child protection investigators. Thus, direct questioning of the child by the emergency physician should be limited to a medical history that addresses acute physical symptoms or concerns only. Record verbatim any spontaneous disclosures or statements of significance that the child makes during the course of the history or physical examination.

Document past medical history including any previous genitourinary trauma, urinary tract or anogenital infections, discharge, or toileting concerns. Note immunization status and any recent medications.

Physical Examination Much emphasis is placed on the importance of the physical examination, even though most pediatric victims of sexual abuse have a normal examination. If the child's disclosure suggests the abuse was remote to the time of presentation, then a straightforward physical examination to ensure that the child is currently physically well may be all that is required in the ED. All children should have a parent or supportive adult who is known to them present during the examination. Explain the procedure for the assessment prior to beginning the examination, addressing any parental concerns in advance. For the child, a simple age-appropriate review of systems generally guides them through the various body parts being evaluated. Do not force the examination. Subtle distraction techniques and frequent gentle reassurance are helpful. If the child remains uncooperative, decide whether the examination should continue under procedural sedation or general anesthesia or whether the assessment can be rebooked for a future time.

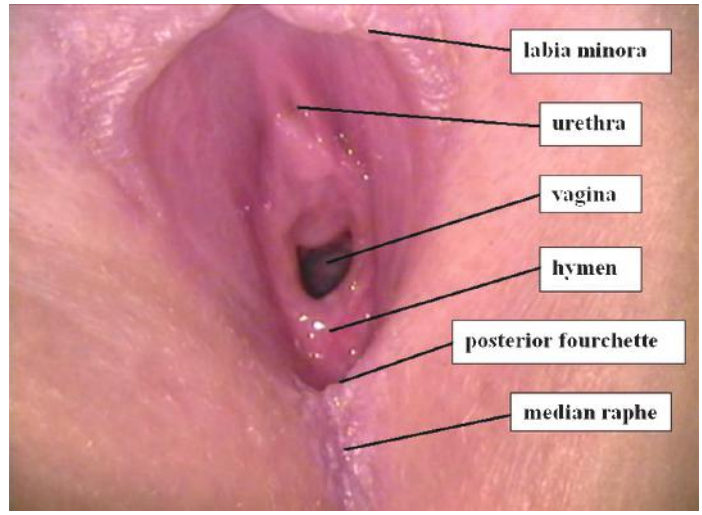

FIGURE 148-6. Normal prepubertal genital anatomy.

A complete examination begins with a comment on the child's overall appearance including emotional state and demeanor. Prior to palpation, ask the child about any painful areas. Thoroughly inspect all parts of the skin and hair and document bruises, petechiae, abrasions, areas of swelling, or bite marks. Carefully examine the oropharynx for signs of trauma.

Anogenital Examination Examination of the anogenital area can generally be accomplished with inspection only. The supine, frog-leg position optimizes visualization of the genital structures. Speculum examinations are not required in the prepubescent child. If the hymenal margin is not well visualized while supine, or if abnormalities are suspected, then examine the child in the prone knee-chest position. This position allows gravity to pull the margins of the hymen down into clearer view. Toddler-age children who are reluctant to undergo genital examination may be examined while lying supine in the parent's lap.

A systematic approach to anogenital examination is helpful to ensure complete documentation. Initial inspection details the appearance of the labia majora, labia minora, and the posterior fourchette. With gentle separation and traction of the labia, the clitoris, urethra, hymen, vaginal vault, and fossa navicularis come into view (**Figure 148-6**). Describe relevant findings using a "clock face" orientation, with 12 o'clock being anterior/superior and 6 o'clock being inferior/posterior. Document any evidence of trauma including bruising, bleeding, edema, lacerations, or abrasions. Accidental genital trauma typically results in bruises or abrasions to the labia or posterior fourchette. The hymen is rarely injured with accidental trauma given its more protected, recessed position. Note all nonspecific findings of erythema, ulceration, hypopigmentation, or discharge. Describe the hymen by noting both the shape and the integrity of the hymen margin (**Figure 148-7**). Typically the hymen is thickened and redundant at both infancy and puberty, due to maternal hormonal effect at birth and endogenous hormonal effect later. Small mounds (bumps), tags, or rolled edges are common nonspecific findings contributing to a wide degree of variation in normal genital morphology.[51] Note any deep notches or clefts to the rim of the hymen as well as any transections, either acute or healed, that extend to the base of the hymen. Acute superficial lacerations generally heal well with no intervention; however, deeper lacerations with extension into the vagina are less common and should be assessed by a gynecologist.

Genital examination of young boys is generally more straightforward. Note the presence of past circumcision and document any evidence of acute trauma including bruises, bite marks, or petechiae.

Anal examination of both boys and girls is most often normal or nonspecific; however, make note of any acute physical findings including bruising, abrasions, fissures, or edema. Recent anal trauma may result in either spasm of the anal sphincter or anal dilatation. Minor anal dilatation is a normal finding, particularly if there is stool present in the rectal vault. Anal dilatation of greater than 2 cm is concerning for a

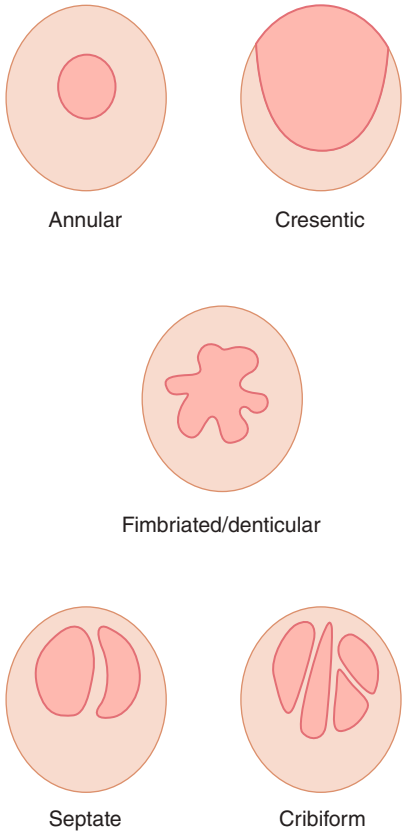

FIGURE 148-7. Normal hymen morphology.

history of trauma but should be interpreted with caution if there has been no disclosure of sexual abuse.[51]

Laboratory and Forensic Investigation Initial investigation is dictated by history and clinical findings. If the child appears stable, laboratory investigations may be limited to assessment for sexually transmitted infections (STIs) and/or forensic evidence collection.

Sexually Transmitted Infections The prevalence of STIs in the pediatric abuse population is exceedingly low, often less than 1% to 4%.[56,57] Current recommendations suggest testing for the presence of STIs in high-risk situations only.[49] High-risk situations include the following: presence of genitourinary symptoms or injury; assailant has or is at high risk for STI; a sibling has an STI; or parents or patient request testing. A non–clean catch urine should be sent for nucleic acid amplification technique testing for gonorrhea and *Chlamydia*. Although urine nucleic acid amplification technique testing is an acceptable standard for vaginal infections, it is not yet approved for rectal or oral swabs. For forensic purposes, positive tests should be confirmed with culture or with a second nucleic acid amplification technique probe. Vesicles or ulcerations are not common in the pediatric patient and, if present, should be swabbed for viral studies. Serologic studies for syphilis and the human immunodeficiency virus are not routinely indicated but may be considered if clinical suspicion warrants or if requested by the patient or parent.

Forensic Specimens Be familiar with the forensic evidence collection kits provided by the criminal investigation units in your area. All forensic specimens must be properly labeled and packaged, with appropriate chain-of-evidence documentation. Place the child's underwear and clothing (if worn at the time of the assault) in a paper bag and then seal the bag. Obtain forensic swabs from any areas suspicious for oral, genital, or ejaculatory fluid contact. Examination with Woods light may help guide collection of specimens.

TREATMENT AND DISPOSITION

Treatment begins at initial contact with the family. A timely assessment performed by a reassuring health professional is often the first step toward a positive therapeutic outcome for both the patient and family. If the history involves significant behavioral or emotional concerns, a referral to mental health professionals may be indicated on either an urgent or elective basis depending on the child's current state.

Pharmacologic treatment should be dictated by the individual's history and physical examination findings. Pregnancy and STI prophylaxis are not routinely recommended in the young pediatric patient following a disclosure of sexual abuse; however, they should be considered for older girls and adolescents.[49,58] Arrange counseling and follow-up in an outpatient setting to ensure appropriate repeat assessment. It is important to ensure resolution of any physical injuries, to assess for any new symptoms, and to inquire as to any emotional or behavioral sequelae.

MEDICAL CHILD ABUSE

Medical child abuse, which has been known in the past as **Munchausen syndrome by proxy** or **pediatric condition falsification**, has also been termed **caregiver fabricated illness**.[59] This condition is an uncommon form of child abuse in which a parent or caregiver induces or fabricates illness or injury in a child. Cases are generally highly complex, often necessitating detailed and comprehensive assessments by multiple subspecialty pediatric teams. Although the role of the emergency physician may seem minor, it is often the detailed emergency documentation of numerous clinical presentations and responses to investigation and intervention that provides objective information needed for eventual diagnosis.

Be alert to the possibility of this condition when presented with a pediatric case that involves persistent or recurrent illness that is not adequately explained and yet results in multiple medical or surgical procedures. Often the medical diagnoses that the caregiver describes do not match the objective findings, and the child tends not to respond to the usual therapies. Hospitalization is often required to coordinate a multidisciplinary evaluation.

REPORTING

Although laws governing the reporting of suspected child maltreatment vary around the world, in all states and provinces in the United States and Canada, **any physician who has reason to believe that a child is at risk of abuse or neglect has a legal obligation to report to local child welfare authorities**. The legal duty to report overrides any duty of patient confidentiality. It is not necessary to be certain of the diagnosis of abuse, but one should have *reasonable suspicion* that abuse or neglect may have occurred. Healthcare providers reporting concerns of suspected maltreatment are protected from civil litigation. Reports must be made in a timely manner because the risk of future maltreatment to other children in the home must be considered.

Informing parents of your obligation to report to child protection services should be respectful and nonaccusatory. Communication should focus on accurately identifying the underlying medical problem, managing the child's injuries, and providing honest, straightforward medical information.

In some cases, particularly when parents are engaged in legal custody disagreements, the history may be quite vague and the physical examination may be entirely normal. If the only concern for abuse or neglect is with the parent or guardian and there is no disclosure from the child and no witnessed abuse or concerning physical findings, then the emergency physician may provide the parent with the appropriate information to make a report on their own. Be familiar with local laws and the methods for reporting. If uncertainty exists about the need to report, consult with a child abuse pediatric specialist.

CHAPTER 149

Sexually Transmitted Infections

Flavia Nobay
Susan B. Promes

INTRODUCTION

Sexually transmitted infections (STIs) are a major public health problem. In 2010, there were 1,307,893 cases of chlamydia infection, 309,341 cases of gonorrhea, and 45,834 cases of syphilis reported in the United States.[1] The World Health Organization estimates that 500 million people are infected each year by a curable STI.[2]

The primary medical goals are identifying and treating STIs, but important secondary goals include preserving future health (including fertility), protection of any sexual contacts, preventive education, and provision of instructions for future screening. Lack of treatment can contribute to infertility, cancer, and urogenital complications. Failure of patients to follow up and adhere to a prescribed medical regimen complicates individual care and public health reduction efforts.

Multiple STIs frequently occur together. Once an STI is diagnosed, further testing for human immunodeficiency virus (HIV) infection and hepatitis B is warranted.[3]

Because of frequent changes in treatment guidelines and resistance patterns, we recommend that the reader access the *Morbidity and Mortality Weekly Report* (http://www.cdc.gov/mmwr) to check any modifications for treatment and also to obtain patient information in several languages.

GENERAL PRINCIPLES FOR DIAGNOSIS AND SCREENING

The signs and symptoms of an STI may be obvious, such as a genital lesion or vaginal discharge, or less specific, such as dysuria, lower abdominal pain, painful intercourse, or spotting and abnormal periods. Less specific signs lead to frequent ED STI underrecognition. Obtain a thorough sexual history in an objective, nonjudgmental manner to determine the risk of STI, HIV infection, or hepatitis. The young (13 to 24 years old), pregnant women, and homosexual men are all at higher risk of STI and subsequent morbidity. The Centers for Disease Control and Prevention have questions that providers can use when obtaining a sexual history and determining a patient's risk for an STI (**Table 149-1**).

Perform a pregnancy test in all females of childbearing potential, because pregnancy can affect treatment options. As appropriate, have chaperones present whenever breast, genital, or rectal examinations are performed. In women, perform a vaginal speculum examination, bimanual examination, and rectal examination. In males, retract the foreskin in uncircumcised patients to fully examine the area. Examine the areas between skinfolds, particularly in obese patients. Obtain directed site test specimens, which may include urine, vaginal, rectal, and urethral samples.

GENERAL RECOMMENDATIONS FOR TREATMENT AND FOLLOW-UP

Based on advice from the Centers for Disease Control and Prevention, we recommend the following[3,5] (**Table 149-2**):

1. When an STI is suspected, especially for gonorrhea and chlamydia infection, treat the patient in the ED with single-dose antibiotic regimens.
2. Obtain a pregnancy test and consult or refer promptly if the patient is pregnant.
3. If one STI is suspected or diagnosed, screen for other STIs (HIV infection, syphilis, and hepatitis) in the ED or through follow-up.
4. Report any notifiable infections such as *Chlamydia trachomatis*, gonorrhea, HIV infection, and syphilis. This is often based on final laboratory testing and can be automated.
5. Counsel all patients with suspected STIs about prevention and co-infection risks (notably HIV and hepatitis) in the ED and ensure follow-up options. Although no method aside from abstinence is 100% effective for STI prevention, male latex condoms and female condoms are useful in preventing STIs.
6. Advise that the partner(s) must seek treatment before any reengagement in sex.
7. Arrange follow-up to ensure relief of symptoms, compliance, and STI cure.

Although the Centers for Disease Control and Prevention recommend that health care providers in all settings routinely screen for HIV infection in all patients aged 13 to 64 years, the ED remains an underused venue for HIV screening.[6] Rapid HIV testing in the ED is not routine but is becoming more prevalent.[7]

SEXUALLY TRANSMITTED INFECTIONS PRESENTING WITH URETHRITIS, CERVICITIS, AND/OR DISCHARGE

CHLAMYDIAL INFECTIONS

Clinical Features In the United States and the United Kingdom, *C. trachomatis* infection is the most frequently reported STI. It is one of the causes of nongonococcal urethritis and commonly coexists with gonorrhea infections. It is most prevalent in people <25 years of age and is frequently asymptomatic, especially in women.[7]

Chlamydial infections in men can cause urethritis, epididymitis, proctitis, or Reiter's syndrome (urethritis, conjunctivitis, and rash). Women generally have asymptomatic cervicitis when infected with *Chlamydia*, although if present, symptoms include vaginal discharge, bleeding between menses, and dysuria. The discharge may be mucopurulent (**Figure 149-1**) when *Neisseria gonorrhoeae* is a co-infectant. **Consider urethral chlamydial infection in the differential diagnosis of sterile pyuria.** Complications in women include pelvic inflammatory disease, ectopic pregnancy, and infertility.

Diagnosis Nonculture methods of detection, such as direct immunofluorescence, enzyme-linked immunosorbent assays, nucleic acid hybridization tests, and nucleic acid amplification testing (NAAT), are preferred tests for diagnosis. NAAT has a high sensitivity (90%) and specificity (99%) for *Chlamydia*. NAAT is approved by the U.S. Food and Drug Administration for urine testing, and some tests are approved for use with vaginal specimens.

Treatment The Centers for Disease Control and Prevention recommend single-dose azithromycin or twice-a-day doxycycline for 7 days.[9] Table 149-2 lists dosages and alternative treatment options.[3] Azithromycin is safe for pregnant women, and pregnant women should undergo a test of cure 3 to 4 weeks after treatment. Amoxicillin is a safe alternative in pregnancy if azithromycin cannot be given.

Refer partners for testing and treatment if there was sexual contact in the last 60 days. Some providers choose to have the patient deliver

TABLE 149-1 Centers for Disease Control and Prevention Recommended Questions for the Five Ps of Sexually Transmitted Infection (STI) Prevention[4]

1. *P*artners
   - "Are you currently sexually active?" "If no, have you ever been sexually active?"
   - "In recent months, how many sex partners have you had?"
   - "Are your sex partners men, women, or both?"
2. *P*revention of pregnancy
   - "Are you currently trying to conceive or father a child?"
   - "Are you concerned about getting pregnant or getting your partner pregnant?"
   - "Are you using contraception or practicing any form of birth control?" "Do you need any information on birth control?"
3. *P*rotection from STI
   - "Do you and your partner(s) use any protection against STI?" "If not, could you tell me the reason?"
   - "If so, what kind of protection do you use?"
   - "How often do you use this protection?" "If 'sometimes,' in what situations or with whom do you use protection?"
   - "Do you have any other questions, or are there other forms of protection from STI that you would like to discuss today?"
4. *P*ractices
   - "What kind of sexual contact do you have or have you had? Genital (penis in the vagina)? Anal (penis in the anus)? Oral (mouth on penis, vagina, or anus)?"
5. *P*ast history of STI
   - "Have you ever been diagnosed with an STI?" "When?" "How were you treated?"
   - "Have you had any recurring symptoms or diagnoses?"
   - "Have you ever been tested for HIV or other STI?" "Would you like to be tested?"
   - "Has your current partner or any former partners ever been diagnosed or treated for an STI?"
   - "Were you tested for the same STI(s)?" "If yes, when were you tested?" "What was the diagnosis?" "How was it treated?"

Abbreviation: HIV = human immunodeficiency virus.

treatment to their partners—endorsed by the Centers for Disease Control and Prevention—as a way of preventing the spread of this STI. Universal adoption of this method at this time is incomplete because of ethical issues and medicolegal consequences including some state prohibitions.[10]

Counsel patients to avoid sexual contact until 7 days have elapsed after completion of antibiotic treatment and their symptoms have resolved. Encourage women to be retested approximately 3 months after treatment because of the high incidence of recurrence.[3]

GONOCOCCAL INFECTIONS

Gonorrhea is the second most commonly reported STI, caused by *N. gonorrhoeae,* a gram-negative diplococcus.

Clinical Features Most gonococcal infections in women are asymptomatic, and many coexist with chlamydial infection. Subclinical gonorrheal infections result in complications ranging from ectopic pregnancy to chronic pelvic pain to pelvic inflammatory disease.[8,9] Women who are symptomatic from a gonoccal infection tend to present with nonspecific lower abdominal discomfort and mucopurulent cervicitis after a 7- to 14-day incubation period. Eighty percent to 90% of men develop symptoms within 2 weeks of exposure. In men, dysuria and profuse, purulent penile discharge (**Figure 149-2**) are the most common presenting symptoms, but symptoms of acute epididymitis and prostatitis may result in an ED visit. Rectal infection with mucopurulent anal discharge and pain occurs in 30% to 50% of women with gonococcal cervicitis, and the rectum can be the only site of infection in homosexual men. *N. gonorrhoeae* also can be isolated from the pharynx but rarely causes pharyngitis.

Signs and symptoms of **disseminated gonococcemia** are petechial or pustular acral skin lesions on an erythematous base (**Figure 149-3**), asymmetric arthralgias, tenosynovitis or septic arthritis, and fever or general malaise. Infection with *N. gonorrhoeae* and other STIs is associated with increased HIV shedding.[11]

Diagnosis The Centers for Disease Control and Prevention recommend that NAAT be performed on cervical, vaginal, urethral, or urine specimens. Specimens can be self-collected by the patient. Not all NAAT is the same; some tests can be used only on certain specimen types, so know what is available at your institution. Culture and nucleic acid hybridization tests require endocervical or urethral swab specimens.

In men, a Gram-stained specimen with the classic intracellular diplococci and polymorphonuclear leukocytes confirms the diagnosis. This diagnostic method is not recommended as a screening tool for asymptomatic men and is not sufficient for endocervical, pharyngeal, or rectal specimens. Diagnosis of disseminated gonococcal infection is difficult, with only 20% to 50% of cultures of blood, lesion, and joint specimens yielding positive results. Culture of cervical, rectal, and pharyngeal specimens may improve the chance of diagnosis.

Treatment Given emerging resistance patterns, the Centers for Disease Control and Prevention recommend dual therapy with ceftriaxone 250 milligrams IM or cefixime 400 milligrams PO plus either azithromycin 1 gram or doxycycline 100 milligrams PO twice a day for 7 days for the treatment of gonorrhea (Table 149-2).[3,5] Fluoroquinolones are no longer recommended for first-line treatment of gonorrhea because of antibiotic resistance. Pregnant women should be treated with a cephalosporin or, if allergic, with 2 grams of either azithromycin PO or 2 grams of spectinomycin IM (not available in the United States) in a single dose. Instructions to sexual contacts are the same as with chlamydial infections. Treat disseminated disease with higher doses of ceftriaxone (1 gram IM or IV every 24 hours for 1 to 2 days) followed by cefixime 400 milligrams PO twice a day for a minimum of 1 week. Gonococcemia requires hospitalization for IV administration of antibiotics and evaluation for possible endocarditis and meningitis. Patients with gonococcal arthritis rarely require surgical drainage and irrigation of affected joints.

NONGONOCOCCAL URETHRITIS

Nongonococcal urethritis is diagnosed when *N. gonorrhoeae* is absent in someone with clinical symptoms. Although nongonococcal urethritis is usually caused by *C. trachomatis,* other causes of nongonococcal urethritis include *Ureaplasma urealyticum*, *Mycoplasma genitalium*, *Trichomonas vaginalis*, herpes simplex virus, and adenovirus. Alternative pathogens are seen more often in older men, and often no singular pathogen is identified. Specific tests for *U. urealyticum* and *M. genitalium* are not indicated.

If a patient's urethral specimen has five or more white blood cells per oil immersion field or the first-void urine specimen suggests infection, treat empirically as chlamydial urethritis. If the symptoms persist, the patient was noncompliant with their prior treatment regimen, the patient was exposed to a new sexual partner, or the previous partner was not treated, repeat treatment for chlamydial urethritis. Otherwise, obtain a specimen for culture for *T. vaginalis* and treat with metronidazole, 2 grams as a single oral dose, or with a combination of tinidazole, 2 grams PO, plus azithromycin, 1 gram PO as a single dose.

TRICHOMONAL INFECTIONS

T. vaginalis is a flagellated protozoan that causes urogenital infections mostly in women, with a prevalence of approximately 3%. The Centers for Disease Control and Prevention recommend routine screening for *Trichomonas* in women with abnormal vaginal discharge. *T. vaginalis* infection is associated with a high prevalence of coinfection with other STIs, notably HIV.[12,13]

Clinical Features Trichomoniasis can range from asymptomatic carrier states to severe, inflammatory disease, and incubation can be 3 to 28 days. The symptomatic presentation commonly has vulvar irritation and a malodorous, thin watery discharge with associated burning, pruritus, dysuria, urinary frequency, and dyspareunia, and occasionally low abdominal pain. Symptoms can worsen during menstruation. The classic yellow-green, frothy discharge is infrequently found, and many

TABLE 149-2 Treatment of Sexually Transmitted Infections

Sexually Transmitted Infection	First-Line Treatment	Alternative(s)	Pregnancy/Lactation
Bacterial vaginosis	Metronidazole, 500 milligrams PO two times daily × 7 d	Tinidazole, 2 grams PO daily × 3 d	Metronidazole, 500 milligrams PO two times daily × 7 d

women have minimal symptoms.[3] Physical examination is consistent with an irritated vulvar region with inflamed vaginal mucosa, and punctate cervical hemorrhages may also be seen. In men, the disease is often asymptomatic but may present as urethritis.

Diagnosis Microscopic confirmation of the classic motile parasites is diagnostic. Protozoan motility is present for 10 to 20 minutes after collection, making wet preparations of cervical smears or spun urine samples not sensitive. Culture is the most sensitive and specific test available, although it may take up to 7 days to obtain results. Because of this delay to diagnosis, commercially available tests using DNA probes and monoclonal antibodies are used in some institutions.

Treatment Patients should avoid intercourse for about 1 week after the last dose of antibiotics. All patients with *Trichomonas* infection should be treated irrespective of symptoms, and sexual partners should be treated to prevent reinfection. Metronidazole, 2 grams PO in a single dose or 500 milligrams PO twice daily for 7 days, cures 90% to 95% of patients.[13] Single-dose regimens are associated with better adherence and less vaginal candidiasis, whereas the lower dose, prolonged course has fewer systemic side effects.[3] Patients must avoid alcohol when taking metronidazole given the disulfiram-like reaction. Metronidazole gel is less effective than oral treatment.[13]

Trichomonas infections are linked to an increase in pregnancy-related complications. Because **metronidazole is a pregnancy category B drug**, it is the drug of choice for treating symptomatic pregnant patients, with no evidence linking metronidazole exposure with teratogenic effects.[14] Despite the Centers for Disease Control and Prevention recommendations of a 2-gram singular dose coupled with evidence supporting the safety of metronidazole treatment in symptomatic pregnant women, some clinicians avoid oral treatment in the first trimester. Treatment of partners includes administration of the same medications as for the patient plus an STI clinic referral given the high rate of co-transmission of other STIs.

SEXUALLY TRANSMITTED INFECTIONS PRESENTING WITH GENITAL ULCERS

Genital ulcers are caused by syphilis, herpes virus infection, chancroid, lymphogranuloma venereum, and granuloma inguinale (donovanosis). These infections have high rates of co-infection with HIV. Not all infections associated with genital ulcers are sexually transmitted. Characteristics of the lesions and their accompanying signs and symptoms are provided in **Table 149-3**.

SYPHILIS

Treponema pallidum, a spirochete, is the causative agent of syphilis as well as yaws and pinta. The organism enters the body through mucous membranes or nonintact skin. *T. pallidum* remains very sensitive to penicillin. The incidence of syphilis in the United States was on the rise from 2001 to 2009, possibly because of behavior associated with drug use and male-to-male transmission.[1]

Clinical Features Syphilis consists of three phases: primary, secondary, and tertiary or latent syphilis. The disease may be diagnosed in any of these three stages.

A

B

FIGURE 149-3. Disseminated gonococcal infection. **A.** Maculopapules on the hands. **B.** Lesion on the extensor surface of the wrist in a sexually active adult female. The macropapule has a petechial component and an erythematous periphery.

TABLE 149-3 Clinical Features of Genital Ulcerative Infections

Disease	Clinical Diagnosis	Presence of Pain	Inguinal Adenopathy	Comment
Syphilis	Indurated, relatively clean base; heals spontaneously	No	Firm, rubbery, discrete nodes; not tender	Primary: chancre Secondary: rash, mucocutaneous lesions, lymphadenopathy Tertiary: cardiac, ophthalmic, auditory, central nervous system lesions
Herpes simplex virus infection	Multiple small, grouped vesicles coalescing and forming shallow ulcers; vulvovaginitis	Yes	Tender bilateral adenopathy	Cytologic detection insensitive; false-negative culture results common; type-specific serologic test
Chancroid (*Haemophilus ducreyi*)	Multiple painful, irregular, purulent ulcers with potential exudative base	Yes	50% painful, suppurative, inguinal lymph nodes potentially requiring drainage	Cofactor for human immunodeficiency virus transmission; 10% have co-infections with herpes simplex virus infection or syphilis
Lymphogranuloma venereum	Small and shallow ulcer, associated proctocolitis with fistulas and strictures	No	Tender lymph nodes	Caused by *Chlamydia trachomatis* L1, L2, L3
Granuloma inguinale (donovanosis)	Painless, beefy red, bleeding ulcers	No	No	Endemic in Africa, Australia, India, New Guinea; rare in United States

Primary syphilis, or the initial stage of infection, is characterized by a painless chancre with indurated borders on the penis (**Figure 149-4**), vulva (**Figure 149-5**), or other areas of sexual contact.

The incubation period is approximately 21 days, with lesions disappearing after 3 to 6 weeks. There are no constitutional symptoms, and a lesion may even be absent with primary disease. The lesion resolves spontaneously.

Secondary syphilis develops 3 to 6 weeks after the end of the primary stage and is characterized by rash and lymphadenopathy. Nonspecific symptoms of sore throat, malaise, fever, and headaches are common. The rash often starts on the trunk (**Figure 149-6**) and flexor surfaces of the extremities, spreading to the palms (**Figure 149-7**) and soles. The rash takes on many forms but is often dull red-pink and papular. Secondary syphilis resolves spontaneously.

Tertiary or latent syphilis develops in about one third of patients after secondary syphilis, occurring 3 to 20 years after the initial infection. Involvement of the nervous and cardiovascular systems is characteristic, with widespread granulomatous lesions (gummata). Specific manifestations include meningitis, dementia, neuropathy (tabes dorsalis), and thoracic aneurysm.

Diagnosis *T. pallidum* cannot be cultured in the laboratory, and there is no single optimal test. The sensitivity and specificity of tests for syphilis depend on the stage of the disease and the type of test. Direct visualization of the organism using darkfield microscopy is diagnostic of primary, secondary, or early congenital syphilis, no matter what the results on serology. However, failure to visualize the organism does not exclude syphilis. Nontreponemal tests (Venereal Disease Research Laboratory

[VDRL] test, rapid plasma reagin test) detect nonspecific antibodies to cardiolipins, which are released as a result of infection. The VDRL and rapid plasma reagin tests are used as screening tests and also, once diagnosis is made, to assess disease activity and response to treatment. If used for screening, the VDRL and rapid plasma reagin tests are associated with both false-negative and false-positive results. Tests do not become positive until about 1 to 4 weeks after a chancre appears. Positive results must be confirmed with an immunoassay specific for *T. pallidum* antibodies. Some laboratories now begin the testing sequence with sensitive and specific *Treponema*-specific assays (reverse screening) and follow response to treatment with nontreponemal tests.[15]

For **secondary syphilis**, nontreponemal antibody tests are nearly 100% sensitive with high specificity.[16] The blood of treated patients usually becomes nonreactive on nontreponemal antibody tests. **Patients who develop disease and have a reactive result on a specific treponemal antibody test will have a reactive test result for life regardless of disease activity or treatment.**

A presumptive diagnosis of syphilis is made if a positive result on a nontreponemal antibody test (i.e., rapid plasma reagin or VDRL) is supported by a positive confirmatory result on a treponemal antibody test (i.e., fluorescent treponemal antibody absorption test).[16,17] Treat based on strong clinical grounds while results of confirmatory tests are pending, if follow-up is uncertain. When uncertain about testing interpretation, review the Centers for Disease Control and Prevention Web site (http://www.cdc.gov/STD/syphilis/default.htm) for detailed clarification of laboratory diagnosis or contact the local health department.

Treatment **For primary and secondary syphilis** treat with penicillin G benzathine, 2.4 million units IM in a single dose. Doxycycline twice daily for 2 weeks may be used in penicillin-allergic patients (Table 149-2). Pregnant women should be treated with parenteral penicillin G; if allergic, they must be desensitized and then given this medication. The **Jarisch-Herxheimer reaction** occurs most frequently in treatment of early syphilis and is characterized by an acute febrile reaction associated with headache and myalgias within the first 24 hours after treatment. Inform patients about this possible reaction. Recommend treatment of sexual partner(s) exposed in the previous 90 days. For a more detailed explanation of partner treatment, please refer to the Centers for Disease Control and Prevention Web site: http://www.cdc.gov/std/ept/default.htm.

Treat **tertiary syphilis** with 2.4 million units of penicillin G benzathine IM weekly for 3 weeks. Either a primary care physician or the department of public health should closely follow all patients for repeat serologic testing at 6 and 12 months.

HERPES SIMPLEX INFECTIONS

Herpes simplex virus (HSV) type 1 or type 2 infections are lifelong. Genital herpes is caused by exposure of mucosal surfaces or nonintact skin to the HSV virus. Approximately 25% of the U.S. population has serologic evidence of herpes infection. Most genital infections are caused by the HSV-2 virus; but anogenital infections are also caused by HSV-1.[18] Only 10% to 25% of individuals who are HSV-2 seropositive report a history of genital herpes, which suggests that most infected people have unrecognized symptomatic or completely asymptomatic infections. Viral shedding in persons who are unaware that they are infected is likely responsible for the majority of HSV transmission.[3]

Clinical Features "Classic" outbreaks of primary genital HSV infection begin with a prodrome lasting 2 to 24 hours that is characterized by localized or regional pain, tingling, and burning. Next, constitutional symptoms of headache, fever, painful inguinal lymphadenopathy, anorexia, or malaise are common. Women are more likely to have constitutional symptoms than men. As the disease progresses, papules and vesicles on an erythematous base become evident. The vesicles erode in hours to days. Patterns of HSV-1 and HSV-2 infection appear identical: vesicles usually are uniform in size, and the tense center umbilicates to form a depressed center. Lesions usually crust and then re-epithelialize and heal without scarring.

In men, HSV ulcers often appear on the shaft or glans of the penis (**Figure 149-8**). In women, ulcers can occur on the introitus (**Figure 149-9**), urethral meatus, labia, and perineum. Lesions are exquisitely painful and sometimes are associated with serous discharge. In

FIGURE 149-8. Genital herpes in a male. These formerly vesicular lesions have crusted over. [Reproduced with permission from Goldsmith LA, Katz SI, Gilchrest BA, et al: *Fitzpatrick's Dermatology in General Medicine*, 8th ed. © 2012 by McGraw-Hill Inc., New York.]

FIGURE 149-9. Genital herpes in a female. These formerly vesicular lesions have crusted over. [Reproduced with permission from Goldsmith LA, Katz SI, Gilchrest BA, et al: *Fitzpatrick's Dermatology in General Medicine*, 8th ed. © 2012 by McGraw-Hill Inc., New York.]

both sexes, lesions may be found on the perianal area, thighs, or buttocks. Dysuria is common in women and may progress to urinary retention secondary to severe pain.

Complete healing usually occurs within 3 weeks, and viral shedding persists for 10 to 12 days after the onset of the rash. Recurrent outbreaks generally are milder than the initial episode. There are typically fewer grouped lesions, and viral shedding occurs at a lower concentration and for a shorter duration (i.e., about 3 days).[19] The disease can be transmitted despite the absence of ulcers.

Diagnosis Diagnosis is usually made on clinical features. If uncertain, a Tzanck test may demonstrate large intranuclear inclusions. Laboratory diagnosis is either by cell culture or polymerase chain reaction. When obtaining a specimen for analysis, puncture the vesicle and swab the fluid. Swab the base of the lesion vigorously, because the virus is cell associated.[3] Lack of HSV detection does not indicate a lack of HSV infection, because viral shedding is intermittent.

Treatment Treatment hastens recovery but does not cure. Antiviral medications decrease the time until all lesions are crusted and healed, decrease pain and constitutional symptoms, and decrease the period of viral shedding by several days.[3]

Treat the first clinical episode with acyclovir, famciclovir, or valacyclovir (Table 149-2). Extend treatment duration if lesions persist. To treat proctitis or oral infections, use higher dosages (acyclovir, 400 milligrams five times a day for 7 to 10 days). For hospitalized patients, give acyclovir, 5 to 10 milligrams/kg IV every 8 hours for 5 to 7 days. Famciclovir and valacyclovir have high oral bioavailability and are alternative oral agents with easier dosing regimens for patients.

Treat episodic recurrent infection for 5 days with acyclovir, famciclovir, or valacyclovir at dosages reduced from primary therapy (Table 149-2). Begin treatment within 1 day. Suppressive therapy is available for individuals who experience more than six episodes per year, which reduces recurrence and shedding but does not eliminate either event. **Treat severe recurrent infections** (seen primarily in immunocompromised patients) with acyclovir, 5 to 10 milligrams/kg every 8 hours IV, for at least 2 days before switching to oral therapy. A primary diagnosis of HSV should prompt the search for other STIs including HIV.

CHANCROID

Haemophilus ducreyi is a pleomorphic gram-negative bacillus that causes chancroid, seen as painful genital ulcers and lymphadenitis. This disease is on the decline in most of the world with sporadic male outbreaks.[20] Chancroid increases HIV transmission and often is accompanied by other infections when chancroid is present; 10% of infected patients in the United States also have HSV or *T. pallidum*.[20]

Clinical Features A painful erythematous papule appears at the site of infection (usually confined to the genital region) after an incubation period of 4 to 10 days. One to 2 days later, the lesion becomes eroded,

FIGURE 149-10. Painful, punched out ulcer of chancroid. [Reproduced with permission from Fleischer AB Jr, Feldman SR, McConnell CF, et al: *Emergency Dermatology: A Rapid Treatment Guide.* © 2002, McGraw-Hill, New York.]

ulcerated, and often pustular (not vesicular). The ulcers are usually 1 to 2 cm in diameter with sharp, undermined margins and are very painful (**Figure 149-10**). The friable base of the ulcer is covered with yellow-gray necrotic exudates. Multiple lesions are present in up to 50% of patients (more so in women), and "kissing lesions" (infection of adjacent skin areas due to autoinoculation) are frequent. Painful inguinal lymphadenopathy develops 1 to 2 weeks after primary infection (**Figure 149-11**). A bubo will develop if chancroid is untreated, and the lymph nodes become necrotic or pus filled. Constitutional symptoms are rare, and ulcerations are rarely recurrent.

Diagnosis Diagnosis can generally be made on clinical grounds with a painful ulcer and regional lymphadenopathy, but other infections (such as HSV infection and syphilis) are possible. A swab of a lesion or pus from a suppurative lymph node can be cultured, but a special medium is required that is not widely available, and culturing has a sensitivity of <80%. There is no current Food and Drug Administration–approved polymerase chain reaction test.

Treatment Azithromycin PO in a single dose, ceftriaxone IM in a single dose, ciprofloxacin for 3 days, or erythromycin base for 7 days are all

FIGURE 149-11. Chancroid with characteristic penile ulcers and associated left inguinal adenitis. [Photo contributor: H. Hunter Handsfield. Atlas of Sexually Transmitted Diseases. New York: McGraw-Hill; 1992. Reproduced with permission from Knoop K, Stack L, Storrow A, Thurman RJ: *Atlas of Emergency Medicine,* 3rd ed. © 2010, McGraw-Hill, New York. Fig 9-22.]

effective for the treatment of *H. ducreyi* infection (Table 149-2), with the choice based on local antibiotic resistance patterns and patient factors. Generally, azithromycin and ceftriaxone are used in patients without HIV infection, with ciprofloxacin as an alternative. Erythromycin is inexpensive, but the need for multiple doses and GI toxicity make it less desirable. Incision and drainage or aspiration of buboes can be considered for symptomatic relief, prevention of fistulas, and secondary ulcers.

Symptoms improve in about 3 days, and lesions are visibly improved within a week. Larger ulcers may require 2 to 3 weeks to heal. Partners should be treated if they have had sexual contact in the last 10 days, regardless of symptoms.[3] Pregnant women are usually treated with ceftriaxone or erythromycin as an alternative. All patients should be tested for HSV, syphilis, and HIV at or near the time of diagnosis of chancroid and again 3 months later if tests are initially negative.

LYMPHOGRANULOMA VENEREUM

Three specific serotypes (L1, L2, and L3) cause lymphogranuloma venereum, also referred to as struma, tropical bubo, or Durand-Nicolas-Favre disease. Lymphogranuloma venereum is endemic worldwide but is seen only sporadically in the United States. The Netherlands has seen an increased incidence of this STI in homosexuals.[21] The primary lesion can take many forms and be confused with the lesions of other STIs (Table 149-3).

Clinical Features The painless primary chancre is almost never noticed and lasts only 2 to 3 days (**Figure 149-12**). Generally, 1 to 3 weeks after the appearance of the initial lesion, unilateral inguinal lymphadenopathy is noted (60% of cases) (**Figure 149-13**). Often the overlying skin has a purplish hue. The initial lesion progresses to suppurative lymphadenopathy, resulting in either spontaneous abscess rupture or firm inguinal masses. Lymphogranuloma venereum proctitis (rectal ulcers, bleeding, and discharge) is also seen, primarily in homosexual men, and can be confused with new onset of ulcerative colitis. Scarring of these masses may cause linear depressions parallel to the inguinal ligament, forming the so-called *groove sign* (**Figure 149-14**). Lymphogranuloma venereum infections can cause fever, chills, arthralgias, erythema nodosum, or rarely meningoencephalitis. Lymphogranuloma venereum is easily confused with syphilis, chancroid, and HSV, and it also facilitates the transmission and acquisition of HIV.

Diagnosis Chlamydia serologic testing for lymphogranuloma venereum is not standardized and not helpful except to support the diagnosis in the appropriate setting. Culture, direct immunofluorescence testing, and nucleic acid detection of a lesion swab or bubo aspirate are not widely available, nor is genotyping. Given these diagnostic constraints, patients with a clinical picture suggestive of lymphogranuloma venereum and epidemiologic information should simply be treated. The Centers for Disease Control and Prevention may be able to assist with testing.

FIGURE 149-12. Lymphogranuloma venereum chancre. This ulceration was painless to the patient. [Reproduced with permission from Goldsmith LA, Katz SI, Gilchrest BA, et al: *Fitzpatrick's Dermatology in General Medicine,* 8th ed. © 2012 by McGraw-Hill Inc., New York.]

FIGURE 149-13. Lymphogranuloma venereum. Marked lymphadenopathy with small central eschar/ulcer. [Reproduced with permission from Wolff KL, Johnson R, Suurmond R: *Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology,* 5th ed. © 2005, McGraw-Hill, New York.]

Treatment Doxycycline for 21 days is the usual regimen (Table 149-2). Alternatives include erythromycin, azithromycin, or extended treatment with fluoroquinolones.[3] Mild untreated cases resolve spontaneously in 8 to 12 weeks. Treat pregnant or lactating women with erythromycin or azithromycin. Refer partners with whom the individual has had sexual contact within the past 60 days for treatment. Sexual activity should be avoided until the full course of antibiotic treatment is completed and lymphadenopathy has resolved.[3]

GRANULOMA INGUINALE (DONOVANOSIS)

Granuloma inguinale, also called donovanosis, is caused by *Klebsiella granulomatis*, a gram-negative intracellular bacterium. The disease is rare in the United States but is endemic in India, southern Africa, and central Australia.

FIGURE 149-14. An example of the linear depression parallel to the inguinal ligament in lymphogranuloma venereum, the groove sign. [Reproduced with permission from Goldsmith LA, Katz SI, Gilchrest BA, et al: *Fitzpatrick's Dermatology in General Medicine*, 8th ed. © 2012 by McGraw-Hill Inc., New York.]

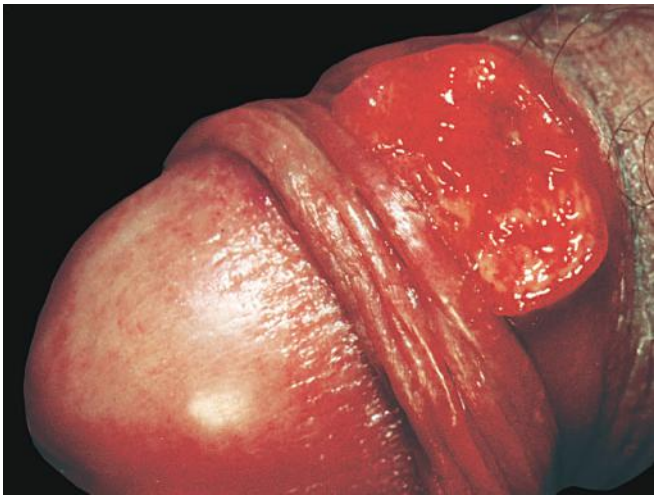

FIGURE 149-15. Granuloma inguinale in a male. The painless, ulcerative lesion is classically beefy red and bleeds easily. [Reproduced with permission from Goldsmith LA, Katz SI, Gilchrest BA, et al: *Fitzpatrick's Dermatology in General Medicine*, 8th ed. © 2012 by McGraw-Hill Inc., New York.]

Clinical Features After a variable incubation period of 2 weeks to 6 months, granuloma inguinale begins as subcutaneous nodules on the penis or labial-vulvar area. The nodules then progress to the more classic painless, ulcerative lesions (**Figure 149-15**). These lesions are highly vascular, which explains both their appearance (beefy red) and their tendency to bleed easily on contact. Lymphadenopathy is not usually present, but subcutaneous granulomas may occur and mimic lymphadenopathy. Superinfection may complicate these open, bleeding lesions and complicate the diagnosis. Granuloma inguinale is not highly contagious, and multiple exposures are required to contract the disease. Autoinoculation can occur, leading to oral and GI tract involvement.

Diagnosis *K. granulomatis* is difficult to culture, and diagnosis often requires visualization of characteristic Donovan bodies on tissue biopsy.

Treatment Doxycycline PO for at least 3 weeks stops progression of the lesions (Table 149-2), although longer treatment may be needed to allow complete healing of the ulcers. Azithromycin, ciprofloxacin, erythromycin base, and trimethoprim-sulfamethoxazole are alternatives for at least 3 weeks and until the lesions heal. Doxycycline, ciprofloxacin, and sulfonamides are contraindicated in pregnancy. Erythromycin base is the recommended treatment for pregnant or lactating women with the potential addition of a parenteral aminoglycoside. Individuals with whom the patient had sexual contact within 60 days of the appearance of the lesions should also be treated if symptomatic.[22]

GENITAL WARTS

Over 40 different genotypes of human papillomavirus (HPV) can infect the human genital tract by direct transmission. It is estimated that just under 25% of the U.S. population is currently infected with genital HPV.[23] As many as half of these infections are in adolescents and young adults, age 15 to 24 years.[23] HPV infection is so common that most sexually active adults become infected at some point in their lives. The significance of genital warts goes beyond their discomforting presence, with many genotypes being oncogenic.

Two Food and Drug Administration–approved vaccines are available against HPV. The quadrivalent vaccine (Gardasil®) works against the two most important oncogenic HPVs (genotypes 16 and 18) and those that cause genital warts (genotypes 6 and 11). The bivalent vaccine (Cervarix®) works against genotypes 16 and 18 only. The three-dose vaccine is routinely recommended for 11- and 12-year-old girls and is given over 6 months. The vaccine series can be started at 9 years of age. Catch-up vaccination is recommended for 13- through 26-year-old females who have not yet received or completed the vaccination series.[24] Gardasil is used in males age 9 to 27 years old to prevent genital warts.

FIGURE 149-16. Condylomata acuminata in a 25-year-old male with a 3-month history of penile lesions. Multiple cauliflower floret–like papules are seen on the penile shaft and foreskin. [Reproduced with permission from Wolff K, Johnson RA: *Fitzpatrick's Color Atlas and Synopsis of Clinical Dermatology*, 6th ed. © 2009 by McGraw-Hill, Inc., New York.]

Clinical Features Genital warts are flesh-colored papules or cauliflower-like projections that usually appear after an incubation period of 1 to 8 months and may coalesce to form condylomata acuminata (**Figure 149-16**). In women, they are seen on the external genitalia (**Figure 149-17**) and in the perianal region. Genital warts are usually painless, but depending on their anatomic location can be friable, painful, or pruritic and often enlarge during pregnancy. Infected males often complain of nonhealing penile lesions, occasionally with pruritus and urethral discharge. Perianal condylomata have been seen in up to 80% of women with vulvar condylomata and are seen frequently in homosexual males.

Diagnosis Diagnosis is clinical.

Treatment Many topical treatments exist that can be used for days to weeks, but these are not usually initiated in the ED. Treatment decisions are based on the size and number of lesions, the amount of discomfort they are causing, and patient preferences. The treatment of external genital warts may help reduce viral load but is not a cure. All treatment options are considered equally effective and chosen based on the discretion of the patient and provider.

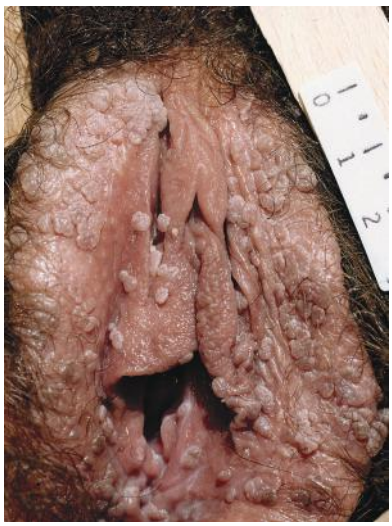

FIGURE 149-17. Condylomata acuminata of the vulva. Multiple pink-brown, soft papules are seen on the labia. [Reproduced with permission from Wolff K, Johnson RA, Saavedra AO: *Fitzpatrick's Color Atlas and Synopsis of Clinical Dermatology*, 7th ed. © 2013 by McGraw-Hill, Inc., New York.]

Patients with HPV infections rarely require emergent management. However, counseling in the ED regarding this distressing condition is relatively common. Emphasize the following: it is common for sexually active people to have HPV at some point in their lives, and most people clear serologic evidence of HPV spontaneously without external evidence of the disease. Condoms are protective with HPV, but they are not preventative, and the only way to decrease exposure is to limit the number of sexual partners. It is an incorrect assumption that having HPV indicates an oncogenic certainty or a change in fertility.

PRACTICE GUIDELINES

The Centers for Disease Control and Prevention publishes guidelines for the diagnosis and treatment of STI every few years. The most recent full publication was issued in 2010 and is available at http://www.cdc.gov/std/treatment/2010/default.htm.

SPECIAL CONSIDERATIONS

TREATMENT OF SEXUALLY TRANSMITTED INFECTIONS DURING PREGNANCY

Refer pregnant patients with STIs to the physician providing their prenatal care. Penicillin, ceftriaxone, azithromycin, cefixime, metronidazole, erythromycin, and acyclovir are thought to be safe for use during pregnancy and can be started pending follow-up.

PROPHYLAXIS AFTER SEXUAL ASSAULT

Sexual assault is discussed in detail in chapter 293, "Female and Male Sexual Assault," but a brief review of prophylactic regimens follows. Once all appropriate forensic investigation and culture specimens have been taken, three-agent prophylaxis with single doses of ceftriaxone, 250 milligrams IM; metronidazole, 2 grams PO; and azithromycin, 1 gram PO, or doxycycline, 100 milligrams PO, twice daily for 7 days should be given, with adjustments as needed for allergy and pregnancy. Hepatitis B vaccine (initial and remaining doses to complete three-shot course) without hepatitis B immune globulin should be given to those who are unimmunized. HIV prophylaxis requires decision making on a case-by-case basis and is discussed in chapter 293. Repeat evaluation for STIs should be done in 1 to 2 weeks to make sure that infection has been eradicated.

CHAPTER 150

Toxic Shock Syndromes

Stephen Y. Liang

INTRODUCTION

The two classic toxic shock syndromes are attributed to *Staphylococcus aureus* or to group A *Streptococcus* (*Streptococcus pyogenes*). Each is a life-threatening illness stemming from toxin production by gram-positive organisms, creating hemodynamic compromise and fulminant multiorgan dysfunction. This cascade makes diagnosis a challenge, with the features looking like the more common entities of sepsis and septic shock. Characteristic epidemiology, pathophysiology, clinical presentations, and management strategies set these syndromes apart (**Table 150-1**). Early recognition and definitive treatment are the keys to improving patient outcomes.

TABLE 150-1 Distinguishing Characteristics of Toxic Shock Syndrome and Streptococcal Toxic Shock Syndrome

	Toxic Shock Syndrome (TSS)	Streptococcal Toxic Shock Syndrome (STSS)
Organism	*Staphylococcus aureus* (including MRSA)	Group A *Streptococcus* (*Streptococcus pyogenes*)
Toxin	Toxic shock syndrome toxin-1 (TSST-1) Staphylococcal enterotoxins	Streptococcal pyrogenic exotoxins (most commonly A and B)
Risk factors	Retained foreign body (e.g., tampon, female barrier contraceptive) Skin and soft tissue infections Varicella Surgery Trauma Childbirth Influenza	Necrotizing soft tissue infections Varicella Surgery Trauma Childbirth Influenza
Presence of pain	Uncommon	Common
Presence of rash	Common	Uncommon
Blood culture positivity	5%	60%
Mortality	≤5%	20%–45%

Abbreviation: MRSA = methicillin-resistant *Staphylococcus aureus*.

STAPHYLOCOCCAL TOXIC SHOCK SYNDROME

INTRODUCTION AND EPIDEMIOLOGY

Staphylococcal toxic shock syndrome (TSS) was first described in 1978 in a series of seven children presenting with systemic illness punctuated by fever, headache, confusion, vomiting, diarrhea, scarlatiniform rash, desquamation, hypotension, and multiorgan dysfunction.[1] A toxigenic strain of *S. aureus* isolated from mucosal (nasopharyngeal, tracheal, vaginal) and sequestered sites (abscess, empyema) in five of the patients was the causative organism. During the early 1980s, TSS was linked to tampon use in young menstruating women,[2,3] with incidence rates as high as 13.7 per 100,000 menstruating women between the ages of 15 and 24.[4] Education on the proper frequency and duration of use of tampons coupled with the removal of highly absorbent tampons from the market are widely credited with reducing menstrual TSS rates, although tampon use remains an important risk factor for menstrual TSS to this day in the United States, Canada, and Western Europe.

Nonmenstrual TSS is associated with a wide range of skin and soft tissue infections including abscesses, cellulitis, mastitis, and infected surgical and postpartum wounds, including vaginal and cesarean deliveries.[5] Sinusitis and superimposed infections of burns, abrasions, and varicella lesions have been described in other cases, particularly in children. Patients with influenza may develop TSS in the setting of secondary *S. aureus* respiratory tract infections (e.g., pneumonia, tracheitis).[6] Because the vagina and nares are known sites of *S. aureus* colonization, retained foreign bodies, including **female barrier contraceptives** (*e.g.*, diaphragm, contraceptive sponge) and **nasal packing material**, are risk factors for developing nonmenstrual TSS. Nasal packing is not a current common trigger, and routine prescription of antibiotics is not needed to stop this from occurring.[8] Nonmenstrual TSS affects men and women alike, and patients tend to be older and have more comorbid illnesses than those seen with the menstrual form of the disease.

Population-based surveillance shows that TSS incidence has been stable in the United States for the past 30 years.[9,10] Women between the age of 13 and 24 years have a higher incidence of menstrual TSS, at a rate of 1.41 per 100,000 persons.[9] The overall case fatality rate for TSS is 4.1%, with higher rates in nonmenstrual TSS (5%) compared to menstrual TSS (3%).[11]

PATHOPHYSIOLOGY

TSS is a superantigen-mediated disease. Toxigenic *S. aureus* strains produce pyrogenic exotoxins including toxic shock syndrome toxin-1 (TSST-1) and staphylococcal enterotoxins that bind directly to the major histocompatibility complex class II molecule and T-cell receptor on antigen-presenting cells.[12] Massive T-cell and antigen-presenting cell activation leads to enhanced cytokine expression (e.g., interleukin-1, -2, and -6; tumor necrosis factor-α; interferon-γ), establishing a proinflammatory state. Increased vascular permeability, hemodynamic shock, metabolic acidosis, coagulopathy, and multiorgan dysfunction ensue, mirroring that of the cascade triggered by lipopolysaccharide (endotoxin) in gram-negative sepsis.

Almost all menstrual TSS cases are tied to TSST-1.[13,14] Disease starts with colonization of the vagina by a toxigenic strain of *S. aureus* capable of producing TSST-1. Approximately 9% of women are vaginally colonized with *S. aureus*, only 1% of whom are considered toxigenic.[15] TSST-1 must cross the vaginal epithelium for clinical disease to occur, and the host cannot possess neutralizing antibodies to TSST-1 that might confer immunity. One reason why menstrual TSS rates have remained low yet consistent throughout the years may be due to the development of durable immunity to TSST-1,[15] perhaps from either transient or persistent asymptomatic colonization with toxigenic *S. aureus*.[16]

In contrast to menstrual TSS, TSST-1 is implicated in only half of nonmenstrual TSS cases,[17] with the remaining share attributed to staphylococcal enterotoxin B and other members of that family.[18] Vulnerability to nonmenstrual TSS usually starts with infection or colonization involving a toxigenic strain of *S. aureus* at a localized site, notably mucosa, skin, wound, lung, or a foreign body.

CLINICAL FEATURES

A case definition created for the National Notifiable Diseases Surveillance System by the U.S. Centers for Disease Control and Prevention (**Table 150-2**) provides criteria for reporting TSS in its most severe form, although many of these symptoms may not be evident on initial evaluation of the patient presenting to the emergency department and should not be used to exclude the diagnosis of TSS. These definitions are periodically updated at the National Notifiable Diseases Surveillance System Web page (http://wwwn.cdc.gov/nndss).

Time of onset of initial symptoms is highly variable, ranging from as little as 48 hours in postoperative nonmenstrual TSS[5] to several days after the start of menstruation in menstrual TSS.[3] **Patients presenting early on in the disease process may exhibit a nonspecific prodrome** consisting of any combination of fever, chills, malaise, myalgias, headache, sore throat, vomiting, diarrhea, or abdominal pain. The progression of an unexplained febrile illness to include hypotension, erythroderma, and multiorgan dysfunction should raise clinical suspicion for TSS. Hypotension with a systolic blood pressure of ≤90 mm Hg in adults or less than the fifth percentile for children <16 years of age heralds severe disease as a consequence of systemic vasodilation and increased capillary permeability. Decreased urinary output signals acute kidney injury, which may result from renal hypoperfusion, rhabdomyolysis, or other causes. Lethargy, agitation, and confusion can result from shock or be related to cerebral edema. Respiratory failure can occur from acute respiratory distress syndrome or pulmonary edema from toxic cardiomyopathy. Patients with TSS may also present to care with second- or third-degree heart block or, more rarely, ventricular arrhythmias.

The erythroderma of TSS is characterized as a painless, diffuse, red, macular rash resembling "sunburn." The rash can be either patchy or confluent, and it can be modest and evanescent, involving the palms and soles. Desquamation, notably of the hands and feet, begins anywhere from 1 to 3 weeks after the initial onset of symptoms. Mucosal involvement can include conjunctival and scleral hemorrhage as well as vaginal, cervical, or oropharyngeal hyperemia ("strawberry tongue") and ulceration. In the patient at risk for menstrual TSS, pelvic examination gauges mucosal disease and allows a look for retained foreign bodies such as tampons.

Surgical wounds infected or colonized with toxigenic *S. aureus* in nonmenstrual TSS patients may have little or no erythema, induration, or purulent drainage to raise clinical suspicion of infection,[5,19] likely due to unique properties associated with TSST-1 and staphylococcal enterotoxin B. Any wound in a patient presenting with concern for TSS should be considered a potential source for toxigenic *S. aureus*.

TABLE 150-2 Case Definition for Toxic Shock Syndrome

Clinical criteria:

- Fever: temperature ≥38.9°C or 102.0°F
- Rash: diffuse macular erythroderma
- Desquamation: 1–2 weeks after onset of rash
- Hypotension: systolic blood pressure ≤90 mm Hg (adult) or <5th percentile by age (children <16 years of age)
- Multiorgan involvement (≥3 organ systems):
  - Gastrointestinal: vomiting and/or diarrhea at onset of illness
  - Muscular: severe myalgia or CPK ≥2 times the upper limit of normal
  - Mucous membrane: vaginal, oropharyngeal, or conjunctival hyperemia
  - Renal: BUN or serum Cr ≥2 times the upper limit of normal for laboratory or urinary sediment with pyuria (≥5 leukocytes per high-power field) in the absence of urinary tract infection
  - Hepatic: total bilirubin, ALT, or AST ≥2 times the upper limit of normal
  - Hematologic: platelet count <100,000/mm^3
  - Central nervous system: disorientation or alterations in consciousness without focal neurologic signs when fever and hypotension are absent

Laboratory criteria: *Negative* results on the following tests, if obtained:

- Blood or cerebrospinal fluid cultures (blood culture may be positive for *Staphylococcus aureus*)
- Serologies for Rocky Mountain spotted fever, leptospirosis, or measles

Case classification:

- Probable: ≥4 clinical criteria + laboratory criteria met
- Confirmed: 5 clinical criteria + laboratory criteria met, including desquamation (unless death occurs prior to desquamation)

Abbreviations: ALT = alanine aminotransferase; AST = aspartate aminotransferase; CPK = creatine phosphokinase; Cr = creatinine.

DIAGNOSIS

Timely diagnosis of TSS relies on identifying patient risk factors; recognizing an evolving pattern of febrile illness, hemodynamic compromise, and organ injury; and considering the diagnosis before profound illness occurs even if all of the case criteria are not met. **TSS is a clinical diagnosis.**

Laboratory evaluation reveals the adverse sequelae of organ hypoperfusion and dysfunction, but nothing more specific. Usually, a CBC, comprehensive metabolic panel with liver function tests, coagulation studies, creatine phosphokinase level (particularly if myalgias are a primary complaint), urinalysis, chest radiograph, and an ECG are obtained to assess organ function. Leukocytosis, anemia, or thrombocytopenia may be present. Azotemia indicative of acute kidney injury can be accompanied by electrolyte disturbances including hyponatremia, hypocalcemia, and hypophosphatemia.[20] Metabolic acidosis in the presence of hypotension is common. Hypoalbuminemia from capillary leakage and liver function abnormalities with coagulopathy can also be seen. Absent coagulopathy, CT of the brain accompanied by lumbar puncture is often needed in those with altered sensorium.

Obtain blood cultures, but **positive blood cultures are uncommon**: *S. aureus* is grown in less than 5% of TSS cases.[5] In contrast, **cultures from wounds, mucosal sites, and retained foreign materials are frequently positive for *S. aureus***. Get all possible cultures early, optimally before initiating antibiotic therapy, to facilitate identification of a toxin-producing strain of *S. aureus* and to allow antibiotic susceptibility testing.

Differential Diagnosis **Streptococcal toxic shock syndrome** and **myonecrosis** due to *Clostridium perfringens*, both commonly associated with traumatic and surgical wounds, are important considerations in the differential diagnosis of TSS. Toxic shock syndrome due to *Clostridium sordellii*, associated with gynecologic surgery, childbirth, miscarriage, and abortions, can also present similarly, but often without

fever. **Staphylococcal scalded skin syndrome**, mediated by exfoliative toxin A or B, can present with fever, lethargy, and desquamation similar to TSS, but is not typically accompanied by hypotension or multiorgan dysfunction. In the absence of erythroderma, TSS is indistinguishable from sepsis or septic shock due to any number of gram-positive or gram-negative bacteria. Other infectious diseases classically associated with fever, rash, and multiorgan dysfunction include **Rocky Mountain spotted fever and leptospirosis.** Also, consider **meningococcemia** if any severe headache or a petechial rash is seen. Noninfectious illnesses including **Stevens-Johnson syndrome**, **toxic epidermal necrolysis**, and **Kawasaki's disease** are occasional alternative diagnoses.

TREATMENT

The initial management of TSS in the ED is based on treating shock and eliminating the source of infection. Start with aggressive isotonic crystalloid fluid resuscitation, and use vasopressors and inotropes as needed if volume alone does not resolve hypotension or organ hypoperfusion. Mechanical ventilation may be necessary for respiratory failure. Drain abscesses and other infected fluid collections, obtain surgical consultation for debridement of potentially infected wounds, and remove retained foreign bodies that might represent a focus for toxigenic *S. aureus* (e.g., tampons, nasal or surgical packing material). Patients suspected of having TSS require hospital admission, usually to the intensive care unit, given the hemodynamic compromise, respiratory failure, and multiorgan dysfunction.

Administer antibiotics to treat infection, eliminate *S. aureus* carriage, and reduce recurrences, although the role of antibiotics in curbing the inflammatory response of TSS is unclear (**Table 150-3**). With the growing prevalence of methicillin-resistant *S. aureus* (MRSA), decisions about empiric antistaphylococcal therapy should hinge on local *S. aureus* antibiotic resistance patterns. Both community- and hospital-acquired MRSA strains have been reported to cause TSS through TSST-1[21] and staphylococcal enterotoxin production, although the exact proportion of TSS cases attributable to MRSA is not known. Empiric therapy should consist of **vancomycin**, 15 milligrams/kg IV every 12 hours (maximum single dose of 2.25 grams), with adjustment of the dosing interval based on creatinine clearance. **Linezolid**, 600 milligrams IV every 12 hours, is an alternative to treat MRSA and may also directly suppress TSST-1 production.[22] If the concern for MRSA is low, an antistaphylococcal penicillin, such as oxacillin, 2 grams IV every 4 hours, or nafcillin, 2 grams IV every 4 hours, is adequate. Clindamycin, 900 milligrams IV every 8 hours, is added as a second agent given its ability to inhibit protein synthesis and toxin production in TSS,[23] but should not be used as monotherapy. The duration of antibiotic therapy is based on the clinical response and typically ranges from 7 to 14 days.

Reserve IV immune globulin for cases where supportive care, source control, and antibiotic therapy fail to elicit improvement within the first 6 hours of care. Although dosing recommendations will vary by patient age and comorbidity, many require higher doses of IV immune globulin to inhibit staphylococcal toxins.[24] Give IV immune globulin only after consultation with infectious disease or critical care specialists. An initial dose of 1 to 2 grams/kg is recommended. Immunoglobulin A deficiency is an absolute contraindication to the use of IV immune globulin. High-dose corticosteroids are not recommended in the treatment of TSS.[25]

TABLE 150-3 Differential Diagnosis and Recommended Antibiotic Regimens for Staphylococcal Toxic Shock Syndrome

Differential diagnosis	
Streptococcal toxic shock syndrome	
Rocky Mountain spotted fever	
Stevens-Johnson syndrome	
Clostridial myonecrosis	
Leptospirosis	
Toxic epidermal necrolysis	
Staphylococcal scalded skin syndrome	
Meningococcemia	
Kawasaki's disease	
Recommended Antibiotic Regimen	**Organism**
Vancomycin, 15 milligrams/kg IV *or* Linezolid, 600 milligrams IV *and* Clindamycin, 900 milligrams IV	MRSA
Oxacillin, 2 grams IV *or* Nafcillin, 2 grams IV *and* Clindamycin, 900 milligrams IV	MSSA

Abbreviations: MRSA = methicillin-resistant *Staphylococcus aureus*, MSSA = methicillin-sensitive *Staphylococcus aureus.*

STREPTOCOCCAL TOXIC SHOCK SYNDROME

INTRODUCTION AND EPIDEMIOLOGY

Streptococcal toxic shock syndrome (STSS) is a complication of invasive infections involving group A *Streptococcus* (*S. pyogenes*), including skin and soft tissue infections, pneumonia, and bloodstream infections. First recognized in 1987, STSS shared many of the same clinical features of TSS seen with *S. aureus*.[26] However, in a case series of 20 patients published just 2 years later, STSS emerged as a disease associated with necrotizing fasciitis and myositis, marked by a significantly higher morbidity and mortality compared with that of TSS.[27] Annual incidence rates for invasive group A *Streptococcus* (GAS) infection have ranged from 3 to 6 cases per 100,000 persons,[28-30] with those age 65 years and older or under the age of 1 greatest affected. In prospective population-based surveillance across 11 European countries in 2003 and 2004, 13% of invasive GAS infections were complicated by STSS, with half of all STSS cases reported in patients with necrotizing fasciitis.[29] More recently, population-based surveillance at sentinel sites in the United States have reported STSS in 3.4% of invasive GAS infections.[31] Mortality rates for STSS are high, ranging from 19% to 44% in recent studies.[28-30,32]

Despite the preponderance of invasive GAS infections at the extremes of age, STSS cases occur in all age groups. Underlying medical conditions including heart, liver, and kidney disease; diabetes mellitus; alcoholism; and drug abuse are more common in patients who develop STSS,[30,33] but many patients are healthy prior to the illness.[27,34] Surgical procedures, traumatic injuries, vaginal or caesarean delivery, varicella infection in children,[35] and influenza are all associated with STSS and other invasive GAS infections. Rare outbreaks of severe GAS infection with some progressing to STSS have occurred in daycare centers,[36] healthcare facilities,[37] and other institutional settings.

In recent years, STSS has been linked to infections involving group B, C, and G streptococci.[38] *Streptococcus suis* (a pathogen in pigs) is another newly identified trigger of invasive soft tissue infections accompanied by an STSS-like syndrome in China.[39]

PATHOPHYSIOLOGY

As with *S. aureus* TSS, STSS is mediated by toxins that function as superantigens. Streptococcal pyrogenic exotoxins, predominantly A and B, are produced by GAS in severe infections. These toxins also bind to the major histocompatibility complex class II molecule and T-cell receptor on antigen-presenting cells, thereby activating T cells and triggering cytokine expression.[12] Fever, increased vascular permeability, hemodynamic compromise, and multiorgan dysfunction are the products of this systemic inflammatory response. Virulence factors including M proteins confer resistance to phagocytosis and may impart other properties that further enhance the severity of disease.

Breaches in skin and mucosal surfaces (e.g., oropharynx, vagina), as well as minor trauma without obvious skin disruption resulting in hematoma, contusion, or muscle injury, are common starting points

for severe GAS infections. In many cases, a portal of entry is never identified.

CLINICAL FEATURES

Fulminant STSS, as defined by the Centers for Disease Control and Surveillance case definition (**Table 150-4**), is often preceded by a nonspecific prodrome of fever, chills, sweats, malaise, arthralgias, cough, sore throat, rhinorrhea, anorexia, nausea, vomiting, abdominal pain, and diarrhea in adults and children alike.[27,40] A diffusely erythematous and macular rash is infrequently seen in STSS and may progress to desquamation, although its presence is not required to solidify the diagnosis of STSS. Confusion, somnolence, and agitation may follow. Given the strong association between STSS and necrotizing soft tissue infections, many patients are likely to present initially with **pain out of proportion to physical findings** at a localized site, often an extremity or the abdomen.[27] Progressive violaceous discoloration, skin crepitus and necrosis, and bullae formation at the site are ominous signs of underlying necrotizing fasciitis and myositis. Compartment syndrome can be a complication. Refractory hypotension rapidly ensues from a combination of vasodilation, capillary leakage, and myocardial depression from toxic cardiomyopathy.[34] Acute kidney injury, myocardial and cerebral ischemia, acute respiratory distress syndrome, rhabdomyolysis from muscle destruction, liver dysfunction, and disseminated intravascular coagulation can lead to death within hours to days.

DIAGNOSIS

As with *S. aureus* TSS, the surveillance case definition for STSS may not be fully met on the initial presentation.

Laboratory evaluation has no specific diagnostic role, although it usually includes CBC, comprehensive metabolic panel with liver function tests, coagulation studies, creatine phosphokinase level (particularly if myositis or necrotizing fasciitis is suspected), arterial blood gas analysis, urinalysis, chest radiograph, and an ECG. Athough leukocytosis may be modest, a marked bandemia, sometimes in excess of 40%, can be present.[27] Anemia, thrombocytopenia, and coagulopathy may be evident. Transaminitis, azotemia, metabolic acidosis, hypoalbuminemia, and hypocalcemia are common findings, particularly as hypotension and capillary leakage progress. In necrotizing soft tissue infections, creatine phosphokinase will be elevated.

Obtain blood and wound cultures prior to administering antibiotics when possible to confirm the presence of GAS and guide therapy. **Blood cultures are positive in up to 60% of STSS cases; cultures from infected sites almost always yield GAS.**[27,40]

Consult a surgeon immediately for all patients believed to have a necrotizing soft tissue infection. CT and MRI showing soft tissue destruction establishes this diagnosis but should never delay timely surgical evaluation.

Differential Diagnosis Staphylococcal TSS, myonecrosis associated with *C. perfringens* or *Clostridium septicum*, nonclostridial myonecrosis due to mixed anaerobes and other bacteria, and *C. sordellii* toxic shock syndrome are principal contenders in the differential diagnosis of STSS. Other systemic infections including meningococcemia, Rocky Mountain spotted fever, and leptospirosis are potential candidates as well.

TREATMENT

Management of STSS begins with aggressive isotonic fluid resuscitation to restore volume and tissue perfusion. In light of the profound refractory hypotension and capillary leakage associated with STSS, large volumes of IV crystalloid fluid (10 to 20 L/d) may be required. Vasopressors or inotropic therapy are often necessary. More than half of patients with STSS will develop acute respiratory distress syndrome, often requiring intubation and mechanical ventilation.

Obtain surgical consultation for early and often extensive operative debridement, fasciotomy, and even amputation if a significant burden of infected and necrotic tissue exists. Admit to the intensive care unit.

Given the overlap in clinical presentations between STSS and septic shock and the high mortality associated with both, empiric broad-spectrum antibiotic therapy to cover GAS and other potential pathogens is best until culture data are available (**Table 150-5**). Use a β-lactamase inhibitor (e.g., piperacillin-tazobactam, 4.5 grams IV every 6 hours) or a carbapenem (e.g., meropenem, 1 gram IV every 8 hours) in combination with clindamycin, 900 milligrams IV every 8 hours,[41] the latter for suppression of toxin formation.[42] In areas where MRSA is prevalent, add vancomycin, 15 milligrams/kg IV every 12 hours (maximum single dose of 2.25 grams). Adjust antibiotic dosing for acute kidney injury.

Once the presence of GAS is identified, consider narrowing antibiotic therapy to penicillin G, 4 million units IV every 4 hours (for a total of 24 million units per day), in combination with clindamycin.[43] The duration of antibiotic therapy should be at least 14 days but may be longer based on the extent of the infection and the patient's clinical response.

Although retrospective studies have shown decreased mortality with IV immune globulin,[44,45] a multicenter, randomized controlled trial has failed to find benefit.[46] Obtain consultation before giving IV immune globulin to treat STSS.[47]

Surveillance case definitions for TSS and STSS are available from the Centers for Disease Control and Prevention Web site at http://www.cdc.gov/nndss.

TABLE 150-4 Case Definition for Streptococcal Toxic Shock Syndrome

Clinical criteria:

- Hypotension: systolic blood pressure ≤90 mm Hg (adult) or <5th percentile by age (children <16 years of age)
- Multiorgan involvement (≥2 organ systems):
  - Renal: serum Cr ≥2 milligrams/dL (≥177 μmol/L) for adults or ≥2 times the upper limit of normal for age. In patients with preexisting renal disease, >2-fold elevation above baseline.
  - Coagulopathy: platelet count ≤100,000/mm^3 (≤100 × 10^6/L) or disseminated intravascular coagulation, defined by prolonged clotting times, low fibrinogen level, and presence of fibrin degradation products
  - Hepatic: total bilirubin, ALT, or AST ≥2 times the upper limit of normal for the patient's age. In patients with preexisting liver disease, >2-fold elevation above baseline.
  - Acute respiratory distress syndrome: acute onset of diffuse pulmonary infiltrates and hypoxemia in the absence of cardiac failure or by evidence of diffuse capillary leak manifested by acute onset of generalized edema, or pleural or peritoneal effusions with hypoalbuminemia.
  - Skin: generalized erythematous macular rash that may desquamate
  - Soft tissue necrosis, including necrotizing fasciitis or myositis, or gangrene

Laboratory criteria:

- Isolation of group A *Streptococcus*

Case classification:

- Probable: All clinical criteria met + absence of other identified etiology for illness + isolation of group A *Streptococcus* from a nonsterile site
- Confirmed: All clinical criteria met + isolation of group A *Streptococcus* from a sterile site (e.g., blood, cerebrospinal fluid, synovial fluid, pleural fluid, or pericardial fluid)

Abbreviations: ALT = alanine aminotransferase; AST = aspartate aminotransferase; Cr = creatinine.

CHAPTER 151

Sepsis

Michael A. Puskarich
Alan E. Jones

INTRODUCTION AND EPIDEMIOLOGY

Sepsis is a heterogeneous syndrome characterized by widespread inflammation and potential organ harm initiated by a microorganism. Although gram-positive and gram-negative bacteria account for the majority of cases, fungi, viruses, mycobacteria, rickettsiae, and protozoans can trigger sepsis. Invasion of the blood is not necessary to develop or identify sepsis, which is determined by the host response to the infectious insult. As sepsis severity increases, a multifactorial series of events lead to impairments in oxygen delivery, secondary to macro- and microvascular malperfusion, as well as direct cellular damage secondary to inflammation. Eventually, multisystem organ failure occurs, and mortality is high.

The varying clinical presentation, differences in coding, and methodologic differences between studies lead to a wide range of estimates of the annual incidence of severe sepsis, ranging from 300 to 1000 cases/100,000 persons per year.[1] Over 500,000 patients each year present to the ED with suspected severe sepsis, the largest group of all sepsis patients hospitalized. The incidence is increasing and is multifactorial in origin; a key component of this increase relates to an aging patient population, which is not surprising given the fact that sepsis incidence increases >100-fold with age (0.2 per 1000 in children age 10 to 14 years to 26.2 per 1000 in those >85 years of age).[2]

The mean ED length of stay of a patient with sepsis is 5 hours. Once admitted, more than half of patients with severe sepsis will require care in an intermediate or intensive care unit,[2] where it represents the leading cause of death. Despite advances in care, mortality rates from severe sepsis remain high, with approximately 20% dying[3] during hospitalization in optimal clinical trial scenarios[4,5]; this rate approaches 50% when considering the sicker subset of those with septic shock.[6] These mortality rates exceed many other high-visibility acute care conditions such as acute myocardial infarction,[7] massive pulmonary embolism,[8] and cerebrovascular accident.[9] Morbidity is high and prolonged, and a long-term deficit in cognition and functioning is common.[10] Finally, sepsis care is costly; estimates from 10 years ago suggest a mean case cost of $22,100 with annual national costs reaching $16.7 billion,[2] figures that have certainly increased in the last decade.

Since 1987, gram-positive bacteria outside of the surgical setting are the predominant pathogens of sepsis.[11] With the rise of antimicrobial resistance, methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant *Enterococcus*, and other multidrug-resistant organisms are more common.[12] Similarly, the incidence of fungi as the source has risen, particularly in immunosuppressed patients. The most likely causative microorganism varies based on the likelihood of exposure to drug-resistant microorganisms (due to recent healthcare exposures) and the anatomic site of infection, with pneumonia, intra-abdominal, urinary, and skin/soft tissue being the most common locations.

DEFINITIONS

Sepsis syndromes are a continuum, with specific definitions regularly updated to include children[13,14] (**Table 151-1**). Although the definitions provide a conceptual and practical framework for recognition of the systemic inflammatory response to infection, definitions often are not sensitive or specific in the real-world clinical setting. In general, sepsis is defined as suspected or confirmed infection with evidence of systemic inflammation (demonstrated either through evidence of the systemic immune response syndrome or laboratory abnormalities), whereas severe sepsis is generally defined as sepsis plus evidence of new organ dysfunction thought to be secondary to tissue hypoperfusion. Septic shock exists when cardiovascular failure occurs, evidenced as persistent hypotension or need for vasopressors despite adequate fluid resuscitation; this latter category has a particularly poor prognosis.

SYSTEMIC INFLAMMATORY RESPONSE SYNDROME PROGNOSIS

Having systemic inflammatory response syndrome criteria does not confirm the presence of infection or sepsis because these features are shared by many other noninfectious conditions such as trauma, pancreatitis, and burns (**Figure 151-1**). **The systemic inflammatory response syndrome response is not a diagnosis or a good indicator of outcome; it is a crude means of stratification of patients with systemic inflammation.** In a prospective study of the epidemiology of patients demonstrating systemic inflammatory response syndrome (infectious and noninfectious), mortality rates were 3% in patients without systemic inflammatory response syndrome, 6% in those meeting two criteria, 10% in those meeting three criteria, and 17% in those meeting all four criteria.[14] Death rates were similar whether or not patients had positive blood cultures.

Complementary methods of classification of sepsis based primarily on physiologic abnormalities include the third Acute Physiology and Chronic Health Evaluation acuity system,[15] the Sequential Organ Failure Assessment score, and the Mortality in Emergency Department Score[16]; each allows for prognostication. These scoring systems are typically limited to research and are not for guiding patient care. Any evidence of septic shock confers the highest mortality risk assessment.

Serum lactate across a wide spectrum[17] provides excellent prognostic data in those with sepsis, but is not a singular test to diagnose or exclude sepsis. Lactate has traditionally been attributed to anaerobic metabolism secondary to tissue hypoperfusion; it also accumulates from changes in *aerobic* metabolism that occur in response to widespread inflammation.[18] As lactate increases, the risk of mortality rises, with the degree of lactate elevation and hypotension being independent predictors of mortality.[19,20] Specifically, 28-day mortality rate associated with modest elevation of serum lactate to 2 to 4 mmol/L approaches 15% even in those patients without hypotension,[21] and the rate continues to rise with increasing lactate levels. In general, venous or arterial lactate levels on either point-of-care bedside devices or measured in a central laboratory are useful if done with good clinical technique[22]; even better are serial levels using the same method of sampling (arterial or venous) to identify improvement that mirrors clinical responses.[22] This is called **lactate clearance** and is defined as a drop over time; lactate clearance provides an independent prognostic value in addition to

TABLE 151-1 Definition of Sepsis in Adults and Children

Systemic Inflammatory Response Syndrome (SIRS) criteria:

1. Fever (temperature >38.3°C) or hypothermia (temperature <36°C)
2. Pulse rate (>90 beats/min or >2 SDs above the normal value for age)
3. Tachypnea (respiratory rate >20 breaths/min)
4. Leukocytosis (WBC >12,000 cells/μL) *or* leukopenia (WBC <4000 cells/μL), *or* normal WBC with >10% immature forms

Sepsis: *Infection (documented* ***or*** *suspected), and some of the following:*

General Parameters:

Fever (temperature >38.3°C)

Hypothermia (temperature <36°C)

Pulse rate (>90 beats/min or >2 SDs above the normal value for age)

Tachypnea

Altered mental status

Significant edema or positive fluid balance (>20 mL/kg during 24 h)

Hyperglycemia (plasma glucose >140 milligrams/dL or 7.7 mmol/L) in the absence of diabetes

Inflammatory Parameters:

Leukocytosis (WBC >12,000 cells/μL)

Leukopenia (WBC <4000 cells/μL)

Normal WBC with >10% immature forms

Plasma C-reactive protein (CRP) >2 SDs above the normal value

Plasma procalcitonin >2 SDs above the normal value

Hemodynamic Parameters:

Arterial hypotension (SBP <90 mm Hg, MAP <70 mm Hg, or an SBP decrease >40 mm Hg in adults or <2 SDs below normal for age)

Organ Dysfunction Parameters:

Arterial hypoxemia (P_{aO2}/F_{IO2} <300)

Acute oliguria (urine output <0.5 mL/kg per hour for at least 2 h despite adequate fluid resuscitation)

Creatinine level increase >0.5 milligrams/dL

Coagulation abnormalities (INR >1.5 or aPTT >60 s)

Ileus (absent bowel sounds)

Thrombocytopenia (platelet count <100,000 cells/μL)

Hyperbilirubinemia (plasma total bilirubin >4 milligrams/dL)

Tissue Perfusion Parameters:

Hyperlactatemia (above upper limits of laboratory normal levels)

Decreased capillary refill or mottling

Severe Sepsis: *Sepsis-induced tissue hypoperfusion or organ dysfunction (any of the following thought to be due to infection)*

Sepsis-induced hypotension

Lactate level above upper limits of laboratory normal levels

Urine output <0.5 mL/kg per hour for at least 2 h despite adequate fluid resuscitation

Acute lung injury with P_{aO2}/F_{IO2} <250 in the absence of pneumonia as infectious source

Acute lung injury with P_{aO2}/F_{IO2} <200 in the absence of pneumonia as infectious source

Creatinine level >2.0 milligrams/dL

Bilirubin level >2 milligrams/dL

Platelet count <100,000 cells/μL

Coagulopathy (INR >1.5)

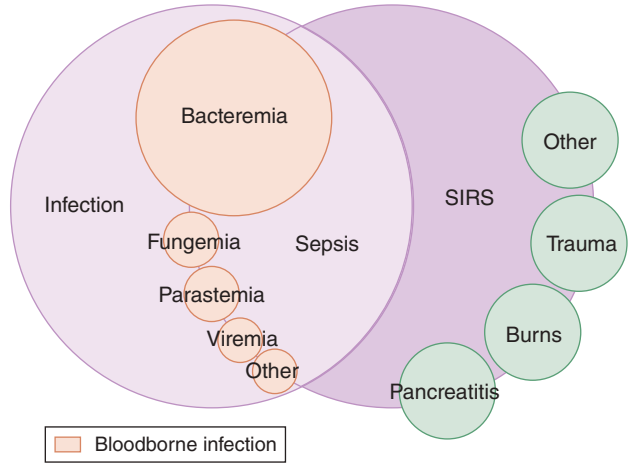

FIGURE 151-1. Interrelationship between systemic inflammatory response syndrome (SIRS), sepsis, and infection.

vital signs and other measurements. Patients with sepsis who do not clear lactate (adequate is at least a 10% drop with therapy over the first few hours) have a higher mortality rate than patients who do clear the lactate.[23,24] The major limitation is that **lactate is nonspecific and can be elevated in a number of conditions, and it must be used together with clinical judgment**.

PATHOPHYSIOLOGY

In sepsis, the host immune response fails to control and/or overreacts to invasive pathogens, leading to two critical events.[25,26] The first event involves marked abnormalities in the inflammatory response in the host. The host response typically varies from a hyperinflammatory response in the early stages of sepsis, to a blunted inflammatory response in the later stages of sepsis, which leads to an increased risk of secondary hospital-acquired infections. The blunted inflammatory response results in programmed death of key immune, epithelial, and endothelial cells, leading to tissue injury and perpetuating multiorgan dysfunction.

The second event is an imbalance in procoagulant and anticoagulant functioning; in the most extreme of situations, this results in the clinical syndrome of disseminated intravascular coagulation. Disseminated intravascular coagulation results in micro- and macrovascular clot formation, impaired microvascular tissue perfusion, and thrombosis of small vessels. Notably, subclinical disseminated intravascular coagulation is often lurking despite relatively normal basic laboratory findings, with impaired microvascular perfusion (detectable in research settings) that is associated with a worse prognosis.[27] Continued microvascular ischemia likely contributes to organ failure, as well as to the release of proinflammatory intracellular contents, which further stimulates the innate immune response and perpetuates the underlying pathology.[28] As these events progress, they intensify the inflammatory response and a destructive cycle ensues, as illustrated in **Figure 151-2**. At this time, there are no specific therapies to remedy microvascular dysfunction.

CLINICAL FEATURES

While some presentations of severe sepsis are immediately clinically apparent, sepsis can present in a subtle or occult manner, particularly early in the course. Given that systemic inflammation produces physiologic changes, vital sign abnormalities—notably fever, hypotension, and/or tachycardia—are a hint to sepsis, recognizing that many patients with these findings may have another cause. In ED patients with undifferentiated hypotension, 40% will ultimately have an infectious cause of symptoms.[29]

Although traditionally sepsis is categorized as an example of distributive shock (peripheral vasodilation evidenced by warm extremities with

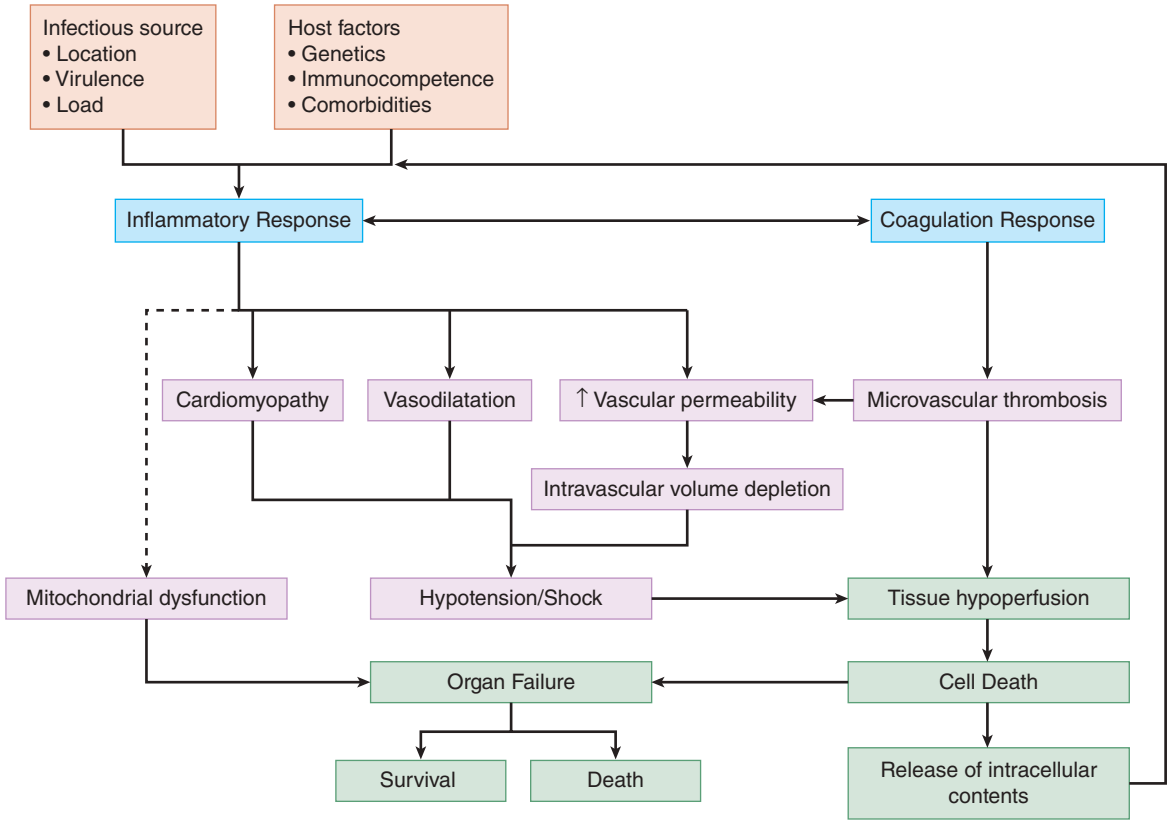

FIGURE 151-2. Pathogenic sequence of events in septic shock.

a compensatory increased cardiac output), this presentation does not accurately describe all patients with sepsis. ED patients with sepsis are often volume depleted from decreased intake and increased fluid losses (from emesis, diarrhea, or insensible losses associated with fever and tachypnea). Intravascular volume depletion directly affects preload, cardiac output, and ultimately peripheral perfusion. Further complicating matters is **septic cardiomyopathy**, a reversible process characterized by impaired systolic function and diastolic relaxation.[30] Finally, the combination of intravascular volume depletion and septic cardiomyopathy may manifest as "cold shock," impaired peripheral perfusion and cool extremities.

PULMONARY INJURY

Widespread inflammation secondary to sepsis commonly affects pulmonary function even in the absence of pneumonia. Acute lung injury is common and may result in acute respiratory distress syndrome, which is characterized by new lung edema from increased alveolar and capillary permeability. Classification of acute respiratory distress syndrome is based primarily on the degree of hypoxemia.[31] The three mutually exclusive categories are mild (P_{aO2} divided by fraction of inspired oxygen [F_{IO2}] of 200 to 300), moderate (P_{aO2}/F_{IO2} of 100 to 200), and severe (P_{aO2}/F_{IO2} <100), within 1 week of a clinical insult or change in respiratory status coupled with new bilateral pulmonary infiltrates on chest radiographs not explained by effusions, lung collapse, or nodules and not fully explained by heart failure or volume overload. Clinically, severe refractory hypoxemia, noncompliant lungs noted on mechanical ventilation, and a chest radiograph showing bilateral pulmonary alveolar infiltrates suggest the diagnosis. Mortality increases from 27% to 45% with increasing severity of acute respiratory distress syndrome.

RENAL INJURY

The kidney is another common sepsis target; acute kidney injury can present with azotemia, oliguria, or anuria. Factors increasing acute kidney injury risk include pre-existing kidney dysfunction or vasculopathy, depth and duration of hypotension, dehydration, and use of nephrotoxic substances (e.g., aminoglycoside antibiotics, nonionic intravenous contrast). Renal ischemic injury from hypoperfusion is a major factor in the pathogenesis of acute kidney injury in sepsis, although toxic products resulting from neutrophil-endothelial interactions, endothelial damage by various mediators, reperfusion injury, and microvascular thrombosis also contribute.

HEPATIC INJURY

The most frequent hepatic abnormality is cholestatic jaundice, although it occurs infrequently. Increased concentrations of transaminase, alkaline phosphatase (one to three times the normal level), and bilirubin (usually not >10 milligrams/dL) may be observed. Marked elevations of transaminases or bilirubin are less common unless septic shock is present; if seen, consider a biliary source of infection. Smaller elevations in liver function tests can result from intermittent or prolonged macro- or microvascular hypoperfusion and ischemia or can be secondary to direct endotoxin, cytokines, or immune complex damage. Red blood cell hemolysis from microvascular coagulation can also rarely cause jaundice.

GI CHANGES

The most common GI manifestation of sepsis is ileus, which may persist for days after shock resolves. Major blood loss secondary to upper GI bleeding is rare in septic patients. Minor GI blood loss within 24 hours of developing severe sepsis can result from painless erosions in the mucosal layer of the stomach or duodenum.

HEMATOLOGIC CHANGES

Multiple abnormalities are possible in the hematologic system in the setting of sepsis, including neutropenia or neutrophilia, thrombocytopenia, or disseminated intravascular coagulation. Neutrophilic leukocytosis with a "left shift" results from demargination and release of newer

granulocytes from the marrow storage pools. However, the presence of excessive bands (the immature neutrophil) is neither sensitive nor specific for infection. **Neutropenia** occurs rarely and is associated with an increase in mortality; it results from increased peripheral use of neutrophils, damage to neutrophils by bacterial by-products, or depression of marrow granulocyte production by inflammatory mediators. Functional neutropenia also creates a relative immunosuppression, particularly later in patients' hospital course. Both red cell production and survival decrease during sepsis, but anemia is not expected unless it existed prior to the infection, the infection is extremely prolonged, or there is concomitant bleeding.

Thrombocytopenia may arise as a consequence of disseminated intravascular coagulation but is present in >30% of cases of sepsis even in the absence of overt disseminated intravascular coagulation, and lower platelet levels are associated with worse outcomes.[32,33] Proposed mechanisms of thrombocytopenia include inhibition of thrombopoiesis, increased platelet turnover (due to a consumptive coagulopathy), increased endothelial adherence, and increased destruction secondary to immunologic mechanisms.

Finally, fulminant **disseminated intravascular coagulation** where clinical clotting and bleeding exist is rare but associated with a very poor prognosis.[26] Occult disseminated intravascular coagulation, with microvascular flow abnormalities, subclinical increased activation of the coagulation system, and evidence of increased fibrinogen split products in the absence of overt bleeding and clotting, is much more common. The activation of the hemostatic (clotting) system is due primarily to the activation of the extrinsic pathway of clotting. The fibrinolytic system is also activated in sepsis and plays an important role in limiting fibrin deposition in the microcirculation. The release of tissue plasminogen activator activates the fibrinolytic system, at least initially in sepsis. As sepsis progresses, there is an increased release of plasminogen activator inhibitor 1, which blocks plasmin generation and thus contributes to fibrin deposition in the microcirculation and subsequent multiple-organ failure. Laboratory studies suggesting the presence of disseminated intravascular coagulation include thrombocytopenia, prolonged prothrombin and activated partial thromboplastin values, decreased fibrinogen and antithrombin III levels, and increased fibrin monomer, fibrin split products, and D-dimer levels.

METABOLIC CHANGES

Sepsis induces multiple metabolic changes. Abnormalities in lactate metabolism due to tissue hypoperfusion with resultant anaerobic metabolism as well as increased aerobic production of lactate have been discussed previously (see "Systemic Inflammatory Response Syndrome Prognosis"). Hyperglycemia is seen even in patients without a history of diabetes; in this latter group, it is associated with a worse prognosis, in contrast to less impact of glucose elevations in those with known diabetes.[34] Hypoglycemia with glucose levels as low as 10 to 20 milligrams/dL is reported but uncommon, and may result due to depletion of hepatic glycogen and inhibition of gluconeogenesis and/or adrenal insufficiency. Adrenal insufficiency can occur,[35] caused by hypoperfusion of the adrenal glands, adrenal or pituitary hemorrhage, cytokine dysfunction of the adrenals, drug-induced hypermetabolism, inhibition of steroidogenesis by chemotherapeutics (e.g., ketoconazole), and desensitization of glucocorticoid responsiveness at the cellular level.

SKIN

There are five potential cutaneous manifestations of sepsis: direct bacterial involvement of the skin and underlying soft tissues (cellulitis, erysipelas, and fasciitis); lesions from hematogenous seeding of the skin or the underlying tissue (petechiae, pustules, cellulitis, ecthyma gangrenosum); lesions from hypotension and/or disseminated intravascular coagulation (acrocyanosis and necrosis of peripheral tissues); lesions from intravascular infections (microemboli and/or immune complex vasculitis); and lesions caused by toxins (toxic shock syndrome). Look for any necrotizing or surgical source of sepsis, and recall that the toxic shock syndromes present in an overlapping fashion (see chapter 150, "Toxic Shock Syndromes").

DIAGNOSIS

In the ED, **sepsis is a clinical diagnosis** predicated on suspicion or confirmation of infection, systemic inflammation, and evidence of new organ dysfunction and/or tissue hypoperfusion.[36] Septic shock is present or likely in any individual with the preceding signs (Table 151-1) and a systolic blood pressure of <90 mm Hg (or 2 standard deviations below normal for age in children) after an initial fluid bolus (often cited as 20 to 30 mL/kg crystalloid, generally 1.5 to 3 L in adults), or who displays evidence of inadequate organ perfusion.

Many patients with minor infections can meet consensus criteria for sepsis due to evidence of systemic inflammation. If there is new organ dysfunction or tissue hypoperfusion secondary to sepsis, consider more aggressive assessments and interventions. However, in the absence of new organ failure, the diagnosis of sepsis does not necessarily imply a poor prognosis.

The differential diagnosis of severe sepsis and septic shock includes other causes of shock. This includes cardiogenic, hypovolemic, anaphylactic, neurogenic, or obstructive shock (pulmonary embolism, cardiac tamponade), or endocrine disorders (adrenal insufficiency, thyroid storm) that mimic sepsis. **Given the high frequency of sepsis in ED patients with undifferentiated shock (40%), think of this cause when uncertain.** Children may not have hypotension until very late in the course of the disease process due to an ability to upregulate their heart rate as a compensatory response to tissue hypoperfusion. This means considering compensated shock and occult sepsis in infected children who do not appear well, even with normotension.

Once sepsis is diagnosed, seek the source, but **do not withhold** interventions such as resuscitative measures and antimicrobials. Often the source is clear, as the patient may present with signs and symptoms attributable to a pulmonary, genitourinary, skin and soft tissue, or intra-abdominal source. However, a source of infection may not be readily apparent or may be difficult to detect because of altered mental status.

The most common sepsis trigger is **acute bacterial pneumonia**, although viral and bacterial etiologies are difficult to differentiate initially. The most frequent causative organisms are *Streptococcus pneumoniae*, *S. aureus*, gram-negative bacilli, and *Legionella pneumophila*. A chest radiograph may identify air space changes and pneumonia, although radiograph findings can lag behind the clinical presentation (see also chapter 65, "Pneumonia and Pulmonary Infiltrates").

Acute pyelonephritis, typically due to gram-negative enteric bacteria or enterococci, is another frequent cause of severe sepsis. Other abdominal triggers include **cholecystitis** and **cholangitis**, each rare but particularly devastating sources of septic shock, and both require immediate surgical assessment. If there is abdominal tenderness or peritonitis, the possibilities include perforated viscous, appendicitis, diffuse colitis, or intra-abdominal abscesses. Acute pancreatitis can result in a presentation identical to that of septic shock due to widespread inflammation.[37] If peritonitis or organ ischemia/necrosis exists, early surgical consultation is needed. In women of childbearing age, septic abortion and postpartum endometritis or myometritis are unusual etiologies of septic shock.

The most common skin and soft tissue infection triggering a sepsis syndrome is cellulitis due to *S. aureus* or *Streptococcus pyogenes*. Soft tissue infections caused by gram-negative organisms are indistinguishable from those caused by staphylococci or streptococci. Shock associated with a generalized erythematous macular rash may be a toxic shock syndrome. Necrotizing soft tissue infections are usually seen in immunocompromised patients, diabetic patients, or patients with a history of poor vascular circulation (see chapter 152, "Soft Tissue Infections"). Pay close attention to skin and soft tissue infections, particularly in elderly or obtunded patients. Include an assessment for decubitus ulcers and a genitourinary assessment to look for a necrotizing infection such as Fournier's gangrene.

Individuals without an obvious source of septic shock may have a primary bacteremia or endocarditis. The most prevalent causes of primary bacteremia in outpatients are *S. aureus*, *S. pneumoniae*, and *Neisseria meningitidis*. *Pseudomonas aeruginosa* and other gram-negative bacteria are occasional causes of bacteremia and endocarditis in injection drug users. Secondary bacteremia from indwelling medical devices, including

intraperitoneal or intravascular dialysis catheters, chemotherapy ports, peripherally inserted central catheters, ventriculoperitoneal shunts, and pacemaker/defibrillators, is possible. Although bacteremia can be suspected, it takes time for a blood culture to be fully assessed, making ED diagnosis difficult.

Acute bacterial meningitis is a devastating but rare cause of septic shock. Community-acquired meningitis with shock is usually caused by *S. pneumoniae* or *N. meningitidis* (see chapter 174, "Central Nervous System and Spinal Infections"). Brain and spinal abscesses, subdural or epidural empyemas, and viral CNS infections are seldom associated with shock on the initial presentation. Shock is also unusual in neurosurgical patients with *S. aureus* or enteric gram-negative meningitis secondary to neurosurgical procedure or skull fracture.

LABORATORY TESTING AND IMAGING

Tests are useful to assess the general hematologic and metabolic state of the patient and aid in detecting occult bacterial infection, uncovering a specific microbial cause of infection, and identifying occult severe sepsis. Common tests include a CBC with platelet count; serum electrolytes (including calcium and glucose); renal function panel (BUN and creatinine levels); lactic acid level; liver function panel (bilirubin, alkaline phosphate, and aspartate and alanine aminotransferase levels); and urinalysis. An arterial blood gas will aid in assessing the metabolic, ventilatory, and oxygenation adequacy in select patients. Type and screening of red blood cells is wise with any hypotension or anemia. In the setting of active bleeding or suspected disseminated intravascular coagulation, consider prothrombin time, activated partial thromboplastin time, fibrinogen, and D-dimer.

Given the frequency of pneumonia or concomitant acute respiratory distress syndrome, obtain a chest radiograph. Abdominal plain radiographs or CT scans are needed in patients if perforation or diffuse inflammation is suspected as a potential source of intra-abdominal sepsis, and US can identify a biliary source. Soft tissue CT scans to assess for the presence of free air in the tissue or deep space abscesses may assist in making the diagnosis of necrotizing skin and soft tissue infections. Perform head CT and lumbar puncture in any patient with potential meningitis, but do not delay antibiotics pending these tests (see chapter 174). If considering a spinal epidural abscess, an MRI is obtained after resuscitation.

In adults with sepsis, obtain at least two separate sets of specimens for blood culture from different venipuncture sites when possible. Order Gram staining and culture of secretions from any potential site of infection, if possible.

Other tests of interest in the assessment of sepsis include C-reactive protein and procalcitonin, both of which reflect systemic inflammation; neither of these tests can exclude sepsis, and they are not routinely needed in the ED.[37,38] Both of these tests may be better suited to guide the necessity of initiating or continuing antimicrobial therapy outside of sepsis or after a treatment course.[39]

TREATMENT

The cornerstones of the initial treatment and stabilization of severe sepsis are **early recognition, early reversal of hemodynamic compromise, and early infection control**.[36] Base the resuscitation on administering fluids, frequently assessing response, and adding adjunct therapies including vasopressors based on the conditions. The specific method of titrating resuscitation is less important than treating early and aggressively.

The goals of resuscitation are to improve preload, tissue perfusion, and oxygen delivery. There is no "set amount of fluid," although most patients will require a total (bolus plus infusion) of 2 to 5 L of crystalloid in the first 6 hours to achieve optimal outcomes. Similarly, **do not delay vasopressors when blood pressure does not respond to volume or if volume overload seems likely**. Administer appropriate antibiotics, and remove any nidus of infection. Each of these interventions will be discussed in detail below. Once the patient is stabilized, other interventions such as appropriate management of oxygenation and ventilation, fever control to reduce metabolic demand, and control of hyperglycemia may be needed to improve patient outcomes.

EARLY QUANTITATIVE RESUSCITATION

The primary deficit leading to poor outcomes in shock states (typically studied in hemorrhagic shock) is a mismatch between oxygen supply and demand,[40] and after a certain time point, processes initiated by this mismatch are irreversible. In 2001, Rivers et al[41] described the use of an early, structured hemodynamic resuscitation protocol driven by a central venous catheter with continuous oximetric capability to titrate fluids to central venous pressure, vasopressors to mean arterial pressure, and transfusion of blood or inotropes to central venous oxygen saturation (S_{CVO2}). This protocol, termed "early goal-directed therapy," decreased mortality when compared with standard care, although all patients had central venous catheters placed early. Follow-up uncontrolled observational studies confirmed that even partial use of this approach lowered mortality in settings compared with previous times without aggressive early sepsis detection or care.[42-46]

In a second large trial, Jones et al[4] randomized patients to the Rivers early goal-directed therapy protocol or to a protocol that measured lactate clearance of ≥10% rather than S_{CVO2}. The lactate clearance protocol was noninferior to continuous S_{CVO2} monitoring in the setting of ED-based resuscitation of septic shock. Lactate clearance–guided therapy (titrating fluids and vasopressors) became an alternative to invasive S_{CVO2} monitoring and early goal-directed therapy. Although the ideal lactate clearance target remains unclear, a minimum of 10% relative lactate clearance[23,24] and normalization of lactate to <2 mmol/L emerged as goals.[36,47] Still, about one third of patients with severe sepsis have a normal lactate,[47] and up to one half or more have a normal S_{CVO2},[48] limiting either tool in guiding therapy.

The newly released ProCESS trial[49] compared three ED treatment groups after early identification and antibiotics: protocol-based resuscitation using invasive central venous monitoring (the Rivers early goal-directed therapy protocol), protocol-based care using clinical parameters such as blood pressure and shock index (but no catheter-driven care), and nonprotocol usual care chosen by the bedside physician(s). These resuscitative approaches all delivered different care, but all groups received aggressive fluids and pressors in addition to early recognition and antibiotic use; however, **no one approach was superior** in terms of morbidity or mortality. Thus, the ProCESS trial emphasizes that the **early recognition of sepsis, administration of antimicrobials, adequate volume resuscitation, and assessment of the adequacy of circulation are the important elements that improve outcomes, not any specific path of resuscitation**. These observations allow providers or sites the flexibility of crafting the best approach to care but show that mandatory central venous catheterization and monitoring of central venous pressure or S_{CVO2} are not necessary for all patients with sepsis.

VOLUME RESUSCITATION

When resuscitating an ED patient with sepsis, first assess and replenish circulating volume, typically with an initial 20 to 30 milligram/kg crystalloid bolus, preferably through large-bore IVs. This amounts to an approximate 1- to 2-L bolus of saline or lactated Ringer's solution in a 70-kg adult, although some patients require more or less. Saline can produce a hyperchloremic metabolic acidosis if used in large-volume resuscitation, causing some to switch to lactated Ringer's if large volumes are planned. Colloids are not needed in early sepsis care, and hydroxyethyl starch can worsen acute kidney injury.

The most important variable process in volume replacement is determining if a patient is volume responsive. There are several more sophisticated measurements that can be used to make this determination such as cardiac output and stroke volume variation. The latter entails lifting the legs of a supine patient for 60 seconds; improved blood pressure or less variation in the peak blood pressure wave (if an arterial line is present) identifies a volume-responsive patient who will likely benefit from more fluid. If these tools are unavailable, assess the need for further volume expansion with empiric crystalloid boluses until the patient fails

to demonstrate a physiologic or hemodynamic response (e.g., rise in systolic or mean pressure, decrease in heart rate, improvement in peripheral pulses or extremity perfusion, increase in urinary output).

VASOPRESSORS

Once the patient fails to respond to further intravenous volume expansion, provide adequate perfusion pressure with vasoactive agents. In general, a mean arterial pressure goal of 65 mm Hg is sought; routine targeting of a higher mean arterial pressure does not aid outcomes, although in some patients, it may be necessary.[50] A mean arterial pressure is preferable to a specific systolic blood pressure goal; however, use of systolic pressure is often preferred by clinicians, who often seek a goal of 90 mm Hg or higher.

Ideally, deliver vasoactive agents through a central venous line to limit extravasation and resultant tissue necrosis. If a central line is unavailable, use a large, secured peripheral IV temporarily for vasopressor administration. In septic shock, **norepinephrine** at a dose of 0.5 to 30 micrograms/min is the best first choice since the dual α- and β-adrenergic effects result in peripheral vasoconstriction and cardiac inotropy. Dopamine has a higher rate of complications, most notably dysrhythmias and failure, compared with norepinephrine and is no longer routinely recommended.[51] **Vasopressin** is a second-line agent and may allow for the down-titration of the norepinephrine dose.[52] Give vasopressin as a constant infusion at a rate of 0.03 or 0.04 U/min. Do not titrate the dose, because higher rates are associated with vasospasm and high morbidity. **Epinephrine** at a dose of 1 to 20 micrograms/min appears safe and equivalent to norepinephrine when dosed appropriately,[53] although the risk of medication dosing errors related to epinephrine concentration may make norepinephrine a superior choice. If tachydysrhythmias are a problem, phenylephrine is an option as a pure α-adrenergic agonist.

CENTRAL VENOUS OXYGENATION

After volume repletion and perfusion pressure optimization, if tissue perfusion appears to continue to be compromised (cool extremities, poor pulses, worsening organ function), one may assess oxygen balance. Although not needed routinely, insertion of a continuous central venous oxygen saturation (S_{CVO2}) measuring catheter can aid additional therapy as outlined in the early goal-directed therapy approach.[41] If S_{CVO2} is less than 70%, it implies a relative oxygen supply and demand mismatch.

LACTATE CLEARANCE

An alternative is to guide therapy through the use of lactate clearance, because a relative decrease in lactate over time suggests a restoration of adequate tissue perfusion. Measure lactate using the same method 1 to 2 hours apart; improvement of 10% or more is associated with improved clinical outcomes.

TREAT INFECTION

Give broad-spectrum antibiotics as early as possible for severe sepsis.[36] Combination antibiotic therapy as opposed to monotherapy leads to improved outcomes, potentially due to higher rates of bactericidal activity.[55] Recommendations for antibiotic regimens are in **Table 151-2**. Therapy can later be tailored based on clinical response and microbiologic data. Given the rising rates of community-acquired methicillin-resistant *S. aureus* (CA-MRSA), ensure this is covered along with gram-negative pathogens and anaerobic organisms. Vancomycin is often underdosed in clinical practice, which can impair recovery[55]; guidelines suggest an initial vancomycin dose of 25 to 30 milligrams/kg in critically ill patients.[56] In immunosuppressed patients, consider antifungal or antiviral agents.

The Surviving Sepsis Campaign recommends giving antibiotics as soon as feasible, ideally within 1 hour of the recognition of severe sepsis and/or within 3 hours of triage. However, these are suggestions, not a standard of care,[36] and these recommendations are often not achievable.[57] Whether antimicrobials are best given initially or only after hemodynamic stabilization of the patient is unclear; given the poor prognosis associated with delays in either resuscitation or infection therapies, we recommend delivering both concurrently. Ideally, sample any organ infectious source and obtain blood cultures *prior* to the initiation of antibiotics, *but do not delay* the initiation of antibiotics to obtain cultures.[36]

Infection control is not confined to antimicrobial administration; it also includes addressing potential surgical sources of infection. Drain any source and remove indwelling vascular lines and other medical devices suspected as infected once the patient is stabilized.

OTHER THERAPIES: VENTILATION, GLYCEMIC CONTROL, ACTIVATED PROTEIN C, AND STEROIDS

Sepsis is the leading cause of acute respiratory distress syndrome. Data from a large study of patients with acute respiratory distress syndrome found that low tidal volume ventilation (6 mL/kg ideal body weight) leads to superior outcomes compared with large (12 mL/kg) volume ventilation,[58] with the latter likely creating barotrauma from overdistension of the alveoli. Thus, low tidal volume ventilation with a positive end expiratory pressure adequate to prevent alveolar collapse is recommended. Although starting at a low tidal volume is recommended,[36] it is unclear whether a fixed volume of 6 mL/kg is best for all; some titration is permissible. To accommodate low tidal volumes, patients may be allowed some hypercapnia as long as the accompanying acidosis does not threaten hemodynamic deterioration.

Multiple trials note a link between hyperglycemia and worsened outcomes in the setting of sepsis, notably in patients without pre-existing diabetes. Although there is evidence of improved outcomes in patients who achieve tight glucose control (target glucose level of 80 to 110 milligrams/dL), the high rate of hypoglycemia occurring with attempts at this targeted glycemia may explain increased harm seen.[59] More modest efforts (seeking blood glucose <180 mg/dL) allow for similar outcomes with less variation.[59] Glucose control is most important after initial care and is best if protocolized, especially for patients receiving extended sepsis care in the ED.

Therapies to manipulate the coagulation cascade are unproven; the most promising candidate to date, activated protein C, failed to improve outcomes and is not used.[60] Systemic corticosteroids are the only anti-inflammatory agent in use in clinical practice but are controversial. Despite early literature suggesting a mortality benefit,[61] recent data failed to confirm these findings.[62] Corticosteroids shorten the time to shock reversal and are adjunctive agents in patients with *refractory* hemodynamic shock (i.e., requiring more than one vasopressor or active upward titration of vasopressors after adequate volume restoration). Stimulation testing using adrenocorticotropic hormone is not clinically helpful. Although even a single dose of etomidate may alter adrenal activity as measured by laboratory tests,[63] there is no clear evidence that the use of etomidate to facilitate endotracheal intubation alters any clinically important outcome.

SPECIAL POPULATIONS

PATIENTS WITH POSITIVE BLOOD CULTURES

There is no consensus for interpretation or management of positive ED blood cultures. Before assessing positive blood culture reports and choosing a plan, you should know local typical pathogens and contaminants along with patient data, including reason for seeking care, past medical history, immune status, and current condition at the time the positive culture was called to the clinician. *Corynebacterium* spp., *Bacillus* spp., and *Propionibacterium acnes* rarely represent true bacteremia or require action. Other pathogens such as viridans group streptococci, enterococci, and coagulase-negative *Staphylococcus* (the most common organism reported on blood culture notifications) may represent a pathogen or require new care in a given patient. In both ambulatory and ED patients, blood cultures are positive in less than 10% of cases, with only one third to two thirds of those cultures representing true bacteremia.[64]

TABLE 151-2 Empiric Antibiotic Selection in Severe Sepsis and Septic Shock

Host	Likely Pathogens	Initial Antibiotic Selection
Adults (nonneutropenic) without an obvious source of infection	*S. aureus,* streptococci, gram-negative bacilli, others	Imipenem, 500 milligrams every 6 h to 1 gram IV every 8 h *or* Meropenem, 1 gram IV every 8 h *or* Doripenem, 500 milligrams IV every 8 h *or* Ertapenem*, 1 gram IV every 24 h *plus* Vancomycin†, 15 milligrams/kg loading dose
Adults (nonneutropenic), suspected biliary source	Aerobic gram-negative bacilli, enterococci	Ampicillin/sulbactam, 3 grams IV every 6 h *or* Piperacillin/tazobactam, 4.5 grams IV every 6 h *or* Ticarcillin/clavulanate, 3.1 grams IV every 4 h
Adults (nonneutropenic), suspected pneumonia	*S. pneumoniae*, methicillin-resistant *S. aureus*, gram-negative bacilli, *Legionella*	Ceftriaxone, 1–2 grams IV every 12 h *plus* Azithromycin, 500 milligrams IV, then 250 milligrams IV every 24 h *plus* Levofloxacin, 750 milligrams IV every 24 h *or* moxifloxacin, 400 milligrams IV every 24 h *plus* Vancomycin†, 15 milligrams/kg loading dose
Adults (nonneutropenic), suspected illicit use of IV drugs	*S. aureus*	Vancomycin†,15 milligrams/kg loading dose
Adults with petechial rash	*N. meningitidis,* RMSF	Ceftriaxone, 2 grams IV every 12 h *or* Cefotaxime, 2 grams IV every 4–6 h *Consider* Addition of doxycycline 100 milligrams IV every 12 h for possible RMSF
Adults (nonneutropenic), suspected intra-abdominal source	Mixture of aerobic and anaerobic gram-negative bacilli	Imipenem, 500 milligrams IV every 6 h to 1 gram IV every 8 h *or* Meropenem, 1 gram IV every 8 h *or* Doripenem, 500 milligrams IV every 8 h *or* Ertapenem, 1 gram IV every 24 h *or* Ampicillin/sulbactam, 3 grams IV every 6 h *or* Piperacillin/tazobactam, 4.5 grams IV every 6 h
Adults (nonneutropenic), suspected urinary source (hospitalized with pyelonephritis)	Aerobic gram-negative bacilli, enterococci	Levofloxacin, 750 milligrams IV every 24 h *or* Moxifloxacin, 400 milligrams IV every 24 h *or* Piperacillin/tazobactam, 4.5 grams IV every 6 h *or* Ceftriaxone, 1–2 grams IV every 12–24 h *or* Ampicillin, 1–2 grams IV every 4–6 h *plus* gentamicin, 1.0–1.5 milligrams/kg every 8 h‡

(*Continued*)

TABLE 151-2 Empiric Antibiotic Selection in Severe Sepsis and Septic Shock (*Continued*)

Host	Likely Pathogens	Initial Antibiotic Selection
Adults (nonneutropenic), suspected urinary source (complicated urinary tract infection/ urinary catheter)	Enterobacteriaceae, *P. aeruginosa*, enterococci, rarely *S. aureus*	Piperacillin/tazobactam, 4.5 grams IV every 6 h *or* Imipenem, 500 milligrams every 6 h to 1 gram IV every 8 h *or* Meropenem, 1 gram IV every 8 h *or* Doripenem, 500 milligrams IV every 8 h *or* Ampicillin, 1–2 grams IV every 4–6 h *plus* gentamicin, 1.0–1.5 milligrams/kg every 8 h‡
Neutropenic adults	Aerobic gram-negative bacilli, especially *P. aeruginosa, S. aureus*	Ceftazidime, 2 grams IV every 8 h *or* Cefepime, 2 grams IV every 8 h *or* Imipenem, 500 milligrams IV every 6 h to 1 gram IV every 8 h *or* Meropenem, 1 gram IV every 8 h *or* Piperacillin/tazobactam, 4.5 grams IV every 6 h *plus* Levofloxacin, 750 milligrams IV every 24 h *or* moxifloxacin, 400 milligrams IV every 24 h *plus* Vancomycin†, 15 milligrams/kg loading dose *and consider* Fluconazole, 400 milligrams IV every 24 h *or* micafungin, 100 milligrams every 24 h
Patients with suspected anaerobic source: intra-abdominal, biliary, female genital tract infection; necrotizing cellulitis; odontogenic infection; or anaerobic soft tissue infection	Anaerobic bacteria plus gram-negative bacilli	Metronidazole, 15 milligrams/kg IV load then 7.5 milligrams/kg every 8 h# *or* Clindamycin, 600–900 milligrams IV every 8 h
Patients with indwelling vascular devices	Coagulase-negative *Staphylococcus,* methicillin-resistant *S. aureus*	Vancomycin†, 15 milligrams/kg loading dose
Patients with potential for *Legionella* species infection		Azithromycin, 500 milligrams IV then 250 milligrams IV every 24 h *or* Erythromycin, 800 milligrams IV every 6 h *should be added to the regimen*
Asplenic patients	*S. pneumoniae, N. meningitidis, Haemophilus influenzae, Capnocytophaga*	Ceftriaxone, 1 gram IV every 24 h up to 2 grams IV every 12 h if meningitis

Abbreviation: RMSF = Rocky Mountain spotted fever.

*Ertapenem has no antipseudomonal coverage and is not recommended in many intensive care units due to concerns of potentiating pseudomonal antimicrobial resistance.

†In most communities in the United States, methicillin-resistant *S. aureus* colonization is extremely high, and consideration should be given to including vancomycin in addition to the antibiotic recommendations given in the table. Although initial vancomycin dosage is typically suggested at 15 milligrams/kg, this results in delayed time to effective antimicrobial activity, and initial dosages of 25 to 30 milligrams/kg have been recommended by some authorities. If the patient has an allergy to vancomycin, linezolid 600 milligrams IV can be substituted.

‡Multiple daily dosing: 2 milligrams/kg load then 1.7 milligrams/kg every 8 h.

#Metronidazole is often prepackaged as 500-milligram bags. Dosing at 500 milligrams IV every 6 or 8 h to approximate the milligram/kg dosing may speed time to antibiotic administration by decreasing pharmacy mixing time.

An important predictor of true-positive first blood culture is persistence of the organism on subsequent culture *if* the latter was done separately (time and location); in a discharged patient, this requires re-evaluation, either in the ED or by another provider. Decisions about antibiotics or admission are guided by the pathogen and clinical grounds: All highly lethal pathogens should receive therapy and admission, whereas some pathogens in blood culture may clear with or without therapy, with a plan made after all current data are assimilated.

POSTSPLENECTOMY PATIENTS

Patients without a spleen are at increased risk for infection with encapsulated species such as *Salmonella* or *Haemophilus influenzae*. Table 151-2 details treatment recommendations of these patients. Although not relevant at the time of initial sepsis care, these patients should have appropriate bacterial immunization following a splenectomy.

NEUTROPENIC FEVER

Due to an impaired immune system, neutropenic patients are at increased risk for developing sepsis and having worse outcomes. Any fever in a neutropenic patient is suspicious for infection, and all patients should have source organ and blood cultures drawn followed by empiric antibiotics. After conferring with an oncologist, some patients may be treated at home with oral broad-spectrum agents (often including a quinolone) *if* they look well and are closely followed; the rest are admitted.

Sepsis Checklist

- In those with signs or symptoms of infection, look for cryptic shock: check vital signs and lactate early and repeat if in doubt. Occult shock is dangerous.
- Give appropriate antimicrobials to patients with suspected sepsis as soon as possible.
- Look hard for the infection source, including getting blood cultures and seeking a surgical or indwelling medical device infection.
- Give at least 1 to 2 L bolus of intravenous crystalloid to hypotensive patients or patients with elevated lactate and monitor the response.
- Recheck resuscitation responses using more than one measure—better vital signs/shock index, improved clinical appearance, decreasing lactate, or improved central venous pressure.
- A central venous catheter is not mandatory to resuscitate most patients, and central venous pressure trends are more important than absolute values.
- Give more fluids if not better and there is no evidence of volume overload. Often, 3 to 5 L are needed in the first 6 hours.
- Administer norepinephrine as the first-line vasopressor to patients with refractory hypotension despite adequate fluid resuscitation.
- Although not mandatory for all, consider central venous pressure and central venous oxygen monitoring to titrate dobutamine and packed red blood cells, and consider corticosteroids in those with refractory shock.

CHAPTER 152

Soft Tissue Infections

Elizabeth W. Kelly
David Magilner

INTRODUCTION

This chapter discusses soft tissue infections in adults; impetigo and other soft tissue infections in children are discussed in chapter 141, "Rashes in Infants and Children."

ANATOMY AND DEFINITIONS

The skin consists of the superficial epidermis, dermis, and deeper subcutaneous tissues including fat (**Figure 152-1**). The lymphatics run parallel with the blood vessels (not shown in the figure). *Cellulitis* is an infection of the dermis and subcutaneous tissues of the skin. Cellulitis is divided clinically as *purulent* or *nonpurulent,* and management of the two types is different.[1,2] Purulent cellulitis is cellulitis with an abscess, or cellulitis with drainage or exudate in the absence of a drainable abscess. Nonpurulent cellulitis has no purulent drainage or exudate and no associated abscess.[1,2] *Erysipelas* traditionally has been defined as a more superficial skin infection involving the upper dermis with clear demarcation between involved and uninvolved skin with prominent lymphatic involvement. However, in many countries, the term *erysipelas* is considered synonymous with *cellulitis*.[2] *Folliculitis* is an infection of the hair follicle, often purulent, but is superficial without involvement of the deeper tissues. *Skin abscesses* are collections of pus within the dermis and deeper skin tissues, potentially involving the subcutaneous tissues. Abscesses should be differentiated from simple cellulitis, because abscesses should be treated with incision and drainage.[1] *Furuncles* (or boils) are single, deep nodules involving the hair follicle that are often suppurative.[2] *Carbuncles* are formed by multiple interconnecting furuncles that drain through several openings in the skin.[2] *Necrotizing soft tissue infections* are necrotizing infections involving any of the soft tissue layers including the dermis, subcutaneous tissues, fascia, and muscle.[3]

CELLULITIS AND ERYSIPELAS

EPIDEMIOLOGY

Cellulitis accounts for approximately 1.3% of all ED visits. General risk factors for cellulitis are listed in **Table 152-1**.[4,5] Risk factors for specific organisms causing cellulitis are listed in **Table 152-2**.[1,4,6-11] Cellulitis is observed more frequently among middle-aged and elderly patients, whereas erysipelas is more common among children and elderly patients.[12] Patient characteristics demonstrate a male predominance (61%) and a mean age of 46 years, and the vast majority of infections involve either the lower or upper extremities (48% and 41%, respectively). Approximately 10% of patients diagnosed with cellulitis are hospitalized, the majority of these patients are over age 64 years.

MICROBIOLOGY

Approximately 80% of cellulitis cases are caused by gram-positive bacteria. Community-acquired Methicillin-resistant *Staphylococcus aureus* (MRSA) is now the most common cause of skin and soft tissue infections presenting to the ED,[6,13] regardless of patient risk factors. The Infectious Diseases Society of America recommends differentiation of purulent from nonpurulent cellulitis (see detailed definitions above) for treatment decisions.[1] MRSA is likely to be the causative agent in purulent cellulitis. For nonpurulent cellulitis, the role of MRSA is unknown, and empirical therapy for β-hemolytic streptococcal infection with β-lactams is recommended.[1,14,15]

Gram-negative aerobic bacilli are the third most common etiology. Other less common pathogens causing cellulitis are listed in Table 152-2 with associated risk factors.

Erysipelas is usually caused by β-hemolytic streptococci.[12] Bullous erysipelas is a more severe form, and can represent synergy with beta-hemolytic streptococci and methicillin-resistant staphylococcal aureus.[16]

PATHOPHYSIOLOGY

Most symptoms of cellulitis are secondary to a complex set of immune and inflammatory reactions triggered by cells within the skin itself. Although bacterial invasion is what triggers the inflammation, the organisms are largely cleared from the site within the first 12 hours, and the infiltration of cells, such as Langerhans cells and keratinocytes, releases the cytokines interleukin-1 and tumor necrosis factor that enhance skin infiltration by lymphocytes and macrophages. The net effect is a rapid clearing of bacteria but with significant inflammatory response.

CLINICAL FEATURES

Cellulitis In cellulitis, the affected skin is tender, warm, erythematous, and swollen, and typically does not exhibit a sharp demarcation from uninvolved skin. Edema can occur around hair follicles that leads to dimpling of the skin, creating an orange peel appearance referred to as "peau d'orange" (**Figure 152-2**). Symptoms develop gradually over a few days. Lymphangitis and lymphadenopathy are seen occasionally in previously healthy patients, but purely local inflammation is much more common. In cases of purulent cellulitis, exudate drains from the wound[1]; an abscess may or may not subsequently form. Systemic signs of fever, leukocytosis, and bacteremia are more typical in the immunosuppressed. Recurrent episodes of cellulitis can lead to impairment of lymphatic drainage, permanent swelling, dermal fibrosis, and epidermal thickening. These chronic changes are known as elephantiasis nostra and predispose patients to further attacks of cellulitis.

Erysipelas In erysipelas, the onset of symptoms is usually abrupt, with fever, chills, malaise, and nausea representing the prodromal phase. Over the next 1 to 2 days, a small area of erythema with a burning sensation develops. As infection progresses, the affected skin becomes indurated with a raised border that is distinctly demarcated from the surrounding normal skin. The "peau d'orange" appearance is also

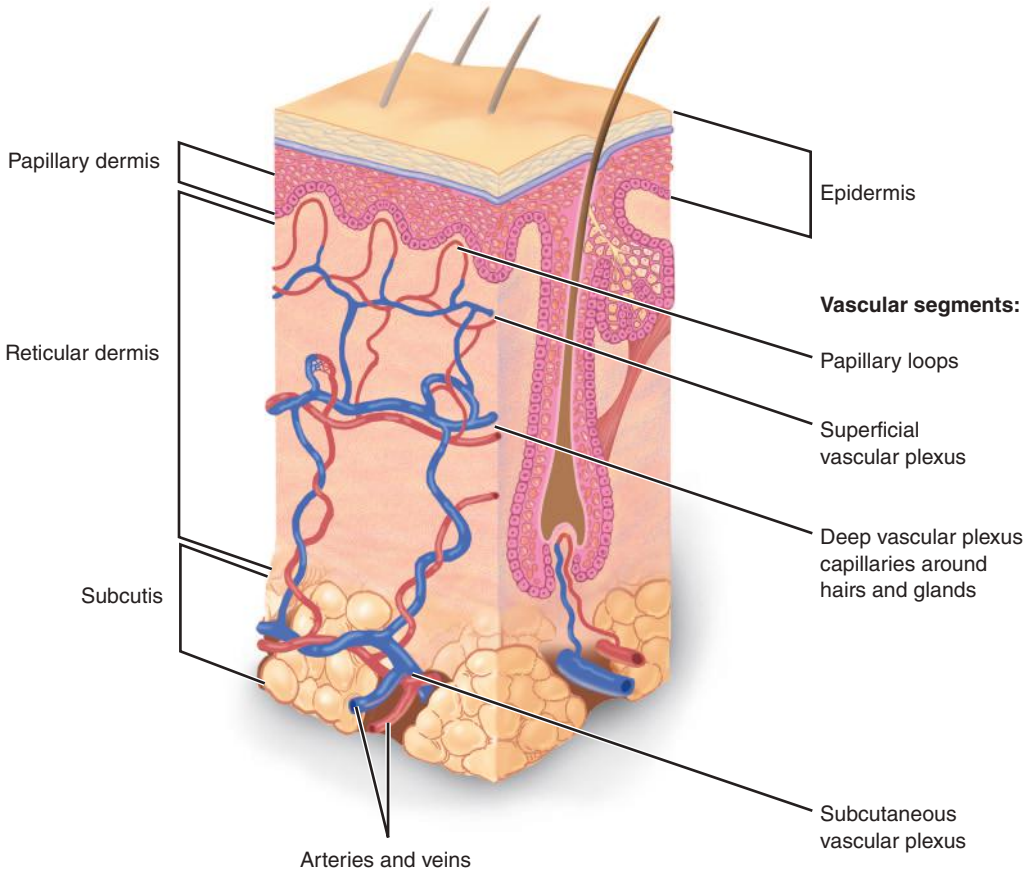

FIGURE 152-1. Schematic diagram of the architecture of the skin. This diagram shows the anatomy of the skin, including the epidermis, dermis, and deeper subcutaneous tissues. Also shown are the blood vessels and a hair follicle. [Reproduced with permission from Wolff et al: *Fitzpatrick's Dermatology in General Medicine*, 7th ed. © 2008, McGraw-Hill, Inc., New York.]

common in erysipelas. A classic description is a "butterfly" pattern over the face (**Figure 152-3**). Complete involvement of the ear is the "Milian ear sign" and is a distinguishing feature of erysipelas because the ear does not contain deeper dermis tissue typically involved in cellulitis. Lymphatic inflammatory changes, known as toxic striations, and local lymphadenopathy are common. Purpura, bullae, and small areas of necrosis warrant a search for possible necrotizing soft tissue infection. On resolution of the infection, desquamation of the site often occurs.

DIAGNOSIS

The diagnosis of cellulitis and erysipelas is clinical. Management should be guided by the clinical differentiation between purulent and nonpurulent soft tissue infections.[1,2] Presence of an abscess defines the soft tissue infection as purulent; purulent cellulitis is defined as cellulitis with drainage or exudate in the absence of a drainable abscess.

Mild disease, for both purulent and nonpurulent forms of cellulitis, is distinguished by the absence of systemic symptoms. In cases of mild infection, blood cultures, needle aspiration, punch biopsy, leukocyte count, or other lab data are of little benefit and are not recommended.[2] Needle aspiration of the leading edge of an area of cellulitis produces organisms in 15.7% of cultures (range, 0% to 40%), and punch biopsy reveals an organism only 18% to 26% of the time.[14] Areas with abscess formation have significantly higher yields; **wound culture** is recommend when the decision has been made to place the patient on antibiotics for purulent cellulitis.[2] Blood cultures are positive in only 5% of cases. For both purulent and nonpurulent cellulitis, in patients with systemic toxicity, extensive skin involvement, underlying comorbidities, immunodeficiency, immersion injuries, failed initial therapy, or recurrent episodes, or in circumstances such as animal bites, cultures of pus, bullae, or blood are recommended.[2,17,18,] Routine radiographic evaluation is unnecessary but should be considered if osteomyelitis (see chapter 281, "Hip and Knee Pain") or necrotizing soft tissue infections are suspected (see section below). **Table 152-3** lists differential diagnoses and characteristics that help distinguish cellulitis from the listed disorder.

Bedside US is useful to exclude occult abscess.[19] Doppler studies may be indicated to distinguish lower extremity deep venous thrombosis from cellulitis. The most important diagnosis to exclude is necrotizing soft tissue infection (see section below).

TABLE 152-1 General Risk Factors for Cellulitis and Erysipelas

Risk Factors
Lymphedema
Skin breakdown/site of entry
Venous insufficiency
Leg edema
Obesity
Neutropenia
Immunocompromise
Hypogammaglobulinemia
Chronic renal disease
Cirrhosis

TREATMENT

General Treatment Treatment is elevation of the affected area, incision and drainage of any abscess found (see section below), antibiotics for cellulitis, and treatment of underlying conditions. Elevation helps drainage of edema. Treat skin dryness with topical agents because skin dryness and cracking further exacerbate symptoms. Treat predisposing conditions such as tinea pedis (see chapter 253, "Skin Disorders: Extremities") and refer to primary care for treatment of lymphedema and chronic venous insufficiency.

Treatment for Purulent Cellulitis or Suspected Methicillin-Resistant *Staphylococcus aureus* See **Table 152-4** for empiric antibiotic recommendations for purulent cellulitis or when MRSA is suspected.[2] Identify

TABLE 152-2 Risk Factors for Specific Organisms Causing Cellulitis

Organism(s)	Risk Factors
Methicillin-resistant *Staphylococcus aureus* (MRSA)	Purulent soft tissue infections Antibiotic use in past month Previous MRSA infection or colonization Patient report of suspected spider bite Previous history of hospitalization or surgery within the past year Residence in a long-term care facility within the past year Hemodialysis Crowded living environments including daycare or homeless shelters, soldiers, prisons Contact sports IV drug users Men who have sex with men Household contacts with MRSA infection Children
β-Hemolytic streptococci	Nonpurulent cellulitis that is culture negative by needle aspiration
Gram-negative bacteria	Elderly patients, cirrhosis, diabetic foot infections, fish bone injury
Aeromonas hydrophila	Fresh water lacerations, contact with wet soil
Vibrio vulnificus, Vibrio parahaemolyticus	Salt water lacerations, fish fin or bone injuries, cirrhosis
Pseudomonas aeruginosa	Neutropenia, IV drug use, hot tub exposure
Anaerobic bacteria including clostridia	Bite wounds,* diabetes mellitus, necrotizing infections, gas in tissues
Polymicrobial	Diabetic foot injections, bite wounds*
Pasteurella species	Dog and cat bites*
Capnocytophaga canimorsus	Dog and cat bites*
Mycobacterium marinum	Fish tank exposure
Streptococcus pneumoniae and Haemophilus influenzae	Nonimmunized children and adults

*See chapters 46 and 211-213, "Puncture Wounds and Bites," "Bites and Stings," "Reptile Bites," and "Marine Trauma and Envenomation."

and thoroughly drain an abscess. Bedside US will aid this procedure. Provide empiric therapy for MRSA for patients who have failed initial non-MRSA therapy, those with a previous history of or risks for MRSA, or those who live in an area with a high prevalence of community-associated MRSA infections.[20] For patients with severe infection or systemic toxicity,

FIGURE 152-2. Cellulitis of the right leg characterized by erythema and mild swelling. [Photo contributed by Lawrence B. Stack, MD. Reproduced with permission from Knoop K, Stack L, Storrow A, Thurman RJ: *Atlas of Emergency Medicine*, 3rd ed. © 2010, McGraw-Hill, New York.]

FIGURE 152-3. Butterfly rash of erysipelas. The sharp demarcation between the salmon-red erythema and the normal surrounding skin is evident. [Reproduced with permission from Shah BR, Lucchesi M: *Atlas of Pediatric Emergency Medicine*, © 2006, McGraw-Hill, New York.]

consider necrotizing fasciitis (see later section on necrotizing fasciitis). It may be difficult to clinically distinguish MRSA cellulitis from methicillin-susceptible *S. aureus* cellulitis. Treatment failure rates are similar for both β-lactam antibiotics and MRSA-specific antibiotics such as trimethoprim-sulfamethoxazole.[21,22]

Treatment of Nonpurulent Cellulitis/Erysipelas Guidelines no longer differentiate the treatment of nonpurulent cellulitis from erysipelas.[2] Oral antibiotics are sufficient for simple cellulitis or erysipelas in otherwise healthy adult patients. See **Table 152-5** for guideline-recommended antibiotic options.[2] Consider surgical consultation in patients with bullae, crepitus, pain out of proportion to examination, or rapidly progressive erythema with signs of systemic toxicity, because these signs and symptoms suggest necrotizing infection (see later section on necrotizing fasciitis).

TABLE 152-3 Differential Diagnosis of Cellulitis and Erysipelas

Diagnosis	Distinguishing Clinical Characteristics
Bursitis	Characteristic locations such as suprapatellar or olecranon, may have palpable fluid collection
Contact dermatitis	Pruritus instead of pain, absence of fever, may have bulla, but patient is nontoxic in appearance.
Cutaneous abscess	Abscess may appear similar to cellulitis initially; eventual fluctuance and purulent drainage
Deep vein thrombosis	Typically not associated with skin redness or fever
Drug reactions	Temporal relation to new drug exposure, pruritus instead of pain, absence of fever
Gouty arthritis	Pronounced pain with involved joint movement
Herpes zoster	Characteristic vesicles, dermatomal pattern
Insect stings	Pronounced pain most at onset
Necrotizing soft tissue infection	Rapid progression; triad of severe pain, swelling, and fever; pain out of proportion to exam; severe toxicity; hemorrhagic or bluish bullae; gas or crepitus; skin necrosis or extensive ecchymosis
Osteomyelitis	Deeper involvement, prolonged course, comorbidities
Superficial thrombophlebitis	Typically not associated with fever, limited to venous path
Toxic shock syndrome	Hypotension, multiorgan involvement, severe toxicity

TABLE 152-4 Empiric Antibiotic Treatment of Purulent Cellulitis* and/or Soft Tissue Abscess

Guide by Severity of Illness	Antibiotics	Comments
No antibiotics for mild disease: Drainable abscess found with no signs of systemic infection	None required for immunocompetent patients where abscess drainage is complete after procedure	1. Presence of an abscess should be carefully investigated clinically and drained; consider use of US.
Oral antibiotics for moderate disease: Purulent cellulitis* without signs of systemic infection **Or** drainable abscess in the presence of mild to moderate signs of systemic infection ***If*** immunocompromised, see below.	Trimethoprim-sulfamethoxazole double-strength 1–2 tablets twice per day PO for 7–10 d† **Or** doxycycline 100 milligrams PO twice per day for 7–10 d† **Or** clindamycin, 300–450 milligrams PO four times daily for 7–10 d†‡	1. Wound culture is recommended in cases where antibiotics are given. 2. Patients who have failed to improve on outpatient antibiotics or are unable to tolerate oral antibiotics should be admitted to the hospital and receive IV antibiotics; see below.
IV antibiotics for severe disease: Purulent cellulitis* with signs of systemic infection **Or** drainable abscess in the presence of moderate to severe signs of systemic infection# or sepsis[f] **Or** an immunocompromised patient	**For MRSA coverage:** Vancomycin 15 milligrams/kg IV every 12 h **Or** linezolid 600 milligrams IV every 12 h† **Or** daptomycin 4 milligrams/kg IV every 24 h† **Or** telavancin 10 milligrams/kg IV every 24 h† **Or** clindamycin 600 milligrams IV every 8 h†‡	1. Admit to the hospital. 2. Additional antibiotic coverage is listed below. 3. Consider admission to intensive care unit for patients who meet criteria for sepsis (see also chapter 151, Sepsis). 5. For all patients with severe disease, see later section on necrotizing fasciitis.
Additional coverage for patients with sepsis or for patients with selected indications (see last column to the right)	**For patients with sepsis, or for unclear etiology, add:** Piperacillin-tazobactam, 4.5 grams IV every 6 h† **Or** meropenem, 500–1000 milligrams IV every 8 h† **Or** imipenem-cilastatin, 500 milligrams IV every 6 h†	For **fresh water** exposure (*Aeromonas* species) or for **salt water** exposure (*Vibrio* species) consider adding Doxycycline 100 milligrams IV every 12 hours,† plus ceftriaxone 1 gram IV every 24 hours†

Abbreviation: MRSA = methicillin-resistant *Staphylococcus aureus*.

*Purulent cellulitis is defined as cellulitis with drainage or exudate in the absence of a drainable abscess. In all cases of purulent cellulitis, the presence of an abscess should be carefully investigated clinically and drained. Bedside US can help diagnose occult abscess formation and verify complete drainage after procedure.

†Optimal treatment duration has not been established. For mild to moderate disease, 5-day oral treatment regimens have been successful but are recommended only in settings where follow-up at 5 days is feasible.

‡Not recommended if local resistance is greater than 10%.

#Physicians should use their clinical judgement; there are no validated criteria to differentiate moderate from severe signs for systemic infection.

[f]Criteria for sepsis in the presence of an infection are two or more of the following: temperature >38°C, tachycardia (>90 beats/min), tachypnea (respiratory rate >24 breaths/min), WBC count <400 cells/μL or >12,000 cells/μL), or immunocompromised patients (see chapter 151, Sepsis). Hypotensive patients should be admitted to the ICU.

TABLE 152-5 Empiric Treatment of Nonpurulent Cellulitis*/Erysipelas

Guide by Severity of Illness	Antibiotics	Comments
Oral antibiotics for mild disease: Typical cellulitis/erysipelas with no focus of purulence, and no signs of systemic infection	Cephalexin, 500 milligrams PO every 6 h† **Or** dicloxacillin, 500 milligrams PO every 6 h† **Or** clindamycin, 150–450 milligrams PO every 6 h†	Cultures are not recommended because of poor yields.
Monotherapy IV antibiotics for moderate disease: Typical cellulitis/erysipelas with mild to moderate systemic signs of infection‡ ***If*** immunocompromised, see below	Ceftriaxone 1 gram IV every 24 h† **Or** cefazolin 1 gram every 8 h† **Or** clindamycin 600 milligrams IV every 8 h†	Patients who have failed to improve on outpatient antibiotics or are unable to tolerate oral antibiotics should be admitted to the hospital and receive IV antibiotics, with coverage dependant on severity of illness.
Broad-spectrum antibiotics for severe disease (including necrotizing fasciitis): Those with sepsis# or those with clinical signs of deeper infection such as bullae, skin sloughing, hypotension, or evidence of organ dysfunction **Or** an immunocompromised patient	Vancomycin 15 milligrams/kg IV every 12 h† **Plus** piperacillin-tazobactam, 4.5 grams IV every 6 h† **Or** meropenem, 500–1000 milligrams IV every 8 h† **Or** imipenem-cilastatin, 500 milligrams IV every 6 h†	1. Consider immediate consultation with surgery for possible debridement (see later section on necrotizing fasciitis for further recommendations). 2. Blood cultures recommended in this treatment group.
Different/additional coverage for patients with selected indications	**Fresh water** exposure (suspected *Aeromonas* species): Doxycycline 100 milligrams IV every 12 h† **Plus** ciprofloxacin 500 milligrams IV every 12 h† **Salt water** exposure (suspected *Vibrio* species): Doxycycline 100 milligrams IV every 12 h† **Plus** ceftriaxone 1 gram every 24 h† **Suspected *Clostridium*** species: Clindamycin 600–900 milligrams IV every 8 h† **Plus** penicillin 2–4 million units IV every 4 h†	1. Consider immediate consultation with surgery for possible debridement (see later section on necrotizing fasciitis below for further recommendations). 2. Blood cultures recommended in this treatment group.

*If exudate or abscess is found on exam, the patient should be treated for purulent cellulitis, see Table 152-4 for treatment recommendations

†Optimal treatment duration has not been established. For mild to moderate disease, 5-day treatment regimens have been successful but are recommended only in settings where follow-up at 5 days is feasible.

‡Physicians should use their clinical judgment; there are no validated criteria to differentiate moderate from severe signs of systemic infection.

#Criteria for sepsis in the presence of an infection are two or more of the following: temperature >38°C, tachycardia (>90 beats/min), tachypnea (respiratory rate >24 breaths/min), WBC count <400 or >12,000 cells/mm^3, or immunocompromised state (see chapter 151 "Sepsis"). Hypotensive patients should be admitted to the intensive care unit.

DISPOSITION AND FOLLOW-UP

Admit patients with cellulitis or erysipelas and evidence of systemic toxicity and those with underlying comorbidities such as diabetes mellitus, alcoholism, or immunosuppression (see later section on necrotizing fasciitis). Healthy patients without systemic toxicity can be discharged to home with follow-up and a list of warning signs to prompt return. Follow-up intervals depend on initial presentation, but generally 2 or 3 days are sufficient to evaluate the success of treatment. Mark the patient's skin with an indelible marker along the perimeter of infection so healing can be determined at follow-up; marks also aid the patient in evaluating worsening infection. Reported risk factors for failure of empiric antibiotic therapy include fever, lymphedema or chronic edema, chronic leg ulcers, prior cellulitis in the same area, and cellulitis at a wound site.[23]

CUTANEOUS ABSCESSES, FURUNCLES, AND CARBUNCLES

Furuncles and carbuncles involve the epidermis, and abscesses involve the deeper soft tissue.[2] Skin abscesses, furuncles, and carbuncles can develop in otherwise healthy patients with no risk factors other than skin or nasal carriage of *S. aureus*. Persons in close contact with those who have an active infection with a skin abscess are at increased risk.

PATHOPHYSIOLOGY

Skin abscesses typically begin as a local superficial cellulitis. Many organisms that colonize normal skin can cause necrosis and liquefaction with subsequent accumulation of leukocytes and cellular debris; however, MRSA causes the majority of skin abscesses presenting to the ED in the United States.[6,13] Loculation and subsequent walling off of these products of infection lead to abscess formation. As the infection progresses and the area of liquefaction increases, the abscess wall thins and ruptures spontaneously, draining either cutaneously or into an adjoining tissue compartment.

Infection can be caused by one or multiple pathogens that typically include skin flora or organisms from adjacent mucous membranes. Pathogens implicated in folliculitis are those that can cause furuncles and carbuncles, namely *Pseudomonas*, *Candida*, and others.

Any process causing a breach in the skin barrier heightens the risk for a skin abscess. Examples include trauma, such as abrasions or shaving; skin foreign bodies; insect bites; and IV drug abuse involving needle injection. Other risk factors for abscess development include diabetes mellitus and immunologic abnormalities. Patients with oral, rectal, or vulvovaginal abscesses are more likely to be infected with multiple organisms, including gram-negative and anaerobic organisms.

CLINICAL FEATURES

Skin abscesses are fluctuant, tender, erythematous nodules, often with surrounding erythema (**Figure 152-4**). Spontaneous drainage of purulent material may occur, and local lymphadenopathy may be present. Signs of systemic toxicity, fever, or chills are rare in the case of simple abscesses. In uncommon cases, skin abscesses may be the result or cause of bacteremia.

Furuncles are clinically very similar to abscesses, and systemic toxicity is rare. Carbuncles are larger infections commonly associated with fever and malaise. Carbuncles are most common on the upper back, chest, buttocks, hips, and axilla but can occur in any hair-bearing region of the body.

DIAGNOSIS

The diagnosis of skin abscesses, furuncles, and carbuncles is clinical; however, physical exam is unreliable for nonsuperficial abscesses.[24] Bedside US is an invaluable tool for distinguishing deep abscess from cellulitis, identifying a foreign body within an abscess, and determining the adequacy of drainage[19,25,26] (**Figure 152-5**).

Radiography is not needed routinely, unless a radiopaque foreign body or underlying osteomyelitis is suspected. Disorders that can mimic abscesses include folliculitis, hidradenitis suppurativa, sporotrichosis, leishmaniasis, tularemia, and blastomycosis, as well as conditions in immunocompromised persons such as *Nocardia* and *Cryptococcus*. Wound cultures are not recommended for simple abscess drainage; however, guidelines recommend cultures when antibiotics are given.[2]

FIGURE 152-4. Subcutaneous abscess is noted in the axilla. [Reproduced with permission from Slaven EM, Stone SC, Lopez FA: *Infectious Diseases: Emergency Department Diagnosis & Management*, © 2006, McGraw-Hill, New York.]

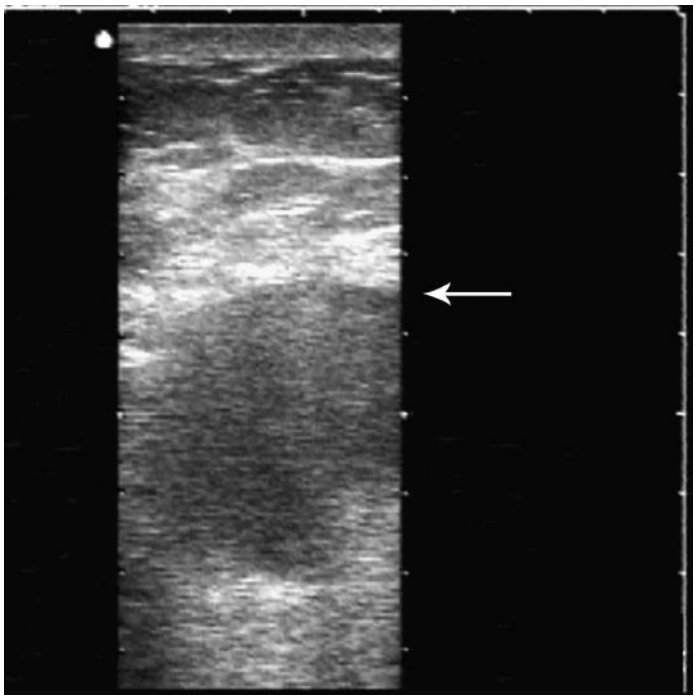

FIGURE 152-5. Long-axis sonogram of a deep midline buttock abscess in the region of the gluteal fold. The skin and immediate subcutaneous tissue exhibit relatively normal echogenicity. The deeper tissues surrounding the rounded abscess cavity appear more hyperechoic and edematous. Note that the superior edge of this large abscess cavity is 3.5 cm from the skin surface (*arrow*). Knowledge of the depth of this abscess cavity was crucial to the individual performing the drainage procedure. [Reproduced with permission from Ma OJ, Mateer JR, Reardon RF, Joing SA: *Ma & Mateer's Emergency Ultrasound*, 3rd ed. 2014, McGraw-Hill Inc., New York. From Chapter 18: Musculoskeletal, Soft Tissue, and Miscellaneous Applications, Figure 18-105, p. 561.]

TREATMENT

It is best to drain extremely large abscesses or those in deep areas in the operating room. Abscesses of the palms, soles, or nasolabial folds can be associated with complications and usually require a specialist.[27] Input from an appropriate specialist is also recommended in areas of the body with cosmetic concerns due to the expected scar formation.[27]

In the case of small furuncles (boils), warm compresses can be used to promote drainage, and no other treatment is needed. Sitz baths are helpful for furuncles in the buttock or perineal regions. Repeat evaluation in 2 to 3 days is best to determine whether suppuration has occurred and surgical drainage is required.

Large furuncles, carbuncles, and skin abscesses require incision and drainage.[28] Simple needle aspiration of abscesses is inadequate to treat abscesses caused by MRSA.[29] Prior recommendations for endocarditis prophylaxis in patients undergoing incision and drainage have changed (see chapter 155, "Endocarditis"). If indicated by the severity of valvular heart disease, the most common regimen is either clindamycin 600 milligrams IV or vancomycin 1 gram IV, 30 to 60 minutes before the procedure.

Incision and Drainage Procedure Before the incision and drainage procedure, obtain consent and explain complications. Use universal precautions, including a face shield with eye protection, because many abscesses are under pressure. There are few complications with superficial abscesses, but these include residual local numbness, the risk of injury to deeper nerves and blood vessels, and poor or delayed wound healing, especially in those with diabetes or peripheral vascular disease. Plan the incision along tension lines to minimize scaring if possible, especially in areas of cosmetic significance.

Position the patient for good access to the abscess. Prepare the area with povidone-iodine solution and drape in a sterile fashion. To provide local anesthesia, approach the abscess from the side and slowly infiltrate the skin over the abscess. Then infiltrate deeper until resistance of the wall of the abscess cavity is overcome. Distend the abscess with several milliliters of lidocaine, taking care to shield the patient and operator from any material forced from the wound due to pressure. The inflamed abscess wall absorbs the lidocaine and lessens pain associated with the procedure.

After appropriate anesthesia, using a No. 11 or 15 scalpel blade, incise the abscess over the area of greatest fluctuance, using the results of preparatory US evaluation to guide the length of the incision. Incisions that are too small or superficial are not likely to provide effective drainage. Express as much pus as possible by gentle compression. Insert a hemostat into the abscess cavity, opening and closing the jaws to break up loculations.

Irrigation of the cavity with saline followed by packing with gauze ribbon to promote drainage is commonly done, but the benefit is uncertain.[30,31] Less painful alternatives to packing include placing a catheter,[32] or tying in a rubber drain after placing two small stab incisions, using a small forceps to reach into one incision, coming out the other, and pulling the drain back through the track before making a knot.[33] Primary closure after abscess drainage shortens healing time for patients treated in the operating room[34] and has been studied in a small randomized controlled trial in the ED;[35] however, recommendations for its use await larger trials.

If placed, maintain packing, catheter, or drain long enough for the cavity to heal from the inside out and to prevent recollection of pus. Patients should apply warm compresses or soaks three times a day. Schedule a follow-up visit in 2 to 3 days for recheck. Maintain catheter or replace packing if the cavity is still draining at the follow-up visit.

Adjuvant Antibiotics Antibiotics are generally unnecessary after incision and drainage of uncomplicated abscesses without significant surrounding cellulitis in healthy patients.[6,36,37] Guidelines recommend antibiotics for patients with multiple lesions, extensive surrounding cellulitis, immunosuppression, or signs of systemic infection; see Table 152-4 for indications and specific antibiotics recommended.[2]

DISPOSITION AND FOLLOW-UP

Most patients with skin abscess, furuncles, and carbuncles are treated as outpatients. Those with systemic toxicity or severe infection may require parenteral treatment and hospital admission. For those discharged to home, remind patients to keep the wound covered and practice frequent hand washing to prevent spread of the infection to household contacts.[28] Patients with open wounds should not participate in activities involving skin-to-skin contacts, such as wrestling or football, until wounds are fully healed. Individuals should not share items such as towels, clothing, soap, razors, or other items that come in contact with a contaminated wound.

NECROTIZING SOFT TISSUE INFECTIONS

Necrotizing soft tissue infections are a spectrum of illnesses characterized by fulminant, extensive soft tissue necrosis, systemic toxicity, and high mortality. Early in their course, these infections can appear deceptively benign.[3,38] Terms used to describe necrotizing soft tissue infections are Fournier's gangrene (see chapter 93, "Male Genital Problems"), necrotizing fasciitis, necrotizing soft tissue infection, or gas gangrene. Risk factors for necrotizing soft tissue infections are advanced age, diabetes mellitus, alcoholism, peripheral vascular disease, heart disease, renal failure, human immunodeficiency virus, cancer, nonsteroidal anti-inflammatory drug use, decubitus ulcers, chronic skin infections, IV drug abuse, and immune system impairment.[39,40] However, infections also occur in young and healthy individuals. The incidence is increasing, but mortality has decreased in the United States from 25% to 10% over the last 20 years.[41] Bacteremia is reported in 25% to 30% of cases and is a strong predictor of mortality. Other patient factors that increase mortality are age <1 year old or >60 years old; IV drug use; comorbid conditions, especially cancer, chronic renal disease, and congestive heart failure; and certain characteristics of the clinical course such as positive blood culture, trunk or perineal involvement, infection related to peripheral vascular disease, and delayed time to diagnosis or treatment.

MICROBIOLOGY

Type I (polymicrobial) infections include 55% to 75% of all necrotizing soft tissue infections, and the causative microbes are a combination of gram-positive cocci, gram-negative rods, and anaerobes. Clostridial infections are now uncommon causes due to improvements in hygiene and sanitation.[38] Type II (monomicrobial) infections are most commonly caused by group A *Streptococcus*. Type II infection is less common (20% to 30%) than type I infection and tends to occur on an extremity in an otherwise healthy host who often has a history of trauma or has had a recent operative procedure at the site of the infection. Community-acquired MRSA is a cause of type II (monomicrobial) infection, particularly in IV drug abusers, athletes, and institutionalized patients.[42,43] Necrotizing infection caused by *Vibrio vulnificus* is classified as a type III infection. This infection is more common in Asia and may occur in patients who have an apparently insignificant break in their skin in a seawater environment. Type IV is associated with fungal infections, primarily in immunocompromised patients.[44]

PATHOPHYSIOLOGY

The rapid necrotizing process typically begins with direct invasion of subcutaneous tissue from external trauma (IV injection, surgical incision, abscess, insect bite, or ulcer) or direct spread from a perforated viscus (usually colon, rectum, or anus). Although spontaneous development is rare, it does occur, and risk factors include diabetes and underlying malignancy. Bacteria proliferate, invade subcutaneous tissue and deep fascia, and release exotoxins that lead to tissue ischemia, liquefaction necrosis, and systemic toxicity.[39]

Skin involvement is secondary to vasculitis and thrombosis of perforating blood vessels. The ischemic tissue environment promotes bacterial growth, propagating the process and resulting in rapid spread of the infection. **Infection can spread as fast as 1 inch/h**. Because thrombosis of large numbers of capillary beds must occur before skin findings develop, early infection has little overlying skin change to indicate the extent of infection.[38] As the disease progresses, widespread gangrene of the skin, subcutaneous fat, fascia, and even skeletal muscle occurs.[39]

In polymicrobial infections, a symbiotic relationship between the different kinds of bacteria seems to promote the necrotizing soft tissue infection. Facultative gram-negative organisms lower the oxygen reduction potential of the tissue and facilitate anaerobic organism growth. Anaerobic organisms impede phagocyte function, favoring aerobic bacterial growth. The alpha-toxin produced by the *Clostridium* species causes tissue necrosis and cardiovascular collapse. *S. aureus* and streptococci produce exotoxins and cause the release of tumor necrosis factor and cytokines that can produce the systemic inflammatory response syndrome and lead to septic shock, organ failure, and death.

The tissue ischemia produced in all such infections impedes immune system destruction of bacteria and prevents adequate delivery of antibiotics.[39] **Thus, antibiotics alone are rarely effective, and immediate surgical intervention remains the cornerstone of successful management**.

CLINICAL FEATURES

Classic symptoms of necrotizing soft tissue infections are severe pain, anxiety, and diaphoresis.[38] Pain is often out of proportion to physical examination findings with tenderness beyond the area of erythema and thus is perhaps the single most important feature to make the diagnosis early. However, some patients may have little pain, and as the condition progresses, the affected areas may become insensate. About 10% to 40% of the time, patients report trauma or a break in the skin roughly 48 hours before onset of symptoms.

On examination, the painful area may demonstrate a brawny edema, and crepitus caused by bacterial gas production may be present. The lack of crepitus does not rule out the diagnosis. Two different studies reported that the only signs present in >50% of patients were erythema, tenderness, or marked edema beyond the area of redness; crepitus was present in only 13% to 31% of patients. Late in the course of the infection, the skin can develop a bronze or brownish discoloration with a malodorous serosanguineous discharge, and bullae may be present (**Figure 152-6**).

Systemic manifestations include a low-grade fever with tachycardia out of proportion to the fever. In fulminant necrotizing infections, particularly from *V. vulnificus*, patients may have cardiovascular collapse due to release of bacterial toxins and release of cytokines, and they may be confused, irritable, or have a rapid deterioration of mental status.

FIGURE 152-6. Necrotizing soft tissue infection. Large cutaneous bullae are seen on the leg of this patient with necrotizing fasciitis. Note the dark purple fluid in the bullae. DIAGNOSIS

The diagnosis is based on clinical assessment in combination with laboratory tests and imaging when the clinical picture is unclear. One or more "hard" signs of necrotizing fasciitis—crepitus, skin necrosis, bullae, hypotension, or gas on x-ray—are present in less than half of patients.[45] Many laboratory abnormalities have been investigated to aid in the diagnosis,[46-52] including the laboratory risk indicator for necrotizing fasciitis.[46,47] Since its derivation, the laboratory risk indicator for necrotizing fasciitis has proven to miss many cases of necrotizing fasciitis,[51] especially those cause by *Vibrio* species,[48] and neck infections.[52] **Table 152-6** lists laboratory factors and imaging findings associated with necrotizing fasciitis to help clinicians with medical decision making.[45-55] Clinicians are

TABLE 152-6 Laboratory and Imaging Results Associated with Necrotizing Fasciitis

Laboratory Factors Associated with Necrotizing Fasciitis

Laboratory Test	Threshold	Comments
C-reactive protein	>150 milligrams/L	Positive result adds 4 in LRINEC score
WBC count	>15,000 cells/mm^3	Positive result adds 1 in LRINEC score, level >25,000 cells/mm^3 adds 2
Hemoglobin	<13.5 grams/dL	Positive result adds 1 in LRINEC score,* level <11 grams/dL adds 2 in LRINEC score*
Sodium	<135 mmol/L	Positive result adds 2 in LRINEC score*
Creatinine	>1.6 milligrams/dL	Positive result adds 2 in LRINEC score*
Glucose	>180 milligrams/dL	Positive result adds 1 in LRINEC score*
Potassium	>5.0 mEq/L	Associated with extremity infections
Band count	>7%	Associated with *Vibrio* species
Serum albumin	≤2.0 grams/dL	Associated with *Vibrio* species
Platelets	≤80,000	Associated with *Vibrio* species

Imaging Findings Associated with Necrotizing Fasciitis

Imaging Test	Finding	Comments
MRI with contrast	Extensive thickening of the intermuscular fasciae with an appearance suggesting incomplete vascularization	1. Presence of gas is highly specific for necrotizing infection (but not common). 2. Absence of MRI abnormalities of the intermuscular fasciae virtually rules out necrotizing fasciitis.
CT with contrast	1. Fascial thickening of deep facial planes 2. Nonenhancing deep fascia on contrast imaging suggesting necrosis	1. Presence of gas is highly specific, but found in one third of cases or less. 2. Accurate diagnosis requires contrast; acute kidney injury is common in patients with necrotizing fasciitis and may contraindicate IV contrast.
Ultrasonography	1. Fluid collections along the fascial plane 2. Fascia irregularity 3. Subcutaneous air	Radiologists warn that abnormal superficial hyperechogenicity absorbs US and may block diagnostic deeper findings and give false reassurance.
Plain radiographs	Gas in soft tissues	Poor sensitivity

Abbreviation: LRINEC = laboratory risk indicator of necrotizing fasciitis.

*LRINEC score of ≥6 is associated with increased risk of necrotizing fasciitis but misses many cases and therefore should not be used in isolation for the diagnosis and management.

encouraged to consult surgery for possible debridement early when the diagnosis of necrotizing fasciitis is being considered rather than waiting for confirmatory studies that may yield equivocal results. There is no single test or sign that can reliably confirm the diagnosis of necrotizing fasciitis early in the course of this disease process. The finger test has been advocated, which involves making a 2-cm incision over involved tissue down to the fascia after local anesthesia, observing for normal blood flow, and inserting a gloved finger to test for normal tissue firmness.[46] A positive test is lack of normal bleeding, or friable tissue to minimal finger pressure. However, its use has never been studied formally.

Plain x-rays may reveal subcutaneous gas in a minority of patients but may miss deep fascial gas and is therefore a poor screening tool. CT with contrast is more sensitive (80% to 97%) but has a false-positive rate of 19%. The most reliable sign of necrosis on CT is nonenhancing deep tissues, which requires contrast, or gas, seen in only ≤36% of patients.[54] IV contrast is a significant risk in this group of patients who frequently sustain acute renal failure due to sepsis. MRI has better sensitivity (90% to 100%), but false-positive rates are as high as 39%.[55] Finally, MRI imposes significant delays to treatment. Bedside US has been advocated,[53] but radiologists caution against excluding necrotizing fasciitis based its findings.

TREATMENT

Begin aggressive fluid resuscitation immediately. Transfusion of packed red blood cells may be needed to correct anemia from hemolysis. Avoid vasoconstrictors, if at all possible, because vasoconstrictors will decrease perfusion to already ischemic tissue.

Early surgical consultation is indicated for all suspected cases of necrotizing fasciitis. Surgery is the gold standard for diagnosis and treatment. Surgical intervention may include fasciotomy, debridement, and/or amputation. Mortality skyrockets if debridement is delayed >24 hours. See Table 152-5, "Empiric Treatment of Nonpurulent Cellulitis/Erysipelas," the row titled "Broad-spectrum antibiotics for severe disease," for patients with selected indications. Provide tetanus prophylaxis as indicated. Controversial therapies that are typically the decision of the surgical consultant include IV immunoglobulin therapy and hyperbaric oxygen therapy.

OTHER SOFT TISSUE INFECTIONS

FOLLICULITIS

Folliculitis is an inflammation of hair follicles related to infection, chemical irritation, or physical injury to the skin. It typically involves a superficial bacterial infection of the hair follicles with purulent material in the epidermis.

Epidemiology/Microbiology Folliculitis is usually caused by *S. aureus*, and nasal carriage of this organism is a risk factor for folliculitis. "Hot tub folliculitis" or "whirlpool-associated folliculitis" is often attributed to *Pseudomonas* species and occurs in inadequately chlorinated hot tubs, whirlpools, and swimming pools. Symptoms of uncomplicated folliculitis and whirlpool-associated *Pseudomonas* folliculitis are often mild and self-limited, and patients do not seek medical attention.

Individuals exposed to whirlpool footbaths at nail salons are at risk for mycobacterial furunculosis. *Candida* species are implicated in patients receiving broad-spectrum antibiotics or glucocorticoids or who are otherwise immunocompromised.[2]

Clinical Features The most common sites of involvement for folliculitis are the apocrine areas of the upper back, chest, buttocks, hips, and axilla, but folliculitis can develop in any hair-bearing region of the body, especially in areas of repeated shaving. Folliculitis presents with clusters of pruritic, erythematous lesions that are usually <5 mm in diameter, with pustules sometimes present at the centers.[2] Pseudomonal folliculitis can develop over areas exposed to contaminated water, and lesions are often larger (up to 3 cm in diameter).

Pseudofolliculitis is a related noninfectious condition more commonly seen in blacks secondary to shaving. It occurs when the hair follicle becomes trapped and, instead of exiting the follicle, curls and grows into the follicular wall. Such findings in the beard region are called "sycosis barbae" or "folliculitis barbae" and can progress to deep infections that can cause facial scarring (see chapter 250, "Skin Disorders: Face and Scalp").

Diagnosis Folliculitis is diagnosed clinically. It should be differentiated from other disorders, such as acne vulgaris, impetigo, fungal infections, contact dermatitis, scabies, insect bites, and viral disorders such as herpes.

Treatment/Disposition and Follow-Up For simple cases of uncomplicated folliculitis or hot tub folliculitis, stopping exposure or removing the offending agent and twice-daily cleansing with mild hand soap often suffices. Lesions usually resolve spontaneously, but if desired, warm compresses may be applied several times daily, and a topical antibiotic such as bacitracin or polymyxin B can also be used. Shaving should be avoided in the involved areas. Pseudofolliculitis is managed by allowing the hairs to grow 2 to 3 mm above the surface and afterward using commercially available razors designed for this condition. For painful or more extensive cases, oral antibiotics with activity against *Streptococcus* and *Staphylococcus*, such as cephalexin, dicloxacillin, or azithromycin, are recommended.

HIDRADENITIS SUPPURATIVA

Hidradenitis suppurativa is a recurrent, suppurative, and scarring disease of the apocrine glands, most commonly found in the axillae and pubic regions of women and people of African descent. The disorder is neither contagious nor due to poor hygiene. Diagnosis is clinical. Identification and treatment are discussed in chapter 252, "Skin Disorders: Groin and Skinfolds."

PILONIDAL ABSCESS

Pilonidal abscesses are located along the superior gluteal fold. Some think that a pilonidal sinus forms along the gluteal fold possibly at the time of embryogenesis, although others believe it to be an acquired condition secondary to local soft tissue trauma. The sinuses are lined with squamous epithelium and hair, and blockage of the sinus tract with hair and other keratinous material leads to bacterial invasion and infection. The causative organisms typically are normal skin flora, with *Staphylococcus* species being the most common. Contamination with peritoneal and fecal organisms is also possible.

Clinical Features Patients tend to develop symptoms in their late teens and early twenties, and without definitive surgical treatment, they tend to suffer recurrent infections, sometimes developing a chronic draining fistulous tract. Pilonidal abscess is a tender, swollen, and fluctuant nodule located along the superior gluteal fold (**Figure 152-7**).

Treatment ED treatment is incision and drainage, with care taken to remove excess hair and debris from the abscess cavity. See "Incision and Drainage Procedure" given earlier for further recommendations. Antibiotics generally are not needed. Outpatient surgical referral should be recommended for definitive treatment. This typically consists of wide

FIGURE 152-7. Pilonidal abscess. Redness, fluctuance, and tenderness in the gluteal cleft are seen with a pilonidal abscess. [Photo contributed by Louis La Vopa, MD. Reproduced with permission from Knoop K, Stack L, Storrow A, Thurman RJ: *Atlas of Emergency Medicine*, 3rd ed. © 2010, McGraw-Hill, New York.]

surgical excision and healing by secondary intention. Surgical treatment, although often successful, may involve difficult wounds and a long healing time. There is a debate in the surgical literature over primary closure versus open healing for pilonidal abscesses. When surgical treatment involves primary closure, wounds heal more quickly but are associated with an increased risk of recurrence.[56] Performing less extensive procedures whenever possible is often in the patient's best interest.

INFECTED EPIDERMOID AND PILAR CYSTS

Epidermoid cysts originate from the epidermis, and pilar cysts originate from hair follicles; both contain a thick, cheesy collection of keratin, not sebum. True sebaceous cysts, as these cysts have erroneously been called in the past, are rare. Sebaceous glands occur diffusely throughout the body. Blockage of the duct of a sebaceous gland may lead to development of a glandular cyst that can exist for a long period without becoming infected. Once bacterial invasion occurs, abscess formation is common. An infected epidermoid or pilar cyst is an erythematous, tender, fluctuant cutaneous nodule. Simple incision and drainage is the appropriate ED treatment. The cyst always contains a capsule that must be removed to prevent further infection. Capsule excision is typically done at follow-up when the initial inflammation has improved or resolved. Occasionally, the wall of the sac can be grasped with a forceps and removed at the time of drainage.

BARTHOLIN GLAND ABSCESS

Bartholin gland abscesses are common in women of reproductive age. An abscess in a perimenopausal woman requires gynecologic follow-up to exclude carcinoma. The Bartholin glands are a pair of pea-sized glands located in the labia minora in the 4 and 8 o'clock positions. They are not palpable if in a noninfected state. Infections are polymicrobial, including vaginal flora, anaerobes, and, in an important minority, *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. Examination of the labia typically reveals a fluctuant 2- to 4-cm mass.

Definitive treatment is marsupialization of the abscess to prevent recurrence. The technique is detailed in **Figure 152-8**. See chapter 102, "Vulvovaginitis" for further discussion.

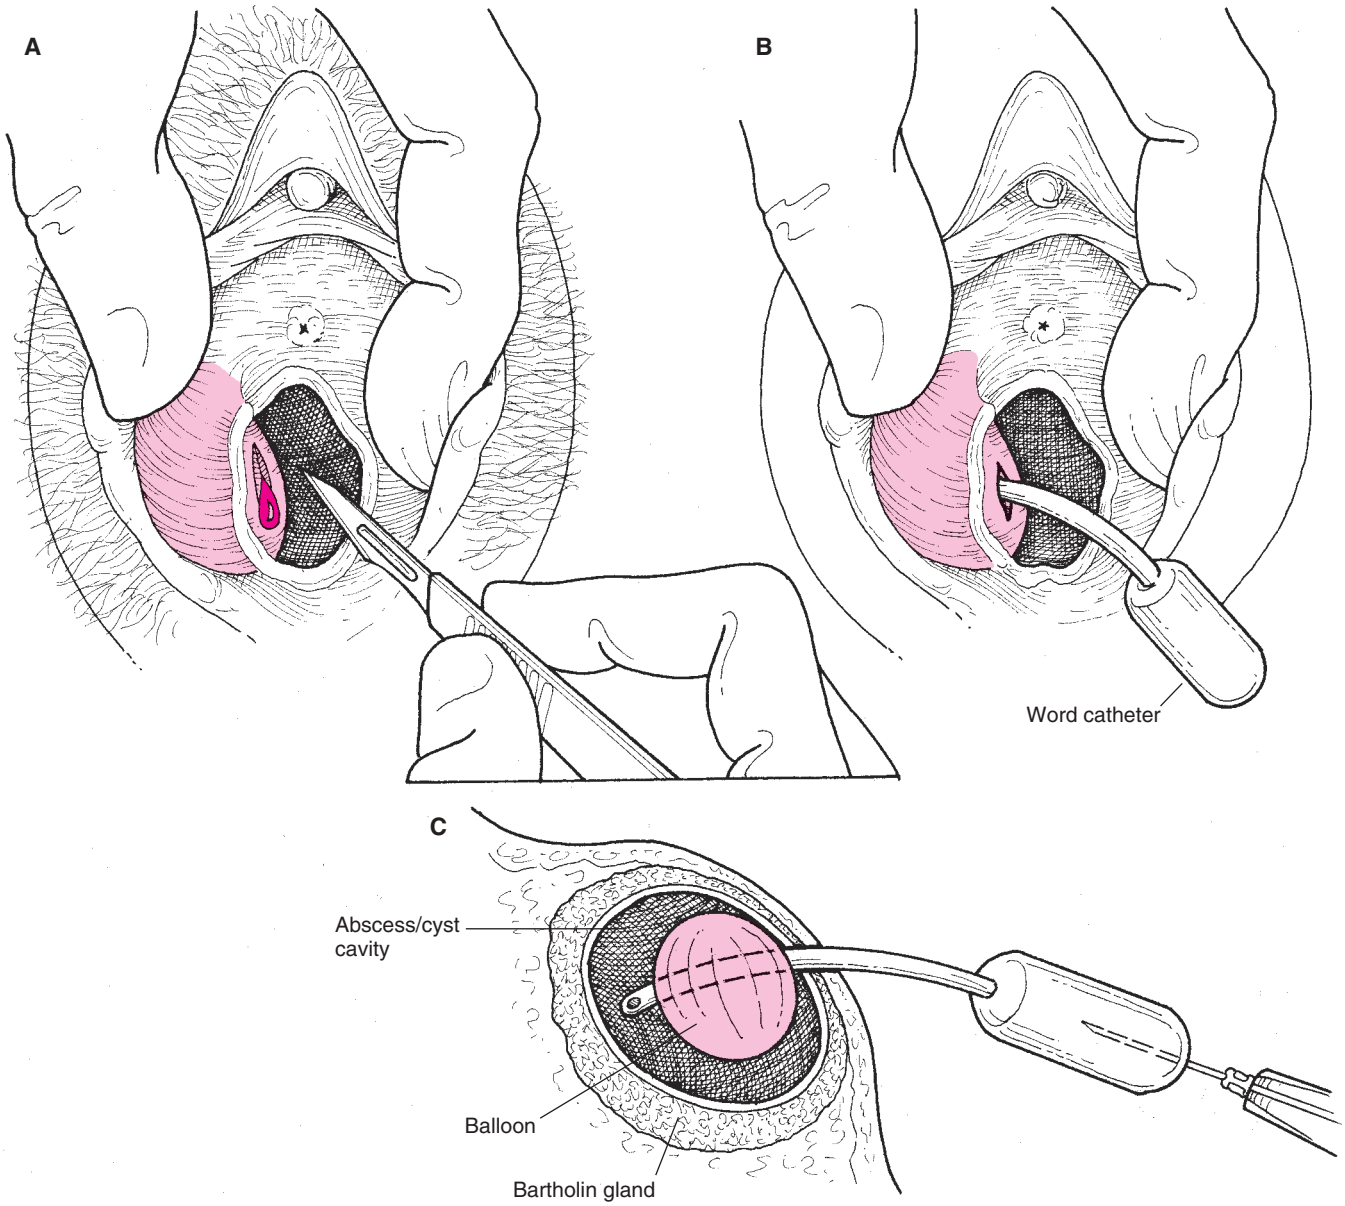

FIGURE 152-8. Incision and insertion of the Word catheter. **A.** Make a 0.5-cm-long stab incision on the mucosal surface of the labia minora. **B.** The cavity has been evacuated and the Word catheter inserted. **C.** The balloon is inflated with saline. PARONYCHIA AND FELONS

Paronychia and felons are discussed in chapter 283, "Nontraumatic Disorders of the Hand."

PERIRECTAL ABSCESSES

Perirectal abscesses are discussed in chapter 85, "Anorectal Disorders."

SPOROTRICHOSIS

Sporotrichosis is a mycotic infection caused by the fungus *Sporothrix schenckii*.

Epidemiology Sporotrichosis occurs worldwide but is most common in tropical and subtropical zones. It is endemic in Central and South America and in Africa. The organism is found most commonly in soil, sphagnum moss, and decaying vegetable matter. It is a common disease among florists, gardeners, and agricultural workers. Inoculation into the host most often occurs when a spine or barb on a plant punctures the skin during handling. Approximately 10% to 62% of patients relate infection to penetrating trauma from plant thorns, wood splinters, or contaminated organic material. The largest outbreak of sporotrichosis in the United States occurred in 1988 and involved 15 states and 84 persons, all of whom handled conifer seedlings shipped in sphagnum moss contaminated with *S. schenckii*.

Transmission from infected animals, especially cats, has been documented. Veterinary workers, animal handlers, and cat owners are therefore at increased risk. The typical patient is a healthy young adult, but the infection can also occur in immunocompromised individuals such as those with alcoholism, diabetes mellitus, hematologic malignancy, organ transplantation, or human immunodeficiency virus infection.

Pathophysiology *S. schenckii* is a thermally dimorphic fungus that changes from its mycelial form to its yeast form on entering a body temperature environment. Disease is usually limited to local cutaneous or lymphocutaneous areas. Osteoarticular involvement, including osteomyelitis, septic arthritis, bursitis, and tenosynovitis, occurs and may extend from a local cutaneous infection or may be secondary to hematogenous spread. Although less common, transmission may occur through inhalation of the fungus through the upper respiratory tract, and subsequent hematogenic dissemination can occur. When inhaled, granulomatous pneumonitis with cavitation may arise.

Clinical Features The incubation period averages 3 weeks following initial inoculation, but varies from a few days to several weeks. After the fungus enters the body through a break in the skin, three types of localized infections may occur. The fixed cutaneous type is characterized by lesions restricted to the site of inoculation and may appear as a crusted ulcer or verrucous plaque (**Figure 152-9**). Local cutaneous type infections also remain local but present as a subcutaneous nodule or pustule. The surrounding skin becomes erythematous and may ulcerate, resulting in a chancre. Local lymphadenitis is common. The lymphocutaneous type is the third and most common type. It is characterized by an initial painless nodule or papule at the site of inoculation that later develops subcutaneous nodules with clear skip areas along local lymphatic channels (**Figure 152-10**). The local reactions in all three types of infections tend to be relatively painless but show no signs of improvement without treatment.

Patients occasionally develop extracutaneous illness from what is most probably hematogenous spread. Most cases of extracutaneous sporotrichosis involve the skeletal system. An indolent form of monoarticular arthritis is the most common symptom. Osteomyelitis, tenosynovitis, and carpal tunnel syndrome are occasionally seen as well. Multiarticular arthritis is usually only seen in patients with immunocompromise. Pulmonary involvement is rare, typically occurring in elderly alcoholic males and clinically resembling tuberculosis. Chronic lymphocytic meningitis can be a delayed complication of sporotrichosis infection and should be considered in patients with chronic meningeal symptoms.

Diagnosis History and physical findings are the keys to diagnosis. Fungal cultures are the best way to isolate the fungus, and tissue biopsy cultures often are diagnostic. Pus, synovial fluid, sputum, blood, or tissue fragment is suitable for culture.

FIGURE 152-9. Fixed sporotrichosis. The ulcer and surrounding erythema of fixed cutaneous sporotrichosis could be confused with a brown recluse spider bite. [Reproduced with permission from Knoop K, Stack L, Storrow A: *Atlas of Emergency Medicine*, 2nd ed. © 2002, McGraw-Hill, New York.]

Routine laboratory tests are nonspecific, but an increased WBC count, eosinophil count, and erythrocyte sedimentation rate may occur. The differential diagnosis includes tuberculosis, subcutaneous abscesses of tularemia, cat-scratch disease, leishmaniasis, staphylococcal lymphangitis, paracoccidioidomycosis, chromoblastomycosis, blastomycosis, bacterial pyoderma, primary syphilis, and infections caused by atypical mycobacteria such as *Mycobacterium marinum*.

Treatment Itraconazole (100 to 200 milligrams daily for 3 to 6 months) is the treatment of choice for localized and systemic infections. Fluconazole is less effective than itraconazole and should be reserved for those few patients not tolerating itraconazole. Ketoconazole has shown even poorer results than fluconazole. IV amphotericin B is effective, but adverse reactions limit its use to disseminated forms of the disease. In endemic regions or in epidemic outbreaks, a saturated solution of potassium iodide is an effective low-cost alternative.

FIGURE 152-10. Sporotrichosis. Chronic lymphocutaneous type—an erythematous papule at the site of inoculation on the index finger with a linear arrangement of erythematous dermal and subcutaneous nodules extending proximally in lymphatic vessels of the dorsum of the hand and arm. CHAPTER 153

Serious Viral Infections

Sukhjit S. Takhar
Gregory J. Moran

INTRODUCTION

Viral infections are among the most common illnesses encountered in the ED. Although many are self-limited, some are life-threatening, have specific treatments, or have public health implications. We review serious viral infections that cause disseminated illness or have a predilection for the CNS.

INFLUENZA

Human influenza is caused by a large, single-stranded RNA virus from the orthomyxovirus family. Influenza A and Influenza B cause the majority of human infections, with influenza A typically being more serious. Other viruses can cause similar febrile respiratory syndromes, including the coronaviruses linked to severe acute respiratory syndrome and Middle Eastern respiratory syndrome, both emanating from limited geographic areas and associated with high mortality.

EPIDEMIOLOGY

Influenza is highly infectious and is transmitted via aerosolized respiratory secretions, large droplets, or fomites. Seasonal influenza has varying severity, typically striking in the winter months of temperate climates. Seasonal disease causes 250,000 to 500,000 annual deaths worldwide and between 5000 and 50,000 deaths in the United States. Outbreaks spread quickly throughout a community, largely among school-age children. Mortality occurs mostly among the elderly and young infants.

New strains occasionally emerge that can lead to pandemics. The 1918 influenza pandemic killed between 50 and 100 million people worldwide, and the potential for devastation by a novel influenza virus drives anxiety among clinicians and public health personnel. Unlike seasonal influenza, mortality during pandemics occurs mostly among healthy adults. In 2009, a pandemic H1N1 strain emerged in Mexico and followed this pattern, reminding us about the potential danger. A highly pathogenic avian strain of influenza emerged in 1997 in China, which was transmitted from infected chickens to humans. A variety of other animal strains of influenza have since been detected. These remain primarily bird viruses that have not developed the ability for efficient human-to-human transmission.

PATHOPHYSIOLOGY

Influenza is transmitted by respiratory secretions, usually by sneezing or coughing, and via touching hands. The incubation period is typically 1 to 4 days. Influenza viruses undergo minor variations (antigenic drift) in their surface antigens that allow the virus to reinfect individuals and reemerge each winter. Occasionally, there are major antigenic changes (antigenic shift) that increase population susceptibility and lead to a pandemic.

CLINICAL FEATURES

Patients with influenza typically present with an abrupt onset of fevers and respiratory symptoms. Most cases are self-limited; however, some patients, particularly the elderly, the very young, and those with comorbid conditions, require hospitalization or die from complications of influenza. Additionally, influenza can lead to exacerbations of chronic medical conditions, such as congestive heart failure or chronic obstructive lung disease. Delirium is common in the elderly.

TABLE 153-1 Risk Factors for Severe Influenza[3]

Children younger than age 2 years
Adults age 65 years and older
Patients with comorbid conditions
Immunosuppressed
Pregnant patients
Patients younger than 19 years receiving long-term aspirin
American Indians/Alaskan natives
Morbidly obese patients
Residents of nursing homes and long-term care facilities

Pneumonia complicates some influenza infections. Primary influenza pneumonia develops quickly and progresses to acute respiratory distress syndrome, often within 24 hours. Bacterial super-infections also occur. Classically, influenza is associated with secondary *Staphylococcus aureus* pneumonia and, more recently, with community-acquired methicillin-resistant *S. aureus*.

DIAGNOSIS

Most cases of influenza are diagnosed clinically when a patient presents with fever, aches, and cough with influenza virus circulating in the community. However, clinical features of influenza overlap with other respiratory infections; laboratory confirmation can occasionally be helpful in patient care and infection control, especially before influenza has been documented in the community.

Rapid antigen assays identify the surface proteins in influenza A and B. These tests are simple to perform and give results within 15 minutes. However, they can have a low sensitivity, with ranges between 10% and 80% reported in clinical use. Specificity of these tests is between 90% and 95%, so a positive test indicates high likelihood of influenza, especially during an outbreak.

Molecular diagnostic tests, such as polymerase chain reaction for nucleic acids, are available and are more sensitive and specific than antigen tests. They are recommended for patients hospitalized with influenza.[1] Several rapid polymerase chain reaction–based tests return results within the time frame of an ED visit, although they are more costly than rapid antigen tests.

TREATMENT

The majority of patients will have a self-limited, uncomplicated illness requiring only symptomatic care. Patients with more severe influenza may benefit from IV fluids, respiratory support, and occasionally vasopressors. Those with pneumonia should be treated with antibiotics, targeting methicillin-resistant *S. aureus* if severe pneumonia exists.

The benefits of neuraminidase inhibitors for otherwise healthy adults and children are debated;[2] the Centers for Disease Control and Prevention recommend treating higher risk populations. Studies of neuraminidase inhibitors for influenza in uncomplicated cases note benefits limited to patients treated within 48 hours of symptom onset. Antiviral treatment can also benefit patients hospitalized with influenza or bacterial complications of influenza, even if started after 48 hours of illness. Consider empiric antiviral treatment for patients with severe or progressive illness and those with higher risk of complications (**Table 153-1**). Oseltamivir is the most widely used neuraminidase inhibitor (75 milligrams twice daily for 5 days), with longer treatment for critically ill patients. Extracorporeal membrane oxygenation aids those with severe cardiorespiratory dysfunction, especially in pandemic settings where younger patients are afflicted.

HERPES SIMPLEX VIRUS INFECTIONS

Herpes simplex virus type 1 (HSV-1) and herpes simplex virus type 2 (HSV-2) are related double-stranded DNA viruses that cause oral and genital infections; rarely, these create devastating CNS disease. **Herpes simplex infections are treatable with antiviral drugs, making early recognition of serious infection important.**

EPIDEMIOLOGY

HSV is common throughout the world. Transmission occurs when a susceptible individual is exposed to the virus. HSV-1 is usually acquired during childhood through nonsexual contact; HSV-2 is almost always sexually transmitted (see chapter 149, "Sexually Transmitted Infections"). HSV-1 seroprevalence varies by socioeconomic status, age, and geographic location. More than 50% of the U.S. population is seropositive for HSV-1, and 15.7% is seropositive for HSV-2.[4] Rates are higher in developing countries. HSV-1 is one of the most common viral causes of encephalitis in the United States. It occurs most commonly in patients <20 years and >50 years of age.[5] The mortality rate for untreated disease is >70%.

Neonates with HSV infection have a high frequency of both visceral involvement and CNS disease. Encephalitis in neonates is most often caused by HSV-2, which is acquired from the maternal genital tract at the time of delivery. The risk is highest when the mother acquires the infection in the third trimester.

PATHOPHYSIOLOGY

HSVs are transmitted through contact with persons with ulcerative lesions or by those who are shedding the virus by the exchange of saliva, vesicle fluid, semen, and cervical fluid. The virus must come in contact with a mucosal surface or abraded skin, where it replicates and causes localized symptoms before becoming latent in the sensory ganglia. HSV-1 typically resides in the trigeminal ganglia, and HSV-2 is found in the sacral ganglia. Reactivated virus travels to the cutaneous surface and results in localized vesicular eruptions (**Figure 153-1**).

In herpes simplex encephalitis, the virus is thought to gain access to the brain by the olfactory or the trigeminal nerve, with a predilection for the medial and inferior temporal lobes of the brain.

Most healthy hosts are able to control the virus and limit its replication to mucosal surfaces. Rarely during primary infection, the virus can spread beyond the local dorsal root ganglia and cause more widespread involvement. Multiorgan disease is much more common in the immunosuppressed and in neonates.

CLINICAL FEATURES

HSV infections occur year round. Symptoms of HSV depend on multiple factors, including the anatomic site involved, the immune status of the host, virus type, and whether the infection is primary or recurrent. Most HSV infections are subclinical. Symptomatic HSV-1 infection most commonly results in recurrent orolabial lesions, whereas HSV-2 is most often implicated in genital herpes. Primary infections typically produce more extensive lesions involving mucosal and extramucosal sites, often accompanied by systemic signs and symptoms. Gingivostomatitis and pharyngitis are typical manifestations of primary HSV-1 infection (**Figure 153-2**), and recurrence presents as herpes labialis (**Figure 153-3**). Less common skin manifestations include herpetic whitlow and herpes gladiatorum (skin). Eczema herpeticum (see Figure 251-14) can occur in patients with atopic dermatitis. **Bell's palsy** may result from latent HSV-1 in the geniculate ganglia (see chapter 172, "Acute Peripheral Neurologic Disorders"). Herpetic keratitis presents as a painful, red eye, and can be identified by characteristic dendritic lesions on fluorescein slit lamp exam. HSV-1 and HSV-2 can cause identical genital lesions. Genital HSV-2 is more common and has a higher relapse rate, but the proportion of genital disease caused by HSV-1 is increasing.[4] Primary genital infections can present with aseptic meningitis, which is a complication more common in women.

The hallmark of HSV encephalitis is acute onset of fever and neurologic symptoms. Patients can present with hemiparesis, cranial nerve abnormalities, ataxia, focal seizures, and altered mental status or behavioral abnormalities. It can be difficult clinically to distinguish HSV encephalitis from other types of meningoencephalitis. Meningitis occurs in up to 25% of females with primary HSV-2 infections. HSV-2 meningitis, unlike encephalitis, has a benign course, and patients recover uneventfully. Some patients develop recurrent lymphocytic meningitis (Mollaret's syndrome).

HSV infections in immunocompromised hosts can lead to widespread dissemination with multiorgan involvement (**Figure 153-4**). Organ transplant patients may develop esophagitis, hepatitis, colitis, and pneumonia (see chapter 297, "The Transplant Patient"). Severely burned patients are also prone to potentially fatal disease. HSV infections can also cause immune-mediated manifestations such as erythema multiforme, hemolytic anemia, and thrombocytopenia.

DIAGNOSIS

The preferred diagnostic test for confirmation of suspected HSV infection depends on the presentation. Because mucocutaneous infection is lifelong, we recommend laboratory confirmation of the clinical diagnosis. A specimen for viral culture can be obtained from the fluid of an unroofed vesicle. The sensitivity of culture is highest in the early stages

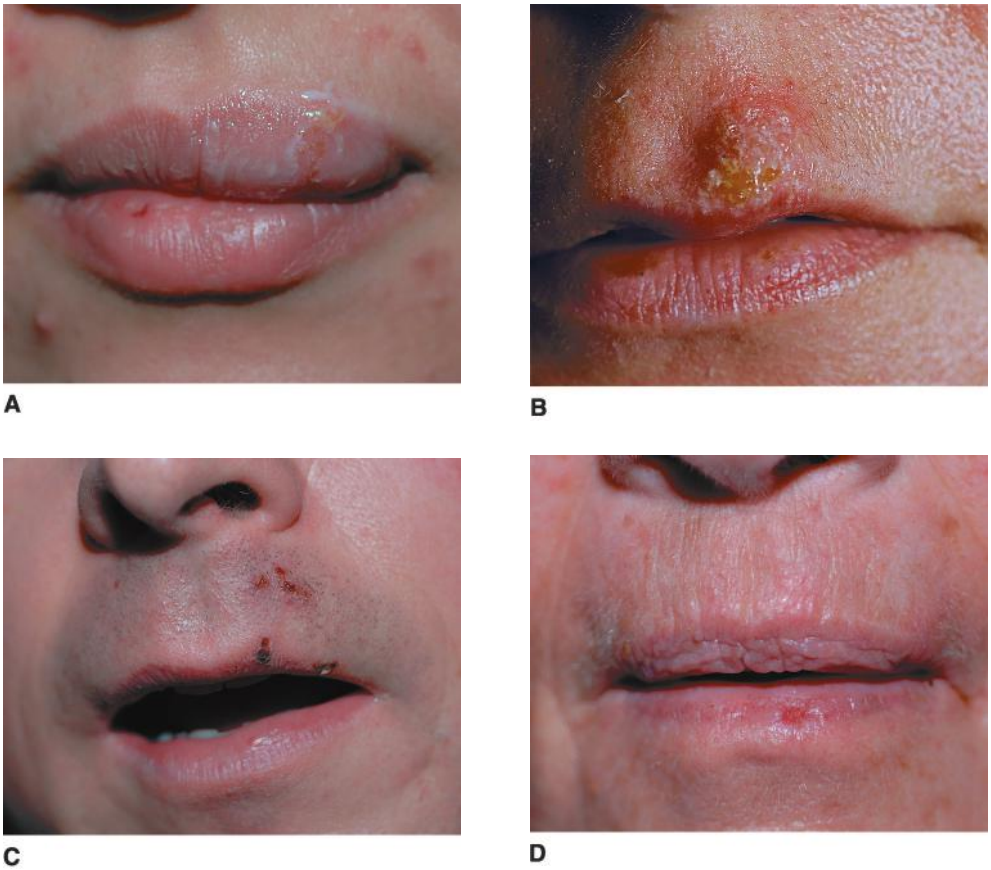

FIGURE 153-3. A through D. Herpes labialis. Typical vesicular lesions of the upper and lower lip. [Reproduced with permission from Wolff K, Johnson RA: *Fitzpatrick's Color Atlas and Synopsis of Clinical Dermatology*, 6th ed., © 2009 by McGraw-Hill, Inc., New York.]

and in primary disease. Polymerase chain reaction testing or a direct fluorescent antibody test can be performed on swabbed tissue. A Tzanck test is generally not useful.

Identification of temporal lobe lesions on CT scan or MRI is strongly suggestive of HSV encephalitis (**Figure 153-5**). An electroencephalogram shows typical intermittent, high-amplitude slow waves localized to the temporal lobes.

Cerebrospinal fluid analysis typically shows a lymphocytic pleocytosis with the presence of red blood cells. However, some patients can have normal cerebrospinal fluid parameters. Polymerase chain reaction testing of the cerebrospinal fluid is the testing modality of choice for HSV meningoencephalitis, with high sensitivity and specificity.[5] Viral DNA can be detected within the first 24 hours, and results remain positive for a week or longer. To perform this test, most laboratories need an additional 0.5 to 1.0 mL of fluid beyond that required for standard analysis. Brain biopsy is reserved for difficult cases and for investigation of alternative diagnoses.

FIGURE 153-4. Disseminated herpes simplex in an immunocompromised host. The rash of disseminated herpes simplex begins as vesicular lesions on an erythematous base, which may umbilicate and may blister and crust over as seen here. TREATMENT

Treatment depends on the severity of the disease and the immune status of the patient (see chapter 149, "Sexually Transmitted Infections"). IV acyclovir is the drug of choice in patients with HSV encephalitis or disseminated disease and in immunocompromised patients with severe mucocutaneous disease (**Table 153-2**). Valacyclovir is a prodrug of acyclovir with higher bioavailability. Famciclovir and valacyclovir require fewer doses per day.

Even with early treatment, patients with HSV encephalitis have a high mortality. Without treatment, mortality is >70%. Survivors are often left with long-term neurologic sequelae. Independent predictors of a poor outcome for patients with HSV encephalitis include a Glasgow Coma Scale score of ≤6, focal CNS lesions on CT scan, increased patient age, and start of antiviral therapy >4 days after onset of symptoms.[5] **Because altered mental status and focal neurologic abnormalities are key features of encephalitis and because it can be clinically difficult to distinguish meningitis from encephalitis, consider adding acyclovir to empiric antibiotic therapy in patients with neurologic findings when the diagnosis of acute bacterial meningitis is also being considered.**[6,7]

Healthy patients with primary HSV-1 or HSV-2 infections can be treated with oral acyclovir, valacyclovir, or famciclovir for 7 to 10 days. Recurrent herpes labialis usually does not require treatment. Those with severe or frequent recurrences may benefit from daily suppressive therapy.

VARICELLA AND HERPES ZOSTER

Varicella-zoster virus is the causative organism of both varicella (chickenpox) and herpes zoster (shingles). It is extremely contagious; prior to routine vaccination, it was usually acquired in childhood.

Varicella occurs year round, but there is a higher incidence during

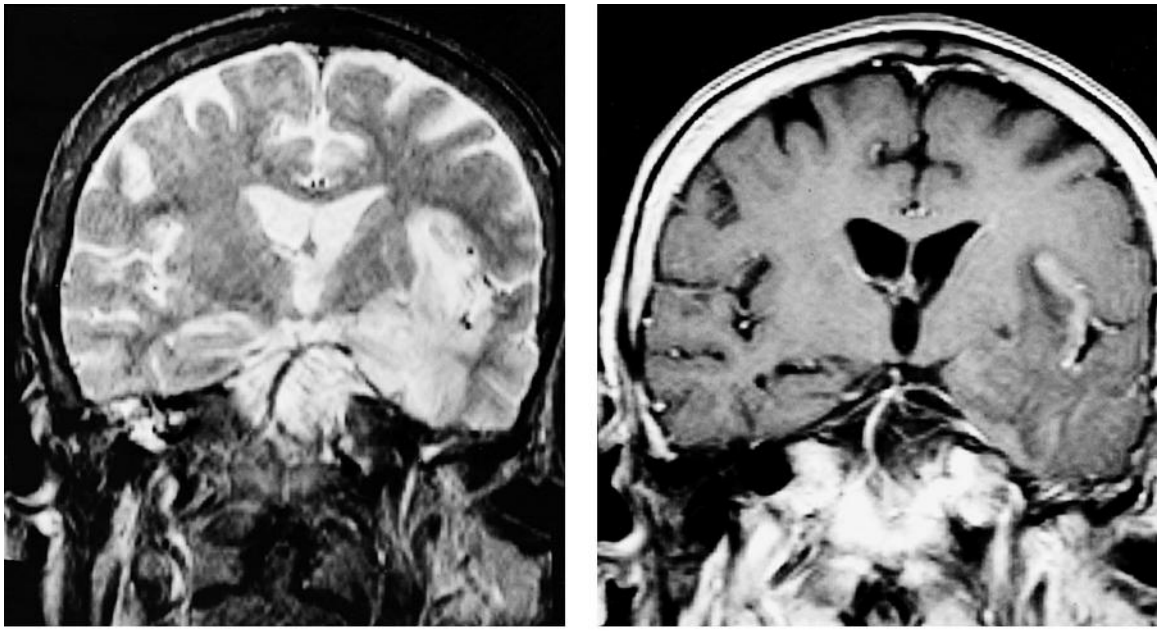

FIGURE 153-5. MRI scans showing hyperintensity involving the left temporal lobe and insular cortex in herpes simplex encephalitis. **A.** T2-weighted coronal MRI scan in the axial plane, taken during the acute stage of the illness. There is increased signal from practically all of the inferior and deep temporal lobe and the insular cortex. **B.** T1-weighted image after gadolinium infusion showing enhancement of the left insular and temporal cortices and early involvement of the right temporal lobe. winter and spring months. The infection rate ranges from 60% to 100% in exposed individuals. The introduction of the varicella vaccine to routine childhood immunizations in 1995 has dramatically reduced the clinical burden of the virus.[8]

Herpes zoster can occur once immune response against the virus wanes, usually with advancing age. Over 90% of adults have serologic evidence of varicella-zoster virus infection, and unvaccinated persons who live to 85 years of age have a 50% risk of herpes zoster.[9] Iatrogenic immune suppression, certain diseases such as lymphoproliferative disorders, human immunodeficiency virus infection, and organ transplantation increase the risk of herpes zoster.

Vaccines are available to prevent both chickenpox and herpes zoster, although neither is 100% effective. Encourage parents to vaccinate their children, and remind those age 60 or older about the availability of a vaccine to prevent herpes zoster. Varicella-zoster immune globulin is available, but its use is generally limited to postexposure prophylaxis for nonimmune pregnant women and the severely immunosuppressed. Healthy individuals who are not immune can be vaccinated after exposure. Exposed individuals should be watched closely, and antivirals should be given to high-risk patients if they develop symptoms.[10]

TABLE 153-2 Antiviral Treatment of Severe Herpes Simplex Virus (HSV) Infection

Infection	Drug	Dosage	Duration
Mucocutaneous HSV infections in immunocompromised patients	Acyclovir	5 milligrams/kg IV every 8 h	7–14 d
	Valacyclovir	500 milligrams–1 gram PO twice per day	
	Famciclovir	500 milligrams PO twice per day	
Herpes simplex encephalitis	Acyclovir	10–15 milligrams/kg IV every 8 h	14–21 d
Neonatal herpes simplex	Acyclovir	10–20 milligrams/kg IV every 8 h	14–21 d
Visceral herpes simplex disease	Acyclovir	10–15 milligrams/kg IV every 8 h	14–21 d

PATHOPHYSIOLOGY

Varicella-zoster virus spreads to the respiratory mucosa of a susceptible host via aerosolized droplets of respiratory secretions of patients with chickenpox. It can also spread from direct contact with vesicle fluid in herpes zoster but is not as highly contagious in this situation. The virus multiplies in regional lymph nodes and then disseminates to the nasopharyngeal surfaces and the skin, causing the characteristic rash. It is contagious until all the lesions have crusted over. Varicella-zoster virus remains latent in the dorsal root ganglion and can later reactivate along dermatomes, resulting in shingles (**Figure 153-6**).

VARICELLA CLINICAL FEATURES

Varicella (chickenpox) is a febrile illness with a vesicular rash. Often it is associated with nonspecific symptoms of headache, malaise, and loss of appetite. The rash is superficial and appears in crops, so patients typically have lesions at varying stages, including papules, vesicles, and crusted lesions (**Figure 153-7**). Lesions are concentrated more on the torso and face and typically crust and slough off after 1 to 2 weeks. Most infections are minor and self-limited. Immunized patients can occasionally develop mild chickenpox.

A range of complications can occur, more often in those at extremes of age or the immunocompromised. Bacterial superinfections of skin lesions, most often with group A streptococci, can cause serious illness including necrotizing fasciitis. Children with lymphoma and leukemia may develop progressive varicella in which vesicles continue to erupt into the second week of illness, sometimes with visceral involvement of the lung, liver, and brain. CNS complications such as cerebellar ataxia, meningitis, meningoencephalitis, and vasculopathy are well described. **Pneumonitis can be severe and is more common in pregnant women.**[8]

HERPES ZOSTER CLINICAL FEATURES

Herpes zoster (shingles) often begins with a prodrome of malaise, headache, and photophobia. The patient notes pain, itching, and paresthesias in one or more dermatomes. These symptoms are followed by the development of a maculopapular rash that becomes vesicular. The eruption does not cross the midline (**Figure 153-8**). Most commonly, herpes

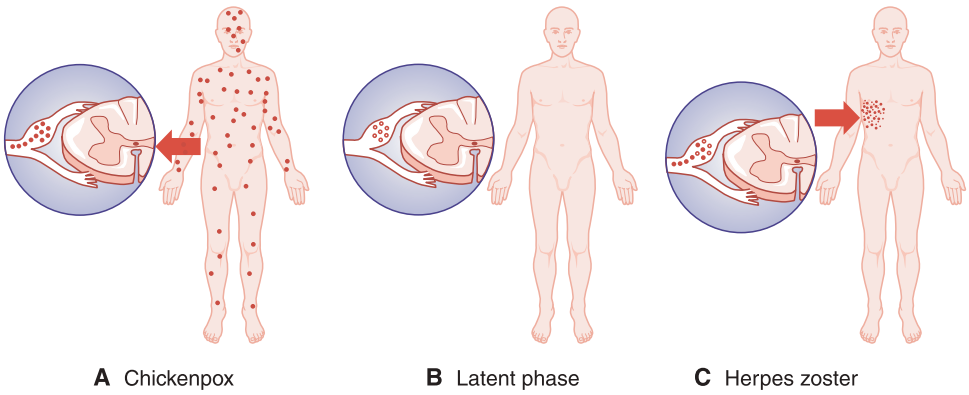

FIGURE 153-6. Primary infection, latency, and reactivation of varicella-zoster virus. **A.** Generalized distribution of primary varicella. **B.** Latent phase. **C.** Reactivation phase of clinical herpes zoster. [Reproduced with permission from Wolff K, Johnson RA: *Fitzpatrick's Color Atlas and Synopsis of Clinical Dermatology*, 6th ed., © 2009 by McGraw-Hill, Inc., New York.]

zoster affects the chest or face, but it can affect any dermatomal level. Herpes zoster ophthalmicus can cause blindness and is the result of reactivation along the ophthalmic distribution of the trigeminal nerve (see chapter 241, "Eye Emergencies"). The seventh cranial nerve can be involved, causing facial nerve paralysis and lesions along the auditory canal (herpes zoster oticus). Postherpetic neuralgia, pain that persists for >30 days, is a feared complication. The incidence increases with advancing age, and pain may last months or years.

Dissemination of varicella-zoster virus can occur in immunocompromised patients. **Herpes zoster involving more than three dermatomes is often a clue to an immunodeficient condition. The presence of herpes zoster in a young, healthy person may be a sign of human immunodeficiency virus infection.** In many cases of disseminated disease, the skin is the only involved structure. However, the virus may spread to the visceral organs and cause pneumonitis, hepatitis, and encephalitis.

DIAGNOSIS

Varicella-zoster virus infections have a characteristic appearance, so a clinical diagnosis is sufficient in most cases. Clinicians should look for the characteristic rash of chickenpox, which involves vesicles that appear in crops in different stages of development. Herpes zoster is diagnosed when clusters of vesicles and papules appear in a dermatomal pattern.

Laboratory diagnosis is needed in patients with atypical illness or severe disease. This is accomplished through viral culture, antigen testing, or polymerase chain reaction testing of vesicle fluid. Although smallpox has been eradicated, it remains a potential threat as a biologic weapon, and the lesions could be confused with those of varicella. The lesions of smallpox are larger and distributed more on the extremities, and all lesions are at the same stage of development.

Obtain a chest radiograph if pneumonitis is suspected. An MRI of the brain, lumbar puncture, and polymerase chain reaction testing for varicella-zoster virus are appropriate for suspected brain involvement.

VARICELLA TREATMENT

Most healthy patients need only supportive care for chickenpox. Acyclovir and similar antiviral agents decrease the number of lesions and shorten the course if therapy is started within 24 hours of rash onset. However, the impact of treatment is modest, so it is not routinely recommended for those who are otherwise healthy. Secondary skin infections are typically caused by group A streptococci and can be treated with a first-generation cephalosporin.

Consider acyclovir for those at higher risk for complications, including adults and children >12 years of age, patients with chronic skin or pulmonary disorders, those receiving long-term salicylate therapy, and immunocompromised patients. Varicella-zoster virus is less sensitive to acyclovir than herpesvirus and requires higher and more frequent dosing. Although chosen by some for dosing simplicity, famciclovir and valacyclovir are not licensed for the treatment of varicella (chickenpox) in the United States.

HERPES ZOSTER TREATMENT

Antiviral agents hasten lesion resolution, reduce new lesions, reduce viral shedding, and decrease acute pain, but **do not reduce the severity of postherpetic neuralgia.**[9] Using antiviral therapy in immunocompromised

FIGURE 153-7. Rash of primary varicella (chickenpox), demonstrating lesions of multiple stages, including papules, vesicles, and crusted lesions. FIGURE 153-8. Dermatome distribution of the classic rash of herpes zoster (shingles).

patients may reduce the risk of severe disseminated disease. **Start antiviral medication within 72 hours of the onset of rash, and consider treatment at >72 hours if new vesicles are still present or developing. Treat immunocompromised patients regardless of the time since rash onset.** Benefits are more pronounced in patients >50 years of age. Therapy is well tolerated, and the risk of adverse events is minimal.

Treat those with disseminated herpes zoster, those with CNS involvement, and severely immunosuppressed patients with herpes zoster with IV acyclovir. Use valacyclovir in those with herpes zoster ophthalmicus, along with ophthalmologist consultation (see chapter 241, "Eye Emergencies").

Herpes zoster can be extremely painful and require opioid analgesia. Corticosteroids in combination with antivirals may provide a modest decrease in acute pain but do not decrease the development of postherpetic neuralgia.[9] **Adjunctive corticosteroids can be considered in older individuals with severe pain who do not have contraindications to their use.**

EPSTEIN-BARR VIRUS INFECTION

Epstein-Barr virus (EBV) is implicated in a variety of human illnesses. It is the causative agent of heterophile-positive infectious mononucleosis. EBV infection is also associated with cancers such as B-cell lymphoma, Hodgkin's disease, Burkitt's lymphoma, and nasopharyngeal carcinoma.

There are two age-related peaks of infection: early childhood and young adulthood. In developing countries, EBV infection is widespread in early childhood and is often asymptomatic. College students and military recruits experience the highest morbidity. EBV requires close contact for transmission. The infection is usually contracted from an asymptomatic individual who sheds the virus.

PATHOPHYSIOLOGY

EBV is transmitted via salivary secretions. After infecting the oropharyngeal epithelium, it disseminates through the bloodstream. The virus infects B lymphocytes and causes an increase in T lymphocytes, which results in enlargement of lymphoid tissue. In immunocompromised patients with decreased T-cell function, the B cells continue to proliferate, and proliferation may lead to neoplastic transformation.

CLINICAL FEATURES

The manifestations of EBV infection depend on age and immune status. Infections in infants and young children are often asymptomatic or have mild pharyngitis. Teenagers and young adults can develop infectious mononucleosis, which presents as fever, lymphadenopathy, and pharyngitis. Tonsillar exudates are frequent and often extensive and may be necrotic appearing (**Figure 153-9**). Splenomegaly occurs in more than half of patients. Symptoms generally resolve over 2 to 3 weeks, and most patients recover uneventfully. Severe fatigue is a prominent feature and can persist for months. **Patients treated with ampicillin or amoxicillin for suspected streptococcal pharyngitis often develop a nonallergic morbilliform rash if they have infection with EBV.**

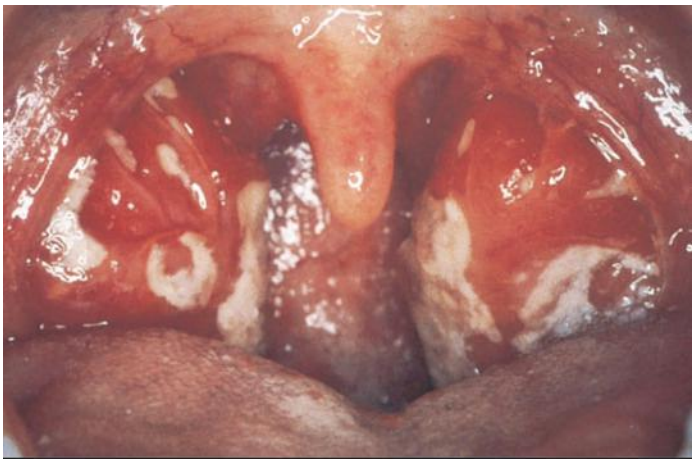

FIGURE 153-9. Classic findings of tonsillopharyngitis associated with infectious mononucleosis caused by Epstein-Barr virus. [Reproduced with permission from Shah BR, Lucchesi M: *Atlas of Pediatric Emergency Medicine,* © 2006 by McGraw-Hill, Inc., New York.]

EBV can affect nearly all organ systems. Neurologic complications such as encephalitis, meningitis, and Guillain-Barré syndrome have been described. Hepatitis, myocarditis, and hematologic disorders are also known complications. Rarely death results from splenic rupture, CNS complications, and airway obstruction. A rare form of chronic EBV infection characterized by a high titer of viral DNA has been reported. Patients are ill for ≥6 months and have histologic evidence of major organ involvement. The prognosis is poor, and treatment is not well defined.

DIAGNOSIS

If infectious mononucleosis is suspected based on the history and physical examination, a CBC and a monospot test can provide confirmation. Typically, there is lymphocytosis with >50% lymphocytes, and atypical lymphocytes are found on examination of the smear. These are reactive cytotoxic T cells that can also be found in other illnesses, including cytomegalovirus infection, human immunodeficiency virus infection, and viral hepatitis. The monospot test identifies heterophile antibodies that agglutinate animal erythrocytes, and a positive result is considered diagnostic of EBV infection in the right clinical setting. The monospot test result may be negative early in the course of disease, requiring a second test later if unclear. The sensitivity of the test is also decreased in infants and the elderly. Testing is particularly important in pregnant patients, because some other causes of heterophile-negative mononucleosis can be teratogenic. Tests for specific antibodies to the EBV viral capsid and nuclear antigen are available but are usually not needed because of the high sensitivity and specificity of the monospot test.

TREATMENT

Rest and analgesia are the mainstays of therapy, with most cases self-limited and not requiring specific therapy. **Use of corticosteroids is associated with increased complications and is recommended only for patients with severe disease, such as upper airway obstruction, neurologic disease, or hemolytic anemia.** Acyclovir is active against EBV but is thought to be effective only for oral hairy leukoplakia associated with human immunodeficiency virus infection. **Advise patients to avoid all contact sports for a minimum of 3 weeks after illness onset to avoid splenic injury.**[11]

CYTOMEGALOVIRUS INFECTION

Cytomegalovirus (CMV) is an important human pathogen that causes a wide variety of diseases, ranging from asymptomatic infections in most to life-threatening pneumonia in transplant patients. Like other herpesviruses, it causes a primary infection and then recedes into lifelong latency.

CMV is not highly contagious, and transmission requires repeated or prolonged exposure. The virus is spread by sexual contact, saliva, breastfeeding, and transplantation, as well as transplacentally and through blood transfusion. Seroprevalence rates approach 100% in Africa and in some Asian countries. In the developed world, it is not unusual for older individuals to acquire a primary infection. This is of particular concern in women of childbearing age because of teratogenic effects. The risk of fetal CMV infection is highest in the first trimester of pregnancy in a previously seronegative mother who acquires a primary infection.

Organ transplant patients can acquire infection, most often between 1 and 4 months after transplant. The risk is highest when a seronegative patient receives a CMV-positive organ.

PATHOPHYSIOLOGY

CMV is usually inoculated on the mucosal surface of the upper respiratory or genital tract, where the virus multiplies and then disseminates. Most infections are only mildly symptomatic. Primary disease in late

adolescence and adulthood results in an infectious mononucleosis syndrome. The virus remains latent in most individuals unless immunity is severely suppressed.

CLINICAL FEATURES

Primary infection in healthy individuals is usually asymptomatic. CMV can cause a heterophile-negative infectious mononucleosis syndrome, characterized by prolonged fever, myalgias, and lymphocytosis, but no exudative pharyngitis. Severe disease in the otherwise healthy host includes hepatitis, colitis, Guillain-Barré syndrome, encephalitis, and hemolytic anemia.[12]

Congenital and neonatal infections are associated with some of the most important complications of primary CMV infection. Symptoms in infants can be devastating and include hepatosplenomegaly, jaundice, microcephaly, petechiae, and growth retardation. Severe infections carry a high mortality, and those who survive often have neurologic sequelae.

Infections in immunocompromised patients can be severe and involve any organ. Infection can be primary or the result of reactivation of latent virus. Severe disease can develop in previously healthy CMV-seropositive individuals with an abnormal T-cell response during critical illness. Infections after solid-organ and hematopoietic stem cell transplantation are a leading cause of morbidity (see chapter 297, "The Transplant Patient"). The infection typically begins in the transplanted organ and subsequently may disseminate, causing pneumonia, hepatitis, and CNS involvement. CMV infections can also cause late-onset chronic graft-versus-host disease in stem cell transplant patients. Symptoms often begin with prolonged fever, night sweats, and fatigue.

In human immunodeficiency virus–infected patients with CD4 counts of <50 cells/mm^3, retinitis is the most common manifestation of infection, causing painless loss of vision. Other manifestations associated with human immunodeficiency virus infection include encephalopathy, colitis, and peripheral polyradiculopathy.

DIAGNOSIS

A specific diagnosis is not made in the ED. Body fluids such as urine, saliva, blood, tears, semen, and vaginal fluid can be subjected to antigen testing, polymerase chain reaction testing, antibody testing, histologic analysis, and viral culture. The hallmark of CMV infection on histologic examination is a large cell containing a large basophilic intranuclear "owl's eye" and intracytoplasmic inclusion bodies.

TREATMENT

Several systemic antiviral agents are active against CMV infection, including ganciclovir, valganciclovir, foscarnet, and cidofovir (**Table 153-3**). Illness in the otherwise healthy host is usually self-limited and does not require antiviral therapy. CMV-induced infectious mononucleosis is treated symptomatically.

Transplant recipients with CMV disease are treated more aggressively (see chapter 297). Treatment may include the use of CMV hyperimmune globulin along with ganciclovir or valganciclovir.[13] Ganciclovir implants are available for human immunodeficiency virus patients with CMV retinitis.

TABLE 153-3 Treatment of Cytomegalovirus Disease

Patient Population	Syndrome	Treatment
Healthy host	Heterophile-negative infectious mononucleosis	Symptomatic care
Bone marrow transplant recipient	Pneumonia, GI disease, graft-versus-host disease	IV ganciclovir plus immunoglobulin
Acquired immunodeficiency syndrome patient	Retinitis, GI disease, neurologic disease	IV ganciclovir, valganciclovir
Organ transplant recipient	Pneumonia, GI disorder, infection of transplanted organ, nonspecific febrile illness	IV ganciclovir

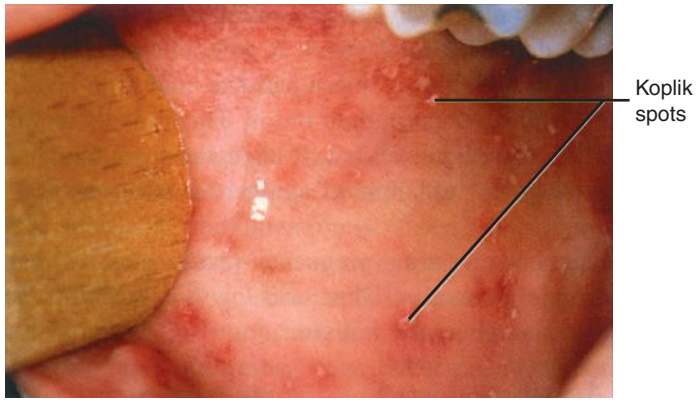

FIGURE 153-10. Oral Koplik's spots on day 3 of measles. [Reproduced with permission from Nester EW, Anderson DG, Roberts CE Jr, Nester MT: *Microbiology: A Human Perspective,* 6th ed. New York: McGraw-Hill, 2008.]

MEASLES

Measles was a common childhood illness before vaccination became routine in the 1960s. Most measles deaths occur among children in developing countries, but developed countries are now seeing occasional outbreaks related to parents choosing not to vaccinate their children, largely due to unfounded fears about vaccine safety. Measles is caused by an RNA virus that is the most infectious virus known to humans and is communicable before symptoms begin. Illness starts with fever, malaise, cough, and runny nose, often with conjunctivitis. Small, white Koplik's spots (**Figure 153-10**) appear on the buccal mucosa early in the illness, followed by a red maculopapular rash that typically starts on the head and spreads throughout the body. **Diagnosis is usually clinical, with pathognomonic Koplik's spots and the characteristic rash**. Measles can be confirmed by detection of immunoglobulin M antibodies, which are present at rash onset. Treatment is supportive, with particular attention to insuring adequate nutrition, especially vitamin A. Mortality in developed countries is less than 1/1000, but can be up to 20% to 30% among infants in developing countries, often from pneumonia.

ARBOVIRAL INFECTIONS

Arboviral infections are infections spread by biting mosquitoes, ticks, and flies. Japanese encephalitis is one of the most common and important causes of encephalitis in the world. The emergence of West Nile virus infection has caused renewed interest in North America regarding epidemic viral encephalitis. This section reviews some of the more important and severe arboviral infections, concentrating on those that occur in North America[14] (**Table 153-4**). Other significant arboviral diseases are discussed in chapter 161, "Global Travelers."

TABLE 153-4 Arboviral Infections in North America

Virus	Geographic Distribution	Groups at Highest Risk
West Nile virus	United States, Canada, Mexico	Elderly adults
St. Louis encephalitis virus	United States, Canada, Mexico	Elderly adults
La Crosse virus	Central, northeastern United States	Children
Eastern equine encephalitis virus	Eastern and Gulf Coast states, eastern Canada	All ages
Western equine encephalitis virus	Western and midwestern United States and western Canada	Infants and elderly adults
Venezuelan equine encephalitis virus	Florida, Texas, Mexico	All ages

EPIDEMIOLOGY

Arboviral infections tend to be seasonal, with increased incidence in warmer months due to the breeding patterns of the arthropod vectors. The major hosts are mammals and birds. When migratory birds are involved, the virus can spread quickly over large distances. Humans are usually an incidental host and acquire the diseases when they venture into areas occupied by the reservoir host.

The age group affected often depends on local prevalence. Japanese encephalitis, which is highly endemic in certain parts of Asia, usually affects children. Most adults have been exposed and are immune. Elderly adults are at risk for St. Louis encephalitis.

Dengue, yellow fever, Rift Valley fever, and chikungunya viruses are among the viruses causing hemorrhagic fever syndromes (see chapter 161). Dengue virus is a common cause of fever and rash (**Figure 153-11**) in tropical areas with large mosquito populations, and transmission has been found in the southern United States. Severe dengue hemorrhagic fever can develop in locals who are exposed to a second infection with a different serotype. Chikungunya fever causes rash, myalgias, arthralgias, and fever. Although fatalities are rare, arthralgias can be debilitating and last for months. The disease is reported in Asia, Africa, and more recently in the Caribbean and southeastern United States. Yellow fever is found in the tropics of Africa and South America. The *Aedes aegypti* mosquito vector for the yellow fever virus was once eradicated in the United States, but it is now starting to reappear. This mosquito can also spread dengue and chikungunya viruses.

Japanese encephalitis virus causes >15,000 deaths yearly, primarily in Asia, and is now spreading to Australia. West Nile virus and the viruses causing La Crosse encephalitis, St. Louis encephalitis, eastern equine encephalitis, and western equine encephalitis are found in North America.[13,14]

PATHOPHYSIOLOGY

A mosquito or other appropriate vector becomes infected after it feeds on the blood of a viremic host. Humans are infected when the arthropod takes a blood meal. The virus replicates near the site of inoculation before it enters the reticuloendothelial system and then disseminates to various target organs.[14,15] There is often a low-grade viremia until the host can produce immunoglobulin M neutralizing antibodies. If the immune system is unable to clear the virus, then the more serious manifestations of hemorrhagic fever or encephalitis may become evident.

FIGURE 153-11. Maculopapular rash of dengue hemorrhagic fever with areas of dermal hemorrhage, petechiae, and edema. [Reproduced with permission from Wolff K, Johnson RA: *Fitzpatrick's Color Atlas and Synopsis of Clinical Dermatology,* 6th ed., © 2009 by McGraw-Hill, Inc., New York.]

CLINICAL FEATURES

Most arbovirus infections are either asymptomatic or cause a nonspecific mild illness. Only a few individuals develop hemorrhagic fever or encephalitis. **Severe human arboviral diseases most commonly manifest as four syndromes: fever and myalgia, arthritis and rash, encephalitis, and hemorrhagic fever.** These syndromes can overlap; viruses that cause encephalitis and hemorrhagic fever may also cause fever and myalgia. Headache is a common symptom of most arboviral infections and may be quite severe. Hemorrhagic fever presents with bleeding from the gums, petechiae, and GI tract. The classic presentation of viral encephalitis is fever, headache, and altered level of consciousness. Patients can be lethargic and confused and occasionally present with seizures.[14] In general, individuals at extremes of age are more likely to have severe disease.

DIAGNOSIS

Obtaining a detailed travel and exposure history and knowing local epidemiologic patterns help in diagnosing arboviral infections. Patients with encephalitis should undergo CT or MRI of the brain. MRI is more sensitive and may show foci of increased signal intensity in the parenchyma.

Cerebrospinal fluid typically shows a lymphocytic pleocytosis and a slightly elevated protein level, although these findings are nonspecific. When encephalitis is in the differential diagnosis, save an extra vial of cerebrospinal fluid for further testing, because less common infections are often diagnosed only with stepwise testing after more common causes have been ruled out.

Serologic testing is the main method for diagnosis of arboviral infections. Viral cultures are labor intensive and technically demanding. Furthermore, patients are viremic for only a few days after the onset of illness. Generally, immunoglobulin M appears within a few days. Patients who are tested very early in the course of illness may have a false-negative result. A presumptive diagnosis of the suspected arboviral infection can be made based on an elevated immunoglobulin M level, and this can be confirmed with an increase in antibody titers between acute and convalescent samples. Many arboviruses are antigenically similar and cross-react on testing. Arboviral infections are reportable to public health authorities in many areas.[16]

TREATMENT

Symptomatic management is the mainstay of treatment after excluding other serious, treatable causes of meningitis and encephalitis. Antiviral drugs, interferon, and steroids are not useful. Empiric treatment with acyclovir and antibiotics is appropriate until HSV encephalitis and bacterial meningitis are ruled out. Anticonvulsant therapy may be required if seizures occur.

Hemorrhagic fever is also treated with supportive care. Patients with hemorrhagic fever require diligent fluid management to avoid overload.[14,15]

EBOLA VIRUS DISEASE AND OTHER HEMORRHAGIC FEVERS

Viral hemorrhagic fevers are caused by several groups of RNA viruses with varying geographic distributions. These rare diseases elicit tremendous fear among the public and healthcare providers, now exacerbated by the large outbreak in Western Africa. Examples include Hantavirus pulmonary syndromes, Lassa fever, and perhaps the most notorious, Ebola virus disease. Geographic exposure and contact with an infected traveler are the most important clues to suspecting viral hemorrhagic fevers in an individual patient. Clinical presentation varies between viruses, with some causing relatively minor illness and some with high

mortality. Symptoms typically begin with fever, myalgia, and malaise, which then progress to GI and other system involvement. Increased vascular permeability results in hypotension, pulmonary edema, and renal failure. Coagulation defects lead to diffuse hemorrhage, which can be worse in patients with thrombocytopenia or platelet dysfunction, sometimes with extensive bleeding, organ damage, and shock. Ebola and most other viral hemorrhagic fevers can be confirmed with acute serology to identify antibodies or, more commonly, reverse transcriptase polymerase chain reaction identification of the virus that is performed at specialized labs such as the Centers for Disease Control and Prevention.

Periodic Ebola virus outbreaks in western Africa have occurred with high mortality. The virus is spread through contact with infected body fluids such as bloody vomit and diarrhea, and the lack of personal protective equipment in developing countries contributes to spread within healthcare facilities.[17] Important aspects of preparing for Ebola and other severe viral hemorrhagic fevers in EDs include screening at triage for illness in travelers returning from areas of current outbreak, and rapid initiation of appropriate isolation. **Ebola and many other viral hemorrhagic fevers require contact and droplet precautions including full gown, gloves, and face mask with eye protection**. Staff should be instructed on proper donning and removal of protective equipment to avoid contamination with body fluids**. It is important to notify the hospital laboratory to take proper precautions and to plan for sending specimens to specialized labs**. Treatment of Ebola and most other VHFs is supportive, with fluids, renal replacement, and respiratory support. Experimental serologic treatments and vaccines are in development.

CHAPTER 154

Human Immunodeficiency Virus Infection

Richard Rothman
Catherine A. Marco
Samuel Yang

EPIDEMIOLOGY

The human immunodeficiency virus (HIV) is the leading cause of infectious disease deaths worldwide. As of 2013, approximately 36 million patients died of HIV-related illnesses, and an estimated 35.3 million people were living with HIV infection/acquired immunodeficiency syndrome (AIDS). Although HIV exists everywhere, the vast majority of new infections (95%) occur in individuals living in low- and middle-income countries. As an example, in sub-Saharan Africa, which is the world's most affected region, nearly 1 in every 20 adults are living with HIV.[1]

Despite the global burden, the number of new HIV infections is falling annually, as are deaths. These improvements result from a global health strategic approach.[2] In 2013, an estimated 1.3 million U.S. citizens had HIV.[3] Despite the overall promising trends, the challenge of reducing new infections persists, with **approximately 50,000 new cases occurring each year in the United States.**

Risks associated with acquiring HIV infection include homosexuality or bisexuality, injection drug use, heterosexual exposure, receipt of a blood transfusion prior to 1985, and maternal HIV infection (risk for vertical and horizontal maternal–neonatal transmission). Rates of HIV attributable to male-to-male sexual contact increased from 55% in 2008 to 62% in 2011. Heterosexual contact accounts for approximately 28% of transmissions, followed by about 8% for injection drug use and 3% for male-to-male sexual contact *and* IV drug use. New HIV infection rates continue to rise among young disadvantaged minority populations (many of whom use the ED for both primary and emergency care). Although African Americans represent only 14% of the total U.S. population, this group accounted for almost half (44%) of new HIV infections in the year 2010. The rate of new infections among black men was the highest of any group by race and sex, notably in men having sex with men. Hispanics also have a higher proportion of new infections (21%) than accounted for by their relative size in the population (14%). Factors associated with the ethnic disparities in HIV include the overall higher prevalence of disease in minority populations, economic barriers that decrease access to testing and treatment, higher rates of incarceration (associated with increased concurrent relationships and higher levels of sexually transmitted infections, both of which increase likelihood of transmissions), and homophobia, which may impede HIV prevention.[4] ED visits by HIV-infected individuals occur at rates higher than the general population[5] due to the characteristics of the populations who use the ED, which are the same groups disproportionately affected by HIV/AIDS.

PATHOPHYSIOLOGY

HIV is a cytopathic retrovirus that kills infected cells. The virus is labile and is neutralized easily by heat and common disinfecting agents such as 50% ethanol, 35% isopropyl alcohol, 0.3% hydrogen peroxide, or a 1:10 solution of household bleach. There are two major subtypes of HIV; HIV-1 is the predominant subtype worldwide and is the cause of AIDS. HIV-2 causes a similar immune syndrome but is restricted primarily to western Africa and is infrequent in the United States, but its incidence is growing.

The HIV virion is a central RNA molecule and a reverse transcriptase protein surrounded by a core protein encased by a lipid-bilayer envelope. After infection, HIV selectively attacks host cells involved in immune function, primarily CD4+ T cells. Within the host cell, HIV-encoded RNA is reverse-transcribed into DNA by the enzyme reverse transcriptase. The viral genome then becomes integrated into the host genome, where it may lie dormant or be actively transcribed and translated to produce virally encoded proteins and new HIV virions. As a result of infection, immunologic abnormalities eventually occur, including lymphopenia, qualitative CD4+ T-cell function defects, and autoimmune phenomena. Defects in cellular immunity ultimately result in development of a variety of opportunistic infections and neoplasms.

HIV exists in saliva, urine, cerebrospinal fluid (CSF), pus, brain, tears, alveolar fluid, synovial fluid, and amniotic fluid. Transmission of HIV occurs through semen, vaginal secretions, blood or blood products, and breast milk, and in utero by transplacental transmission. Transmission does not occur with casual contact. There is only one documented case of transmission from healthcare provider to patient in the United States, which involved an infected dentist in Florida who transmitted the virus to six patients.

NATURAL HISTORY AND CLINICAL STAGES OF HIV INFECTION

Symptoms of acute HIV infection (also called *acute retroviral syndrome*) occur in 50% to 90% of infected patients. The diagnosis is missed in up to 75% of cases due to nonspecific presentation (resemblance to a flulike or mononucleosis-like syndrome) and a lack of suspicion. Symptoms of acute HIV infection usually develop 2 to 4 weeks after exposure and may last for 2 to 10 weeks and include fever (>90%), fatigue (70% to 90%), pharyngitis (>70%), rash (40% to 80%), headache (30% to 70%), and lymphadenopathy (40% to 70%); other reported symptoms are weight loss, headache, and diarrhea.[6]

Seroconversion and detectable antibody response to HIV usually occur 3 to 8 weeks after infection, although delays of up to 11 months have been reported. This phase is followed by a long period of asymptomatic infection, during which patients generally have no findings on physical examination except for possible persistent generalized lymphadenopathy (enlarged lymph nodes in at least two noncontiguous sites other than inguinal nodes). The mean incubation time from exposure to the development of AIDS in untreated patients is estimated at 8.23 years for adults and 1.97 years for children <5 years of age. Virologic studies

TABLE 154-1 Stage 3 AIDS–Defining Opportunistic Illnesses in HIV Infection

Bacterial infections, multiple or recurrent*
Candidiasis of bronchi, trachea, or lungs
Candidiasis of esophagus
Cervical cancer, invasive†
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (>1 month in duration)
Cytomegalovirus disease (other than liver, spleen, or nodes), onset at age >1 month
Cytomegalovirus retinitis (with loss of vision)
Encephalopathy attributed to HIV
Herpes simplex: chronic ulcers (>1 month in duration) or bronchitis, pneumonitis, or esophagitis (onset at age >1 month)
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis, chronic intestinal (>1 month in duration)
Kaposi's sarcoma
Lymphoma, Burkitt's (or equivalent term)
Lymphoma, immunoblastic (or equivalent term)
Lymphoma, primary, of brain
Mycobacterium avium complex or *Mycobacterium kansasii*, disseminated or extrapulmonary
Mycobacterium tuberculosis of any site, pulmonary†, disseminated, or extrapulmonary
Mycobacterium, other species or unidentified species, disseminated or extrapulmonary
Pneumocystis jirovecii (previously known as *Pneumocystis carinii*) pneumonia
Pneumonia, recurrent†
Progressive multifocal leukoencephalopathy
Salmonella septicemia, recurrent
Toxoplasmosis of brain, onset at age >1 month
Wasting syndrome attributed to HIV

Abbreviations: AIDS = acquired immunodeficiency syndrome; HIV = human immunodeficiency syndrome.

*Only among children aged <13 years. (CDC. 1994 Revised classification system for human immunodeficiency virus infection in children less than 13 years of age. MMWR 1994;43[No. RR-12].)

†Only among adults and adolescents aged >13 years. (CDC. 1993 Revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. MMWR 1992;41[No. RR-17].)

of patients during this period suggest that a steady state of HIV replication and CD4+ T-cell death and replacement exists until increased levels of HIV replication occur. **Variables most predictive of disease stage are viral load and CD4+ T-cell counts**, with a steeper decline in CD4+ T-cell count and a higher viral burden associated with more rapid progression and more outcomes. Other non–HIV-related factors, such as age and malignancy, also impact disease progression.

Early symptomatic infection is characterized by conditions that are more common and more severe in the presence of HIV infection but are not AIDS-indicator conditions. These include thrush, persistent vulvovaginal candidiasis, peripheral neuropathy, cervical dysplasia, recurrent herpes zoster, and idiopathic thrombocytopenic purpura. These conditions occur more often as the CD4+ T-cell count drops below 500 cells/mm^3; if the count drops below 200 cells/mm^3, the frequency of opportunistic infections increases dramatically. HIV infection is classified by the Centers for Disease Control and Prevention as stage 3 (AIDS) by either laboratory evidence or clinical evidence of disease[7] (**Table 154-1**).

DIAGNOSIS

HIV TESTING METHODS

HIV infection is diagnosed using identification of HIV nucleic acid, detection of viral-specific antigen, detection of antibodies to HIV, and isolation of the virus by culture (now rarely used in practice). **The standard and most commonly used testing method for HIV is detection of antibodies to the virus**. Testing involves sequential use of an enzyme-linked immunosorbent assay, followed by a Western blot assay. Enzyme-linked immunosorbent assay is approximately 99% specific and 98.5% sensitive; Western blot testing is nearly 100% sensitive and specific if performed under ideal laboratory conditions. Enzyme-linked immunosorbent assay detects the binding of specific serum antibodies to HIV antigens that are adherent to a microtiter plate. Western blot assay detects HIV antibodies to discrete viral antigens that are electrophoretically separated and transferred to nitrocellulose paper. A positive Western blot result requires detection of at least one gene product, although criteria vary by laboratory. Reasons for indeterminate test results include early seroconversion, cross-reacting antibodies, pregnancy, presence of an autoimmune disease, or technical errors.

Acute HIV is the time from HIV transmission to seroconversion. **Diagnosis of acute HIV infection cannot be made with standard serologic tests** because seroconversion has not yet occurred. Methods for earlier detection of HIV-1 include techniques to detect DNA, RNA, or HIV antigens, although these tests are not always available in the ED. Mean times from transmission to detection are shortest for viral load (17 days), followed by p24 antigen (22 days), enzyme-linked immunosorbent assay positivity (25 days), and Western blot positivity (31 days).[8]

BENEFITS OF EARLY DIAGNOSIS

Although acute HIV infection is not diagnosed in up to 75% of all cases, the benefits of early recognition allow an opportunity to limit risk of further transmission (key in this high viral load period) and to start antiretroviral therapy to potentially reduce symptoms and slow disease progression.[8] For patients in whom acute HIV infection is suspected but not confirmed (i.e., those with a high-risk profile presenting with fever of unknown origin and/or a syndrome suspicious for acute seroconversion), counseling and urgent referral from the ED to an outpatient follow-up setting for appropriate testing are best.

RAPID HIV TESTS

As of 2012, there were eight rapid HIV tests approved for use by the U.S. Food and Drug Administration.[9] The first approved point-of-care rapid HIV test was Orasure HIV-1/2®, and it is the only one that uses oral fluid. Sensitivity and specificity are comparable with those of standard serologic testing, and minimal training is required for administration. Relay any point-of-care results to the patient as *preliminary positive* if reactive, confirming with Western blot testing. Negative test results may miss patients in the window period before seroconversion has occurred; this requires a repeat test at 3 months.

THE NEW HIV TESTING ALGORITHM

In June 2014, the Centers for Disease Control and Prevention released new recommendations regarding laboratory testing practices for HIV.[10] The new algorithm calls for use of automated testing for antibody to HIV-1 and HIV-2 simultaneously with detection of HIV-1 p24 antigen, permitting detection of acute infections. In instances where this set of tests is negative, no further testing is advised, and the patient is counseled that he or she tested negative. For those tests with positive results, follow-up testing differentiates HIV-1 and HIV-2. In cases where the differentiation test is negative, a nucleic acid amplification test confirms acute seroconversion. Turnaround time for the combined assay and HIV-1/2 differentiation assay is about 60 minutes. Turnaround time for confirmatory testing with nucleic acid amplification can take up to a few days. This new algorithm allows better early detection; ED-based studies show this is feasible and will detect new, acutely infected patients.[11,12]

CD4+ T-CELL COUNTS

CD4+ T-cell counts of <200 cells/mm^3 and a viral load of >50,000 copies/mm^3 are associated with increased risk of AIDS-defining illnesses. These indices are also frequently used by the primary care physician or HIV specialist as indicators for initiation of antiretroviral therapy (although the threshold value for initiation of treatment is controversial). When this information is unavailable or the stage of disease is unknown, the total lymphocyte count approximates the CD4+ T-cell count. In a recent ED study, a total lymphocyte count <1700 cells/mm^3 had a sensitivity of 95% for a CD4 count of <200 cells/mm^3.[13]

HIV TESTING PRACTICES IN THE ED

Time limitations, cost, difficulty with follow-up, confidentiality requirements, and questions regarding reimbursement are barriers to HIV testing in the ED. The Centers for Disease Control and Prevention 2006 HIV testing guidelines[14] offer a streamlined approach with decreased requirements for pretest counseling and use of opt-out testing (in which no separate written consent is required). State variability exists for both opt-out versus opt-in approaches and documentation requirements for informed consent. The U.S. Preventive Services Task Force gave a "Grade A" recommendation for routine HIV screening for all people age 15 to 65, as well as younger adolescents and older adults who are at an increased risk for HIV infection and all pregnant women, including those in labor whose HIV status is unknown. The Patient Protection and Affordable Care Act requires new insurance policies to pay for preventive services with "Grade A" recommendation.

American College of Emergency Physicians policy recognizes the need for ED HIV testing based on clinical need and supports screening with caveats. Currently, ED HIV testing in the United States remains relatively low (~0.2% of all ED visits), but programs are increasing, particularly in urban and/or academic centers. Determination of which of several approaches (e.g., nontargeted universal vs targeted) is most rational for ED practice is an area of active research, with local prevalence playing a role in the screening plan chosen.

CLINICAL FEATURES AND TREATMENT

INITIAL CARE: GENERAL CONSIDERATIONS

The spectrum of disease caused by HIV infection varies, from those coming to the ED with asymptomatic infection for symptoms unrelated to HIV disease, to symptomatic patients seeking care from involvement of virtually any organ system and with multiple coexisting symptoms. This makes the ED evaluation and diagnosis of HIV-positive patients challenging.

Maintain confidentiality regarding HIV-related diagnoses in the ED. Begin care without discrimination and without assuming any illness trajectory unless advanced directives, including cardiopulmonary resuscitation, are already in place.

Always use universal precautions (in some hospitals termed *standard precautions*). Healthcare workers are often exposed to the blood and body fluids of HIV-infected patients or patients at high risk of harboring the HIV virus. ED-based studies have demonstrated that substantial numbers of patients continue to have unsuspected HIV infection and that HIV seropositivity cannot be predicted accurately, even after assessment of risk factors.

Occupational exposure is covered in the chapter 162, "Occupational Exposures, Infection Control, and Standard Precautions." Testing, treatment, and follow-up are discussed. Other resources for information on HIV exposures are the Centers for Disease Control and Prevention and the University of California, San Francisco National Clinicians' Post-Exposure Prophylaxis Hotline (888-448-4911, http://www.nccc.ucsf.edu).[15]

Focus the history taking and physical examination on identifying the clinical stage of disease to direct attention to the most likely complications. Obtain a thorough report of past and current medications and previous infections, and ask about the patient's ability to perform activities of daily living. A directed exam seeks findings of organ involvement related to the chief complaint. Physical findings that might specifically assist with staging include the presence of oral candidiasis, skin lesions, temporal wasting, and dementia.

Diagnosis and treatment are directed toward recognition of infection (when not previously diagnosed), assessment of the severity of disease, identifying specific organ(s) involved, and institution of therapy. For the most up-to-date information and details on drug dosing, sources include the Centers for Disease Control and Prevention Web site[16] or the Johns Hopkins University School of Medicine guide to care of the HIV-positive patient.[8]

Consultation with an infectious disease specialist and others with expertise in HIV infection is often necessary to provide proper therapy and disposition. Disposition decisions are based on the need for inpatient evaluation or management and the patient's ability to function as an outpatient, which is often driven by oral intake and ambulation ability and availability of appropriate medical follow-up. Healthcare and family resources can aid decision making about care.

Systemic symptoms such as fever, weight loss, and malaise are common in HIV-infected patients and account for the majority of HIV-related ED presentations.[8] In the ED, look for systemic infection, malignancy, drug toxicity, or metabolic abnormalities. This is done by assessing serum electrolytes with renal function, CBC, liver function studies, blood cultures, urinalysis and urine culture, hepatic function tests, and chest radiograph; serologic testing for syphilis, cryptococcosis, toxoplasmosis, cytomegalovirus infection, and coccidioidomycosis is deployed more selectively. Lumbar puncture is needed after neuroimaging if headache, altered sensorium, visual change, or other focal neurologic symptoms or signs are present.

When treating the febrile ill-appearing HIV patient, provide fluid resuscitation, prompt empiric antibiotics, and admission for further evaluation and management. Outpatient evaluation and treatment are indicated only when all of the following conditions are met: the source of the fever does not dictate admission, the patient is able to function adequately at home (e.g., can maintain sufficient oral intake), and timely medical follow-up can be arranged.

HIV STAGE AND CAUSES OF FEVER

Infections are the most common cause of hospitalization among HIV-infected persons. In HIV-infected persons without obvious localizing signs or symptoms, sources of fever vary by stage of disease. Patients with CD4+ T-cell counts of >500 cells/mm^3 generally have causes of fever similar to those in nonimmunocompromised patients, whereas those with CD4+ T-cell counts between 200 and 500 cells/mm^3 are most likely to have early bacterial respiratory infections. For patients with CD4+ T-cell counts of <200 cells/mm^3, the most common causes of fever without obvious localizing findings are early *Pneumocystis jirovecii pneumonia* (formerly known as *Pneumocystis carinii*); central line infection; infection with *Mycobacterium avium* complex, *Mycobacterium tuberculosis*, or cytomegalovirus; drug fever; and sinusitis. Other causes of fever include endocarditis, lymphoma, and infection with *Histoplasma capsulatum* or *Cryptococcus neoformans*. Fever caused by HIV infection alone tends to occur in the afternoon or evening and generally is responsive to antipyretics.

Disseminated *M. avium* complex infection occurs predominantly in patients with CD4+ T-cell counts of ≤100 cells/mm^3 and not on **antiretroviral therapy** or azithromycin prophylaxis. Persistent fever and night sweats are typical symptoms. Associated symptoms include weight loss, diarrhea, malaise, and anorexia. Dissemination to the bone marrow, liver, and spleen results in anemia and elevated alkaline phosphatase levels. Diagnosis may be made by acid-fast stain of stool or other body fluids or by blood culture. Cultures using the lysis-centrifugation method are more sensitive for *M. avium* complex (and histoplasmosis) and should be ordered for patients with late-stage disease and fever of unknown origin. Treatment for *M. avium* complex reduces bacteremia and improves symptoms but does not eradicate disease; it starts with clarithromycin combined with ethambutol and rifabutin. Azithromycin is an alternative therapy.

Immune reconstitution inflammatory syndrome mimics an autoimmune event, with lymphadenitis, fever, and other symptoms commonly starting weeks to months after beginning antiretroviral therapy, often during tuberculosis therapy. Current treatment guidelines advise continuing antiretroviral therapy; nonsteroidal anti-inflammatory agents are recommended for mild to moderate cases; in severe cases, corticosteroids are advised (prednisone 1 to 2 milligrams/kg or equivalent for 1 to 2 weeks). Add the appropriate antimicrobials if there is a known or suspected infection.

Cytomegalovirus is a common cause of serious opportunistic viral disease in HIV-infected patients. Disseminated disease commonly involves the GI, pulmonary, and central nervous systems. The most important manifestation is retinitis (see "Cytomegalovirus Retinitis" below). Treatment is with foscarnet or ganciclovir. Oral ganciclovir can be used for prophylaxis (**Table 154-2**).

Fever in injection drug users is suspicious for infective endocarditis, which often has a nonspecific presentation in the ED (see chapter 155, "Endocarditis"). Most ED physicians admit febrile injection drug users while awaiting the results of blood cultures and echocardiography given the high morbidity and mortality coupled with the difficulties encountered with outpatient follow-up in the drug user population.

TABLE 154-2 Treatment Recommendations for Common Human Immunodeficiency Virus–Related Infections

Organ System	Infection	Therapy
Systemic	*Mycobacterium avium-intracellulare*	Clarithromycin, 500 milligrams PO twice a day *and* Ethambutol, 15 milligrams/kg PO once a day *and* Rifabutin, 300 milligrams/kg PO once a day
	CMV infection	Ganciclovir, 5 milligrams/kg IV twice a day for 2 wk, then 5 milligrams/kg/d *or* Foscarnet, 90 milligrams/kg every 12 h for 3 wk, then 90 milligrams/kg once a day
Pulmonary	*Pneumocystis jiroveci* (*Pneumocystis carinii*) pneumonia	Trimethoprim-sulfamethoxazole dose using 15–20 milligrams of trimethoprim component per kilogram per day PO or IV in divided doses three times a day for 3 wk If partial pressure of arterial oxygen is <70 mm Hg or alveolar-arterial gradient is >35 mm Hg, then add Prednisone, 40 milligrams twice a day for 5 d, then 40 milligrams once a day for 5 d, then 20 milligrams once a day for 11 d *or* Pentamidine, 4 milligrams/kg/d IV or IM for 3 wk
	Mycobacterium tuberculosis infection*	Isoniazid, 5 milligrams/kg PO once a day *and* Rifampin, 10 milligrams/kg PO once a day *or* rifabutin 5 milligrams/kg PO once a day *and* Pyrazinamide, 15–30 milligrams/kg PO once a day *and* Ethambutol, 15–20 milligrams/kg PO once a day
Central nervous	Toxoplasmosis†	Pyrimethamine, 200-milligram loading dose PO followed by 50–75 milligrams PO once a day for 6–8 wk *and* Sulfadiazine, 1–1.5 grams PO every 6 h for 6–8 wk *and* Leucovorin, 10–25 milligrams once a day
	Cryptococcosis‡	Amphotericin B, 0.7 milligram/kg IV once a day for 2 wk *and* Flucytosine, 25 milligrams/kg IV four times a day for 2 wk *then* Fluconazole, 400 milligrams/d PO for 8–10 wk
Ophthalmologic	CMV infection#	Valganciclovir, 900 milligrams PO twice a day for 14–20 d of induction therapy, then 900 milligrams PO daily for maintenance therapy *and* Ganciclovir, 2 milligrams intravitreal injection 1–4 doses over 7–10 d for patients with immediately sight-threatening lesions *or* Foscarnet, 2.4 milligrams intravitreal injection 1–4 doses over 7–10 d for patients with immediately sight-threatening lesions
GI	Candidiasis (thrush–limited to mouth)	Clotrimazole, 10-milligram troches five times a day *or* Nystatin, 500,000 units five times a day, gargle
	Esophagitis (primarily *Candida*)	Fluconazole, 100–400 milligrams/d PO
	Salmonellosis†	Ciprofloxacin, 500 milligrams PO twice a day for 2–4 wk
	Cryptosporidiosis	No known effective cure; best results with highly active antiretroviral therapy
Cutaneous	Herpes simplex	Acyclovir, 200 milligrams PO five times a day for 7 d *or* Famciclovir, 125 milligrams PO twice a day for 7 d *or* Valacyclovir, 1 gram PO twice a day for 7 d *or* for severe disease Acyclovir, 5–10 milligrams/kg IV every 8 h for 7 d

(*Continued*)

TABLE 154-2 Treatment Recommendations for Common Human Immunodeficiency Virus–Related Infections (*Continued*)

Organ System	Infection	Therapy
	Herpes zoster	Acyclovir, 800 milligrams PO five times a day for 7–10 d *or* Famciclovir, 500 milligrams PO three times a day for 7–10 d *or* Valacyclovir, 1 gram PO three times a day for 7–10 d *or* for ocular or disseminated disease Acyclovir, 5–10 milligrams/kg PO every 8 h for 5–7 d
	Candida or *Trichophyton* infection	Topical clotrimazole two or three times a day for 3 wk *or* Topical miconazole two or three times a day for 3 wk *or* Topical ketoconazole two or three times a day for 3 wk

Abbreviation: CMV = cytomegalovirus.

*Specific drug regimen must be adjusted if patient is receiving highly active antiretroviral therapy.

†Maintenance therapy required.

‡Maintenance therapy required; may be discontinued if CD4+ T-cell count is >150 cells/mm^3 for >16 wk.

#Maintenance therapy required until CD4+ T-cell count is >150 cells/mm^3.

Noninfectious causes of fever in HIV patients include neoplasm and drug fever. Non-Hodgkin's lymphoma is the most frequently occurring neoplasm and is characterized by high-grade, rapidly growing mass lesions. New CNS symptoms, particularly a change in mental status in the presence of fever, require neuroimaging. Definitive diagnosis requires biopsy. Radiotherapy and chemotherapy are effective treatment regimens. Drug fever may be secondary to injection drug abuse or adverse drug reactions (see below).

NEUROLOGIC COMPLICATIONS

Neurologic disease is caused by a variety of opportunistic infections and neoplasms and also by effects of HIV infection or treatment on the CNS. Common presenting symptoms include seizures, altered mental status, headache, meningismus, and focal neurologic deficits. The most common causes of neurologic symptoms include AIDS dementia, *Toxoplasma gondii* infection, and *C. neoformans* infection. Since the widespread use of antiretroviral therapy, rates of CNS infection and malignancy have declined, whereas the rate of AIDS dementia remains unchanged.

ED evaluation should include a complete neurologic examination and CT followed by lumbar puncture, especially when patients have CD4+ T-cell counts of <200 cells/mm^3. Fever, meningismus, altered mental status, and headache are independent predictors of space-occupying lesions. In patients with CD4+ T-cell counts of <200 cells/mm^3, isolated headaches that are protracted or have changed in quality, even in the absence of other neurologic findings, are best evaluated by prompt immediate neuroimaging.

Non–contrast-enhanced CT is the first neuroimaging study in the ED in HIV-infected patients with neurologic symptoms or deficits; if concerned about malignancy or abscess, or the CT scan findings are equivocal or negative, contrast-enhanced CT or MRI is next. Specific CSF studies of value include opening and closing pressures, cell count, glucose level, protein level, Gram staining, India ink staining, bacterial culture, viral culture, fungal culture, toxoplasmosis and cryptococcosis antigen assays, and coccidioidomycosis titer. If possible, save an extra tube (5 mL) of CSF for additional testing if the diagnosis remains unclear. Even if the ED evaluation is unrevealing, all patients with new or changed neurologic signs or symptoms are best admitted to the hospital.

HIV-ASSOCIATED DEMENTIA

HIV-associated dementia (also referred to as *HIV encephalopathy* or *subacute encephalitis*) is a progressive disorder heralded by subtle impairment of recent memory and other cognitive deficits. It occurs in 20% to 40% of HIV-positive patients.[17] In the early stages, HIV-associated dementia is often confused with depression, anxiety disorders, or substance abuse. Later phases of the illness are characterized by obvious changes in mental status or aphasia and motor abnormalities. Patients with an established diagnosis of HIV-associated dementia and progressive neurologic or psychological signs or symptoms warrant further evaluation for systemic or CNS processes. CT images in patients with HIV-associated dementia typically show cortical atrophy and ventricular enlargement. HIV-associated dementia is associated with elevated protein levels in the CSF in 50% to 70% of cases. Antiretroviral therapy is the most effective treatment for HIV-associated dementia.

TOXOPLASMOSIS

Toxoplasmosis is a common cause of focal encephalitis in patients with AIDS. It occurs most commonly in patients with CD4+ cell counts <100 cells/mm^3. Symptoms may include headache, fever, focal neurologic deficits, altered mental status, and seizures. Serologic tests are not useful in making or excluding the diagnosis because antibodies to *T. gondii* are prevalent in the general population. The presence of antibodies to *T. gondii* in the CSF is helpful, although there is a high rate of false-negative results. On unenhanced CT scan, toxoplasmosis typically appears as multiple subcortical lesions with a predilection for the basal ganglia. Contrast-enhanced CT scan typically shows multiple ring-enhancing lesions with surrounding areas of edema. MRI is more sensitive than contrast-enhanced CT scan in detecting toxoplasmosis. Other disorders in the differential diagnosis of ring-enhancing lesions on contrast-enhanced CT include lymphoma, fungal infection, and cerebral tuberculosis.

Patients with suspected toxoplasmosis are admitted and treated with a combination of IV pyrimethamine plus sulfadiazine plus leucovorin (folinic acid); trimethoprim-sulfamethoxazole is an alternative (Table 154-2). Steroids (dexamethasone 4 milligrams IV every 6 hours) are helpful when edema or a mass effect exists. For patients responsive to toxoplasmosis therapy, chronic suppressive therapy with pyrimethamine, sulfadiazine, and folinic acid is usually indicated. Oral sulfamethoxazole-trimethoprim, one double-strength tablet daily, is used as prophylaxis in patients with positive toxoplasmosis serologic test results and CD4+ T-cell counts of <100 cells/mm^3.

CRYPTOCOCCOSIS

Cryptococcal CNS infection produces either focal cerebral lesions or diffuse meningoencephalitis. Cryptococcal infection occurs most commonly

in patients with CD4+ counts of <50 cells/mm^3. The most common presenting signs are fever and headache, followed by nausea, altered mentation, and focal neurologic deficits. Presentation may be subtle, and meningismus is uncommon. Neuroimaging studies are usually normal or nondiagnostic.

Diagnosis of CNS cryptococcal infection in HIV patients relies on CSF cryptococcal antigen testing (nearly 100% sensitive and specific), culture (95% to 100% sensitive), or staining with India ink (60% to 80% sensitive). Serum cryptococcal antigen testing helps but has lower sensitivity than CSF testing (~95%). CSF analysis will typically show a pleocytosis with a predominance of lymphocytes. Elevated intracranial pressure is common; if >25 cm H_2O, remove 20 to 30 mL of CSF for therapy.

Patients with CNS cryptococcosis require hospital admission and IV amphotericin B and oral flucytosine for 14 days, followed by fluconazole for 8 weeks to clear the CSF (Table 154-2). Sixty percent of patients respond to therapy, and side effects are frequent, most notably bone marrow suppression. Long-term maintenance therapy with fluconazole (200 milligrams/d) follows initial treatment, although it may be stopped if immune reconstitution occurs.

OTHER NEUROLOGIC DISORDERS

Other less common considerations in the presence of neurologic symptoms include bacterial meningitis, histoplasmosis (usually disseminated), cytomegalovirus infection, progressive multifocal leukoencephalopathy, herpes simplex virus infection, neurosyphilis, and tuberculosis. Noninfectious CNS processes include CNS lymphoma (typically manifested as a subacute neurologic deterioration over several months with a single ring-enhancing lesion on CT), cerebrovascular accidents, and metabolic encephalopathies.

The most common disorder of the peripheral nervous system is HIV neuropathy, characterized by foot pain. Although HIV infection itself is the most common culprit, HIV therapies also are a possible cause, and changing treatment regimens may help. Cyclic antidepressants or membrane-stabilizing drugs may offer pain relief but are not often started in the ED and may cause delirium in patients with concurrent HIV dementia. Short-term opioid analgesia may be needed in severe cases.

OPHTHALMIC COMPLICATIONS

Seventy-five percent of patients with AIDS develop ocular complications, the most common being retinal microvasculopathy characterized by retinal cotton-wool spots identical in appearance to those seen in diabetes or hypertension. Retinal microaneurysms may be seen in the periphery. These lesions are incidental and do not cause visual disturbances. The diagnostic dilemma is to distinguish these findings from early cytomegalovirus infection; prompt ophthalmologic consultation is needed.

CYTOMEGALOVIRUS RETINITIS

Cytomegalovirus retinitis (Figure 154-1) is the most frequent and serious ocular opportunistic infection and is the leading cause of blindness in AIDS patients. In the antiretroviral therapy era, the incidence of cytomegalovirus infection is reduced, due in large part to immune reconstitution associated with the therapy.[18] Retinitis may be asymptomatic early on but later causes changes in visual acuity, visual field cuts, photophobia, and scotoma, and eye redness or eye pain may develop. Findings on indirect ophthalmoscopy are fluffy white perivascular lesions with areas of hemorrhage. First-line therapy is oral valganciclovir; this is often used before intravitreal ganciclovir, IV ganciclovir, IV foscarnet, or IV cidofovir due to its ease of administration, fewer complications, and less toxicity.[19] However, for patients with immediately sight-threatening lesions (lesions <1500 micrometers from the fovea or adjacent to the optic nerve head), intravitreal injection in conjunction with oral valganciclovir is best given promptly to avoid vision loss (Table 154-2). Frequent relapses and progression of disease are common, with 10% of affected patients ultimately going blind.

HERPES ZOSTER OPHTHALMICUS

Herpes zoster ophthalmicus (see chapter 241, "Eye Emergencies") usually presents with paresthesia and discomfort in the distribution of cranial nerve V_1 (ophthalmic branch), followed by the appearance of the typical zoster skin rash. Ocular complications include conjunctivitis, episcleritis, iritis, keratitis, secondary glaucoma, and, rarely, retinitis. Early recognition and treatment can prevent ocular damage.

PULMONARY COMPLICATIONS

The most common causes of pulmonary abnormalities in HIV-infected patients are community-acquired bacterial pneumonia, PCP, tuberculosis, cytomegalovirus infection, cryptococcosis, histoplasmosis, and neoplasms. **The most common cause of pneumonia in HIV-infected patients in the United States and Western Europe is *Streptococcus pneumoniae*.**[20] Pulmonary radiographic findings are helpful in determining likely causes (**Table 154-3**). Admit patients with new-onset or profound pulmonary symptoms, especially in the presence of hypoxemia or any change in sensorium. In patients with known existing pulmonary involvement, disposition and care decisions are based on change from baseline, the effectiveness of ongoing or previous treatment, ability to adhere to therapy, and the ability to obtain outpatient follow-up. The Pneumonia Severity Index and CURB scoring systems are powerful risk assessment tools but not designed for use in those with advanced HIV.

PNEUMOCYSTIS PNEUMONIA

PCP is the most common opportunistic infection among AIDS patients.[21] The causal agent is known as *P. jirovecii* (previously known as

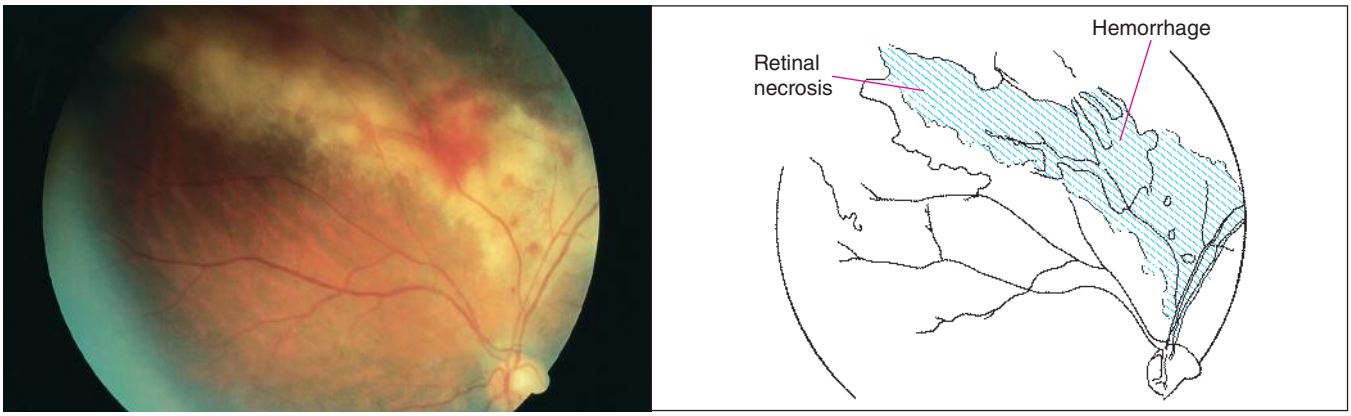

FIGURE 154-1. Cytomegalovirus retinitis. "Pizza pie" or "cheese and ketchup" appearance is demonstrated by hemorrhages and the dirty white granular-appearing retinal necrosis adjacent to major vessels. [Photograph contributed by Richard E. Wyszynski, MD. Reproduced with permission from Knoop KJ, Stack LB, Storrow AB, Thurman RJ: *The Atlas of Emergency Medicine*, 3rd ed, © 2009 by McGraw-Hill Inc., New York.]

TABLE 154-3 Chest Radiographic Abnormalities: Differential Diagnosis in the Patient with Acquired Immunodeficiency Syndrome

Finding	Causes
Diffuse interstitial infiltration	*Pneumocystis jiroveci* (*P. carinii*) infection
	Cytomegalovirus infection
	Mycobacterium tuberculosis infection
	Mycobacterium avium-intracellulare complex infection
	Histoplasmosis
	Coccidioidomycosis
	Lymphoid interstitial pneumonitis
Focal consolidation	Bacterial pneumonia
	Mycoplasma pneumoniae infection
	P. jiroveci infection
	M. tuberculosis infection
	M. avium-intracellulare complex infection
Nodular lesions	Kaposi's sarcoma
	M. tuberculosis infection
	M. avium-intracellulare complex infection
	Fungal lesions
	Toxoplasmosis
Cavitary lesions	*P. jiroveci* infection
	M. tuberculosis infection
	Bacterial infection
	Fungal infection
Adenopathy	Kaposi's sarcoma
	Lymphoma
	M. tuberculosis infection
	Cryptococcosis

P. carinii). Approximately 70% of HIV-infected patients acquire PCP at some time during their illness, and PCP is often the initial opportunistic infection that establishes the diagnosis of AIDS. This infection is the most frequent serious complication of HIV infection in the United States and the most common identifiable cause of death in patients with AIDS. The classic presenting symptoms of PCP are fever, cough (typically nonproductive), and shortness of breath (progressing from being present only with exertion to being present at rest).

Symptoms are often insidious and accompanied by fatigue. Chest radiographs most often show diffuse interstitial infiltrates (Table 154-3), but negative radiographic findings exist in 15% to 25% of patients with PCP.[22] The lactate dehydrogenase level is elevated in patients with PCP, but this test has low sensitivity and specificity, impairing utility. Arterial blood gas analysis usually demonstrates hypoxemia and an increase in the alveolar-arterial gradient. Suspect early PCP if a patient demonstrates a decrease in pulse oximetric values with exercise; even an ED "walk" can detect this exercise desaturation. **Presumptive diagnosis of PCP is often made in the ED if there is hypoxemia without any other explanation.** Inpatient diagnostics include bronchoscopy with specimen analyses.

Initial PCP therapy is trimethoprim-sulfamethoxazole (Table 154-2) PO or IV for 3 weeks (2 double-strength tablets three times daily). Adverse reactions, including rash, fever, and neutropenia, occur in up to 65% of AIDS patients. Pentamidine is an alternative agent (Table 154-2). Give steroids to patients with a partial pressure of arterial oxygen of <70 mm Hg or an alveolar-arterial gradient of >35 mm Hg, usually oral prednisone starting at 40 milligrams twice daily and tapering over 21 days (Table 154-2).

Seventy percent of patients have reinfection within 18 months; thus, prophylactic therapy is key. Oral trimethoprim-sulfamethoxazole, one double-strength tablet daily, is the preferred agent. Prophylaxis for all patients with CD4+ T-cell counts of <200 cells/mm^3 is another common approach to mitigate PCP. Repeat PCP infections are often less responsive to therapy.

TUBERCULOSIS

Approximately 10% of new cases of tuberculosis in the United States occur in HIV-infected persons, varying in regional prevalence based on specific population compositions and public health measures.[23] Clinical manifestations of tuberculosis in HIV-infected patients vary according to the severity of immunosuppression. **Tuberculosis frequently occurs in patients with CD4+ T-cell counts of 200 to 500 cells/mm^3.** Classic manifestations include cough with hemoptysis, night sweats, prolonged fevers, weight loss, and anorexia. With worsening immunosuppression, patient presentation may be more atypical (i.e., fewer of the classic symptoms described above). Classic upper lobe involvement and cavitary lesions are less common as patients become more immunosuppressed, particularly among patients with late-stage AIDS.[24] Negative purified protein derivative skin tuberculosis test results are frequent among AIDS patients due to immunosuppression. Definitive diagnosis of tuberculosis is made by stain and culture of expectorated sputum, although some cases require bronchoscopy. Later stage HIV is also associated with increased frequency of extrapulmonary tuberculosis with clinical manifestation associated with the involved sites of infection. Frequent sites of dissemination are peripheral lymph nodes, bone marrow, CNS, GI, and the urogenital system.

In the ED, think of tuberculosis in any HIV-infected patients with pulmonary symptoms, and begin precautions to avoid transmission. Place the patient in an isolation room and with an appropriate mask immediately and until the diagnosis is excluded, usually after the ED visit. Current treatment guidelines recommend a four-drug initial empirical therapy (Table 154-2; see chapter 67, "Tuberculosis").[19,25-27] Multidrug-resistant tuberculosis remains a concern, increasing the need for suspicion and early isolation. All HIV-infected patients with positive purified protein derivative skin tests should receive isoniazid plus pyridoxine for 9 to 12 months; alternatives include rifampin or rifabutin for 4 months. Also, give empiric treatment to HIV-infected persons in close contact with another patient with active tuberculosis.

BACTERIAL PNEUMONIA

Bacterial pneumonia is the most common pulmonary infection in HIV-infected patients. Common pathogens include *S. pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus aureus*. Productive cough, leukocytosis, and the presence of a focal infiltrate suggest bacterial pneumonia, especially in those with earlier-stage disease. The response to empirical therapy tends to be good; seek a specific pathogen by Gram staining and culture.

FUNGAL PNEUMONIA AND OTHER LUNG DISORDERS

Patients with severe immunosuppression are predisposed to **disseminated fungal infections** such as those caused by *C. neoformans* and *Aspergillus fumigatus*. Other noninfectious disorders of the lung seen in HIV-infected patients include neoplasms (e.g., Kaposi's sarcoma) and lymphocytic interstitial pneumonitis. Cytomegalovirus or *M. avium* complex infections are unlikely unless the CD4+ T-cell count drops to <50 cells/mm^3.

CARDIOVASCULAR COMPLICATIONS

Cardiovascular complications are common in late-stage disease but are difficult to diagnose in the ED. Cardiovascular complications may be related to opportunistic infections, structural defects, or drug toxicity. HIV-associated cardiovascular conditions include cardiomyopathy, infective endocarditis (in injection drug users; see chapter 155, "Endocarditis"), pericardial effusion, congestive heart failure, coronary artery disease, arrhythmias, and HIV-associated pulmonary hypertension. After standard ED evaluation, consultation with a cardiologist and infectious disease specialist is best.

GI COMPLICATIONS

GI complications of HIV infection are common. Approximately 50% of AIDS patients present with GI complaints at some time during their illness. The most frequent presenting symptoms include odynophagia,

FIGURE 154-2. Oral candidiasis (thrush). Extensive thrush is seen on the hard and soft palate of this immunocompromised patient. [Photograph contributed by Lawrence B. Stack. Reproduced with permission from Knoop KJ, Stack LB, Storrow AB, Thurman RJ: *The Atlas of Emergency Medicine*, 3rd ed, © 2009, McGraw-Hill Inc., New York.]

abdominal pain, bleeding, and diarrhea. ED evaluation seeks to identify the severity of symptoms and perform appropriate initial diagnostic studies. Therapy starts with volume and electrolyte repletion, with anti-infective therapy when appropriate. Disposition is based on the duration of symptoms, the clinical appearance of the patient, and the response to ED therapy.

ORAL AND ESOPHAGEAL COMPLICATIONS

Oral Candidiasis/Thrush Oral lesions are common in HIV-infected patients, frequently contributing to malnutrition. The appearance of oral lesions in HIV patients serves as a potential clinical marker for viral load and degree of immunodeficiency. Oral candidiasis ("thrush"; **Figure 154-2**) affects >80% of AIDS patients. The tongue and buccal mucosa are commonly involved, and the plaques are easily scraped from the erythematous base. Differentiation from hairy leukoplakia (adherent, white, thickened lesion[s] on the lateral tongue border) is challenging, but microscopic examination of a potassium hydroxide smear can confirm the fungal presence. The development of oral candidiasis is a poor prognostic sign and is predictive of progression to AIDS. Most oral lesions can be managed symptomatically on an outpatient basis. Clotrimazole or nystatin suspension or troches (five times daily) is the preferred treatment. Refractory or recurrent disease can be managed with oral fluconazole. Amphotericin B is reserved for severe cases.

Other Oral Lesions Other causes of painful oral and perioral lesions include oral hairy leukoplakia, herpes simplex virus infection, and Kaposi's sarcoma. Herpes simplex virus infection usually can be recognized by the presence of typical vesicular lesions, with diagnosis confirmed by identification of multinucleated giant cells in scrapings or by culture. Both herpes simplex virus infection and hairy leukoplakia are responsive to oral acyclovir. Oral Kaposi's sarcoma appears as a nontender, well-circumscribed, slightly raised violaceous lesion. Diagnosis requires biopsy, and topical treatments are palliative and started outside the ED.

ESOPHAGEAL LESIONS

Esophageal involvement may occur with *Candida*, herpes simplex virus, and cytomegalovirus infection. Complaints of odynophagia or dysphagia are indicative of esophagitis, and these symptoms may be debilitating. Disease typically occurs in patients who have oral thrush and CD4+ T-cell counts of <100 cells/mm^3. Treatment of esophagitis in the ED is presumptive with oral fluconazole (Table 154-2) or oral ketoconazole (200 to 400 milligrams/d for 2 to 3 weeks). IV caspofungin or IV amphotericin B may be used when oral treatment fails. Endoscopy, histologic staining and culture of lesions, and biopsy are reserved for patients who fail to respond to therapy or have atypical presentations. Cytomegalovirus and herpes simplex virus infections discovered by endoscopy are treated with ganciclovir and acyclovir, respectively.

DIARRHEA

Diarrhea is the most frequent GI complaint of those with HIV-related co-infections. Causes include bacteria (*Shigella*, *Salmonella*, enteroadherent *Escherichia coli*, *Entamoeba histolytica*, *Campylobacter*, *M. avium-intracellulare* complex, *Clostridium difficile*, and others), parasites (*Giardia lamblia*, *Cryptosporidium*, *Isospora belli*, and others), viruses (cytomegalovirus, herpes simplex virus, HIV, and others), and fungi (*H. capsulatum*, *C. neoformans*, and others). In many cases, a pathogen is never found. Diarrhea is a side effect of protease inhibitors, most notably nelfinavir and ritonavir.

In the ED, look for stool leukocytes, ova, and parasites; in recalcitrant or severe cases, obtain acid-fast staining and bacterial cultures of stool. Bacterial infections generally follow a more acute and fulminant course, whereas parasitic infections are frequently indolent. If bacterial infection is suspected, treat empirically with ciprofloxacin to cover the common pathogens. *Cryptosporidium* and *Isospora* infections are common parasitic causes and are associated with profuse watery diarrhea. Both organisms can be identified by modified acid-fast staining of a stool specimen. *I. belli* infection is usually responsive to trimethoprim-sulfamethoxazole, but relapse is common. Cryptosporidiosis is difficult to treat, usually starting with an antiretroviral therapy coupled with supportive care, including rehydration and electrolyte repletion. Antimicrobial treatment is not beneficial. Consult with an infectious disease specialist to create a long-term management plan.

In patients with end-stage disease, the most common diarrheal pathogens are cytomegalovirus and *M. avium-intracellulare* complex, each requiring biopsy for diagnosis. Prolonged antimicrobial therapy is indicated, and relapse is frequent for both infections. About 15% of patients with late-stage AIDS experience severe, high-volume watery diarrhea absent a clear pathogen, with the presumed diagnosis of AIDS-related enteropathy. Octreotide may aid some of these patients.

ED management consists of repletion of fluid and electrolytes. Patients who appear nontoxic and can tolerate liquids can be referred for outpatient follow-up to obtain test results. Patients with severe diarrhea who do not require antibiotics may benefit from symptomatic therapy, such as attapulgite (Kaopectate), psyllium (Metamucil), or diphenoxylate hydrochloride with atropine (Lomotil).

OTHER GI COMPLICATIONS

Hepatomegaly occurs in approximately 50% of AIDS patients, often with an elevated alkaline phosphatase level but rarely with jaundice. Co-infection with hepatitis B virus and hepatitis C virus is common, especially among injection drug users. Opportunistic infection with cytomegalovirus, *Cryptosporidium*, *M. avium-intracellulare* complex, and *M. tuberculosis* also may cause hepatitis.

Anorectal disease is common in AIDS patients. **Proctitis** presents with painful defecation, rectal discharge, or tenesmus. Common causative organisms include *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Treponema pallidum*, and herpes simplex virus. Proctocolitis includes the same symptoms plus diarrhea, and multiple bacterial organisms may be responsible (most commonly *Shigella*, *Campylobacter*, and *E. histolytica*). Evaluation includes anoscopy with microscopic examination, Gram staining, and culture of pus and/or stool.

RENAL COMPLICATIONS

Renal insufficiency among AIDS patients may be secondary to prerenal azotemia, drug nephrotoxicity, or HIV-associated nephropathy. Renal tubular acidosis is common and explains a finding of hyperchloremic metabolic acidosis. Indinavir therapy is a common cause of nephrolithiasis.

CUTANEOUS COMPLICATIONS

Cutaneous complications occur in approximately 90% of HIV-infected individuals. Generalized cutaneous conditions, such as xerosis (dry skin), seborrheic eczema, and pruritus, are common and may develop before opportunistic infections. Treatment is with emollients and, if necessary, mild topical steroids. Pruritus may respond to oatmeal baths and antihistamines.

CUTANEOUS INFECTIONS

Skin and soft tissue infections occur commonly in the HIV-infected population, including *S. aureus* infection (manifested as bullous impetigo, ecthyma, or folliculitis), *Pseudomonas aeruginosa* infection (which may present with chronic ulcerations and macerations), and syphilis, all treated with standard therapies. Methicillin-resistant *S. aureus* colonization and infection are more prevalent and are associated with low CD4+ cell counts, men who have sex with men, anal intercourse, previous methicillin-resistant *S. aureus* infections, and illicit drug use.[28,29] Human Papillomavirus (HPV) infections manifesting as condyloma acuminata or warts are common; treatment is cosmetic or symptomatic and includes cryotherapy, topical therapy, or laser therapy. Intertriginous infections with *Candida* or *Trichophyton* are frequent in HIV-positive patients; microscopic examination of potassium hydroxide preparations of lesion scrapings aids diagnosis. Treatment is with topical clotrimazole, miconazole, or ketoconazole.

Pruritus is common and related to xerosis, eczema, drug reaction, scabies folliculitis, psoriasis, seborrheic dermatitis, or numerous other cutaneous conditions. ED evaluation includes history, physical examination, removal of offending agents, and treatment of the underlying condition. If no specific diagnosis is found, symptomatic treatment with emollients and antipruritic agents can be effective.[30]

HERPES SIMPLEX VIRUS

Herpes simplex virus infections are common and either localized or systemic. In patients with immunosuppression, infection may become progressive and chronic (see chapter 149, "Sexually Transmitted Infections"). IV acyclovir is the therapy for extensive disease (Table 154-2).

VARICELLA-ZOSTER VIRUS INFECTION

Reactivation of **varicella-zoster virus** is more common in patients with HIV infection and AIDS than in the general population. The clinical course is prolonged, and complications are more frequent. In HIV-positive patients, oral acyclovir, famciclovir, and valacyclovir are options for treatment (Table 154-2). In patients with disseminated disease or ophthalmic herpes zoster, use IV acyclovir.

SCABIES

Scabies occurs in about 20% of HIV-infected patients, but classic intertriginous lesions are less common. Treat any with a scaly, persistent pruritic eruption with permethrin 5% cream, ivermectin, or crotamiton. **Norwegian scabies** occurs in immunosuppressed patients, presenting with extensive hyperkeratosis and crusting of the hands, feet, and scalp. Pruritus is less impressive than is seen in typical scabies. Treatment failures and secondary infection also are common.

KAPOSI'S SARCOMA

Kaposi's sarcoma appears more often in homosexual men than in other risk groups. Clinically, it consists of painless, raised, brown-black or purple papules and nodules that do not blanch. Common sites are the face, chest, genitals, and oral cavity, but widespread dissemination involving internal organs may occur. Treat extensive, painful, or cosmetically disfiguring lesions. Cryotherapy or radiation can be used for localized disease; widespread disease may be responsive to chemotherapy with vincristine, vinblastine, or doxorubicin.

PSYCHIATRIC DISORDERS

HIV infection has a variety of CNS and metabolic disturbances that can produce psychiatric symptoms. HIV infection is also a psychosocial stressor, leading to social isolation, poverty, and hopelessness. In the ED, search for underlying organic causes; delirium suggests an organic disorder or a withdrawal syndrome. Patients with AIDS psychosis develop hallucinations, delusions, or other behavioral changes. Treat as for any psychosis.

Depression occurs in up to 81% of patients.[31] Antidepressant therapy is often started if symptoms of depression continue for >2 weeks and with close monitoring for side effects. Patients with suicidal ideation or profound dysfunction usually require inpatient psychiatric management.

An increased incidence of mania is observed in both the early and late stages of HIV infection. Late-stage mania is closely associated with dementia and carries a poor prognosis. If danger exists, use physical restraints or acute pharmacologic intervention. Neuroleptics and benzodiazepines may be used in combination.

Nearly 50% of those with HIV infection have a history of substance abuse.[32,33] Depression and psychotic symptoms are more prevalent among patients with substance abuse. ED management includes identification and outpatient referral to integrated substance abuse and psychiatric resources.

SEXUALLY TRANSMITTED INFECTIONS

Sexually transmitted infections, HIV, and viral hepatitis share common routes of transmission and may coexist.[34-36] Genital ulcers caused by diseases such as herpes, chancroid, and syphilis are portals of entry for HIV. There is more frequent HIV seropositivity in patients with genital ulcers, gonorrhea, and chlamydial infections. The prevalence of sexually transmitted infections, including syphilis, is increasing and warrants enhanced surveillance.[37] Therapy for sexually transmitted infections is based on current Centers for Disease Control and Prevention guidelines (see chapter 149).

IMMUNIZATION OF HIV-INFECTED PATIENTS

HIV-infected persons should not receive live virus or live bacteria vaccines.[38] The exception to this rule is the measles-mumps-rubella vaccine, which does not have adverse effects in this population.

Killed vaccines pose no danger to immunosuppressed patients.[39] Because symptomatic HIV-infected persons have a suboptimal response to vaccines, all single-dose vaccines are best given as early as possible in the course of HIV infection. **Table 154-4** summarizes the Centers for Disease Control and Prevention recommendations for common immunizations.

ANTIRETROVIRAL THERAPY

After the introduction of antiretroviral therapy, sharp declines in AIDS incidence and mortality occurred,[40] transforming HIV therapeutics into long-term management of a chronic infection. General therapeutic goals include: (1) prolonging and improving the quality of life; (2) reducing

TABLE 154-4 Immunization Recommendations for Adult Human Immunodeficiency Virus–Infected Patients[39]

Vaccine	Adult Recommendation
Tetanus, diphtheria, and pertussis (Tdap)	One booster in adulthood
Tetanus-diphtheria toxoid (Td)	Every 10 years
Measles-mumps-rubella	Avoid in patients with CD4+ T-cell count <200 cells/mm^3
Pneumococcal	One dose
Influenza (inactivated)	One dose annually
Hepatitis B	Three doses over a 2-y period
Varicella	Avoid in patients with CD4+ T-cell count <200 cells/mm^3

viral load as much as possible to halt disease progression and prevent or reduce the development of resistant variants; (3) promoting immune reconstitution, both quantitative (CD4+ T-cell count) and qualitative (pathogen-specific immune response); and (4) reducing side effects and maintaining therapeutic options. A complete drug list and up-to-date guide for the general classes of antiretroviral drugs, principles for initiating therapy, and common adverse reactions can be found on the Centers for Disease Control and Prevention Web site (http://www.cdc.gov/hiv/pubs/mmwr.htm).

The five main classes of antiretroviral drugs are (1) nucleoside reverse transcriptase inhibitors, which interfere with the action of reverse transcriptase (e.g., zidovudine); (2) nonnucleoside reverse transcriptase inhibitors, which bind to reverse transcriptase and block RNA- and DNA-dependent DNA polymerase activity (e.g., efavirenz); (3) protease inhibitors, which block HIV protease, a key enzyme in establishing HIV infectivity (e.g., indinavir); (4) entry inhibitors, which prevent HIV entry into cells by targeting specific viral surface proteins or their corresponding receptors (e.g., enfuvirtide); and (5) integrase inhibitors, which work by blocking integrase, a protein that HIV needs to insert its viral genetic material into the genetic material of an infected cell (e.g., raltegravir).

Preferred initial treatment regimens include at least three drugs—two nucleoside reverse transcriptase inhibitors *plus* one of the following classes: nonnucleoside reverse transcriptase inhibitor, protease inhibitor (boosted with ritonavir), or integrase strand transfer inhibitor. Currently, all HIV-infected patients with CD4+ cell counts of <350 cells/mm^3 or with a history of AIDS-defining illness receive therapy.[41] Other indications for initiation of antiretroviral therapy regardless of CD4+ count include pregnancy, HIV-associated nephropathy, and hepatitis B virus co-infection requiring treatment.[41] Education and counseling also constitute an integral part of antiretroviral therapy. Decisions regarding initiation of and changes in antiretroviral therapy should be made in consultation with the primary care physician and an infectious disease consultant.

TABLE 154-5 Antiretroviral Medications, Major Adverse Effects, and Interacting Drug Effects[42]

Antiretroviral Medications	Adverse Effects	Interacting Drugs	Effects of Interaction
Nucleoside reverse transcriptase inhibitors			
Abacavir	Stevens-Johnson syndrome, hypersensitivity reaction (fever, rash, myalgia)		
Didanosine	Peripheral neuropathy, lactic acidosis, pancreatitis		
Emtricitabine	Skin hyperpigmentation/discoloration, hepatic steatosis (rare), lactic acidosis		
Lamivudine	Lactic acidosis/hepatic steatosis (rare)		
Stavudine	Pancreatitis, lactic acidosis, peripheral neuropathy, ascending muscle weakness, dyslipidemia		
Tenofovir	Pancreatitis, headache, renal failure, diarrhea, nausea, vomiting		
Zidovudine	Bone marrow suppression		
Nonnucleoside reverse transcriptase inhibitors		Anticonvulsants, rifampin	Decreased concentration of antiretrovirals and increased concentration of anticonvulsants
Delavirdine	Transaminitis rash (blisters), headache		
Efavirenz	Depression, psychosis, suicidal ideation		
Nevirapine	Stevens-Johnson syndrome, hepatic failure		
Protease inhibitors		Antiarrhythmics, anticonvulsants, midazolam, metoprolol, rifampin, warfarin, HMG-CoA reductase inhibitors	Decreased concentration of antiretroviral and increased concentration of the interacting drug; increased risk of rhabdomyolysis with HMG-CoA reductase inhibitors
Amprenavir	Toxicity from propylene glycol diluent		
Atazanavir	Increased indirect bilirubin, prolonged PR interval	Proton pump inhibitors	Decreased absorption of atazanavir; concomitant use contraindicated
		Diltiazem	Increased concentration of diltiazem (decrease diltiazem dose by half)
Darunavir	Headache, nausea, diarrhea, rash		
Fosamprenavir	Hyperlipidemia, rash		
Indinavir	Urolithiasis, nephrotoxicity, indirect hyperbilirubinemia		
Nelfinavir	Secretory diarrhea		
Ritonavir	Hyperlipidemia, nausea, vomiting, hyperglycemia	Digoxin	Increased digoxin concentration (monitor levels)
Saquinavir	Hyperglycemia lipodystrophy		
Tipranavir	Intracerebral hemorrhage, hepatotoxicity		
Entry and fusion inhibitors			
Enfuvirtide	Pneumonia, injection site reaction		
Maraviroc	Abdominal pain, postural hypotension		
Integrase inhibitors			
Raltegravir	Increased creatine phosphokinase, nausea, headache		

Abbreviation: HMG-CoA = 3-hydroxy-3-methylglutaryl-coenzyme A.

DRUG INTERACTIONS AND ADVERSE EFFECTS IN HIV-INFECTED PATIENTS

Current antiretroviral therapy programs include a standard three-drug regimen that may cause a range of changes in metabolic or physiologic functions and be toxic. **Table 154-5** shows the currently available antiretroviral medications, their major adverse effects, and their interacting drug effects. These reactions may be compounded by the effects of antibiotic prophylaxis being taken to fight against opportunistic infections.

Drug interactions are pharmacokinetic (changes in the level of one or more drugs) or pharmacodynamic (changes in effect, therapeutic response, or side effect of one or more drugs).[41] Review of current reference sources and consultation with a hospital pharmacologist and an infectious disease specialist are indicated when drug reactions are suspected.

CHAPTER 155

Endocarditis

Richard Rothman
Catherine A. Marco
Samuel Yang

INTRODUCTION AND EPIDEMIOLOGY

The clinical presentation of endocarditis is often nonspecific and variable, with potential to affect nearly every organ system in an indolent or fulminant course. The vast majority of endocarditis is infective; diagnosis relies on a set of explicit criteria, which include findings from blood culture, echocardiography, and close clinical observation. Unrecognized infective endocarditis has frequent complications and high mortality.

In developed countries, the incidence of infective endocarditis ranges from 2 to 11.6 cases per 100,000 patient-years[1-7] and is higher in urban versus rural settings, likely reflecting the impact of injection drug use. The disease is uncommon among children, where it is associated with structural congenital heart disease, rheumatic heart disease, or nosocomial, catheter-related bacteremia. The disorder affects men more commonly than women, and the hospital mortality rate is up to 18%, varying according to the microorganism involved and presence of complications.[1,2]

Most cases occur either in those with a predisposing identifiable cardiac structural abnormality (congenital or acquired), prosthetic valve, or a recognized risk factor for disease (including injection drug use, intravascular devices, poor dental hygiene, chronic hemodialysis, or infection with the human immunodeficiency virus). The mitral valve is the most commonly affected site, followed in decreasing frequency by the aortic, tricuspid, and pulmonic valves.

For native valve–related infective endocarditis in the developed world, **mitral valve prolapse** is a common predisposing cardiac lesion. Other underlying structural defects include congenital defects (most commonly bicuspid aortic valve), degenerative cardiac lesions (particularly calcific aortic stenosis), and rheumatic heart disease. In developing countries, **rheumatic heart disease** creating valvulopathy remains the leading underlying risk factor. For native valve–related lesions, left-sided disease predominates, and mortality ranges from 16% to 27%. Short-term mortality increases in those with left-sided native valve endocarditis when accompanied by other severe comorbid illnesses, abnormal mental status, congestive heart failure, or a bacterial etiology other than *Streptococcus viridans* and *Staphylococcus aureus*, and when treated with medical therapy absent valve surgery.[8]

The estimated risk in **injection drug users** is 2% to 5% per year, with a mean age of diagnosis being 30 years old. When endocarditis occurs in injection drug users, it has a predilection for the tricuspid valve. Other features include increased susceptibility to recurrence (approximately 40%) and increased mortality in those with concurrent human immunodeficiency virus and evidence of immunosuppression (defined as a CD4+ T-cell count of <200/mm^3). Large vegetation size and fungal organism are predictive of poor outcome in injection drug use–associated right-sided endocarditis.[9]

Indwelling vascular devices create greater risks that microorganisms will attach to valves during bacteremia. Healthcare-associated endocarditis occurs when (1) a diagnosis is made >72 hours after admission in patients with no evidence of endocarditis on admission or in whom the disorder develops within 6 months after hospital discharge; or (2) cardiovascular manipulations have occurred in the ambulatory setting within 6 months before endocarditis develops, including central venous catheter use, arteriovenous fistula for hemodialysis, invasive intravascular techniques, or intracardiac devices (e.g., prosthetic valves, pacemaker, left ventricular assist device).[10,11]

Prosthetic valve endocarditis occurs in 1% to 4% of recipients during the first year following valve replacement and in approximately 1% per year thereafter. There is no difference in risk between mechanical versus bioprosthetic valves. Cases with onset within 60 days after surgery are called *early* prosthetic valve endocarditis and are usually acquired in the hospital. Cases starting beyond 60 days after surgery are called *late* prosthetic valve endocarditis and are usually community acquired. Hospital mortality rates are highest for those with early (30% to 80%) versus late (20% to 40%) prosthetic valve endocarditis, attributable to the greater virulence of the causative organisms involved.

PATHOPHYSIOLOGY

The normal endothelium is resistant to infection and thrombus formation unless it is injured by high-pressure gradients and turbulent flow states. Such abnormal hemodynamic states occur commonly in those with preexisting valvular or congenital cardiac defects. In injection drug use, endothelial damage likely occurs by a different mechanism, such as from repetitive bombardment with particulate matter (i.e., talc) present in injected material or from ischemia brought on by vasospasm from the injected drug. Cocaine use is particularly associated with increased rates of endocarditis. The resultant endothelial damage promotes deposition of platelets and fibrin and the formation of sterile vegetations (nonbacterial thrombotic endocarditis).

Nonbacterial thrombotic endocarditis can also arise as a result of hypercoagulable states, such as in patients with malignancy (marantic endocarditis) or systemic lupus erythematosus (Libman-Sacks endocarditis), and in areas surrounding foreign bodies like vascular catheters or prosthetic valves. In the setting of preexistent nonbacterial thrombotic endocarditis, transient bacteremia may result in colonization of vegetations and conversion to infective endocarditis.

Transient bacteremia can occur from trauma to the skin or mucosal surfaces of the oropharynx or GI or GU tracts (all of which are normally laden with endogenous flora). Even in the absence of trauma, spontaneous bacteremia can occur in patients with periodontal disease or other localized infections. In cases of bacteremia, the bacterial load usually does not exceed 10 organisms per milliliter of blood, and the bloodstream is usually sterilized in <30 minutes. In the presence of nonbacterial thrombotic endocarditis, this time interval is sufficient for bacteria to adhere to the vegetation and transform it into an infected lesion.

The coexistence of bacteremia and nonbacterial thrombotic endocarditis does not uniformly result in infective endocarditis. To cause infective endocarditis, the infecting organism must be able to adhere to the nonbacterial thrombus on the endothelium. Different organisms vary in this ability. Furthermore, although nonbacterial thrombotic endocarditis is often present in those who develop infective endocarditis, it not an absolute prerequisite, and highly invasive organisms (e.g., *S. aureus*) can directly invade the endocardium. Adherent organisms stimulate further deposition of platelets and fibrin, leading to sequestration of organisms into a "protected site" that phagocytic cells cannot easily penetrate. As the disease progresses, the vegetation continuously fragments, shedding surface organisms into the circulation and causing sustained bacteremia.

TABLE 155-1 Microbiology of Infective Endocarditis (IE)

Native Valve IE (% of cases)			Intracardiac Device IE (% cases)		
	Nonaddict	IV Drug Addict		Prosthetic Valve IE	Other Devices*
Staphylococcus aureus	28	68	*S. aureus*	23	35
Coagulase-negative *Staphylococcus*	9	3	Coagulase-negative *Staphylococcus*	17	26
Viridans group streptococci	21	10	*Viridans* group streptococci	12	8
Other streptococci	14	3	*Streptococcus bovis*	10	7

Abbreviation: HACEK = *Haemophilus, Actinobacillus, Cardiobacterium, Eikenella,* and *Kingella group*.

*Including pacemakers and implantable cardioverter-defibrillators.

MICROBIOLOGY

A wide range of bacteria and fungi, as well as *Rickettsia* and *Chlamydophila* species, can cause infective endocarditis. Bacteria are the predominant cause overall, with a small number of species responsible for the majority of cases. Causative microorganisms vary based on the specific conditions (i.e., native vs prosthetic valve) and risk factors (injection drug use or intracardiac devices; **Table 155-1**). Overall, recent reports from the United States and European countries indicate that *Staphylococcus* is the single most common cause, followed by streptococci and enterococci.[1,3,12-14]

The increase in the number of cases caused by staphylococci is likely linked to the observed increase in healthcare-associated endocarditis and also more frequent intravenous drug use. Staphylococcal endocarditis can cause rapid destruction of valves, multiple distal abscesses, myocardial abscesses, conduction defects, and pericarditis. Staphylococcal endocarditis has an increased risk of in-hospital death.[1] In contrast, streptococcal endocarditis tends to be indolent. Patients with enterococcal endocarditis generally have underlying valvular disease and risk factors such as diabetes mellitus or manipulation of the GU or lower GI tract.

Blood cultures are the best initial method for detection but are negative in about 5% of patients; in one third to one half of patients, cultures are negative because of prior antibiotic administration. For those cases associated with negative blood cultures and without prior antibiotic administration, infection is due to fastidious organisms, such as the **HACEK group (*Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, and *Kingella*), *Bartonella* species, or *Coxiella burnetii*.**

Skin flora and contaminated injection devices are the most frequent sources of microorganisms in injection drug use–associated endocarditis. *S. aureus* accounts for >50% of cases, followed in decreasing frequency by streptococcal species (including enterococci) and coagulase-negative staphylococci. The well-established predilection for *S. aureus* to infect normal heart valves, particularly tricuspid valves, is seen in injection addicts, although streptococci and enterococci often infect abnormal mitral or aortic valves in these patients.

Microorganisms involved in prosthetic valve endocarditis often reflect contamination during the perioperative period, with *Staphylococcus epidermidis* being a commonly isolated organism. *Aspergillus* and *Candida albicans* account for the majority of cases of mycotic prosthetic valve endocarditis and often have large vegetations and emboli.

CLINICAL FEATURES

The clinical manifestations of endocarditis are on a continuum, from acute in onset to insidious and indolent.[12] Common presenting symptoms include fever, chills, weakness, and dyspnea. The most common complications are congestive heart failure (44%), CNS disorder (30%), and peripheral embolization (22%).[14]

FEVER

Early bacteremia produces nonspecific signs and symptoms (**Table 155-2**), usually beginning within 2 weeks of infection. Symptoms include fever, chills, nausea, vomiting, fatigue, and malaise.[15] Fever (>38°C [100.4°F]) is present in almost all patients (>90% overall and >98% in those with injection drug use–associated infective endocarditis).[5,11,12,13] Fever may be absent in the elderly, those with a history of antibiotic or antipyretic use, and those with congestive heart failure, renal failure, or immunosuppression. Clinical symptoms of sepsis may be present.

CARDIAC MANIFESTATIONS

Congestive heart failure occurs in up to 70% of patients from distortion or perforation of valvular leaflets, rupture of the chordae tendineae or papillary muscles, or perforation of cardiac chambers. Heart murmurs are common, heard in 50% to 85% of patients, although less so in cases of right-sided endocarditis (<50%). Valvular abscesses and pericarditis can result from local extension. Other cardiac complications include heart blocks and dysrhythmias that result from extension of infection through the interventricular septum to the conduction system.

NEUROLOGIC MANIFESTATIONS

About 20% to 40% of patients develop neurologic symptoms, notably cerebral ischemic events (often in multiple areas), CNS abscess, intracranial hemorrhage, mycotic aneurysm, meningitis, or seizures.[16] Embolic stroke involving the middle cerebral artery is the most common CNS complication.[15]

ARTERIAL EMBOLIZATION

Friable vegetation fragments can embolize to any artery, resulting in infarction or abscess in remote tissues; finding multiple brain or lung abscesses should trigger a search for endocarditis. Pulmonary complications include pulmonary infarction, pneumonia, empyema, or pleural effusion. Coronary artery emboli usually arise from the aortic valve and

TABLE 155-2 Clinical Features of Infective Endocarditis

Symptoms	%	Signs	%
Fever	80	Fever	90
Chills	40	Heart murmur	85
Weakness	40	New murmur	3–5
Dyspnea	40	Changing murmur	5–10
Anorexia	25	Skin manifestations	18–50
Cough	25	Osler nodes	10–23
Malaise	25	Splinter hemorrhages	15
Skin lesions	20	Petechiae	20–40
Nausea/vomiting	20	Janeway lesions	<10
Headache	20	Splenomegaly	20–57
Stroke	20	Embolic phenomena	>50
Chest pain	15	Septic complications	20
Abdominal pain	15	Mycotic aneurysm	20
Mental status change	10–15	Renal failure	10
Back pain	10	Retinal lesions	2–10

may cause acute myocardial infarction or myocarditis. Embolic splenic infarction causes left upper quadrant abdominal pain with radiation to the left shoulder. Renal emboli result in flank pain and hematuria. Emboli to the mesenteric arteries cause acute abdominal pain and guaiac-positive stool and can lead to bowel ischemia, whereas emboli to arteries of the extremities may produce acute limb ischemia. Rupture of a cerebral mycotic aneurysm results in subarachnoid hemorrhage. Retinal artery embolism may cause acute monocular blindness.

CUTANEOUS FINDINGS

Cutaneous embolic phenomena are less common due to early clinical presentation and treatment. Cutaneous findings may occur in 5% to 10% of cases and may include petechiae, splinter or subungual hemorrhages of the finger or toenails, Osler nodes (small, tender subcutaneous nodules on the pads of the fingers or toes), and Janeway lesions (small hemorrhagic painless plaques on the palms or soles).[17,18] Digital clubbing is infrequent and found only in those with long-standing disease. Cutaneous signs are not specific and may be seen in other disease states characterized by vasculitis or bacteremia.

ADMISSION

Suspicion of endocarditis usually requires hospital admission[19,20] to allow the key diagnostic steps to occur (culture, echocardiography, and clinical observation).[1] Although prediction rules to exclude infective endocarditis exist,[21] none are currently robust enough to permit use in clinical practice. Consider endocarditis in patients with unexplained fever and with risk factors for the disease. Because the prevalence of endocarditis among febrile injection drug users is high (10% to 15%), clinical findings cannot reliably exclude the diagnosis, and follow-up is often a challenge, patients should be admitted to evaluate for bacteremia and endocarditis. Prolonged unexplained fever, malaise, or other constitutional symptoms without another cause are symptoms concerning for endocarditis. Admit all patients with a cardiac prosthetic valve and fever (or persistent malaise, vasculitis, or new murmur) because of the increased risk for endocarditis and the high morbidity and mortality associated with prosthetic valve infections. Look for any new or changed murmur, and seek evidence of vasculitis or embolization. In stable patients for whom there is a low suspicion of endocarditis who were initially discharged, admit immediately once positive blood cultures are found.

DIAGNOSTIC CRITERIA

The **Duke criteria**[22,23] are widely used criteria for diagnosing infective endocarditis (**Tables 155-3 and 155-4**).

TABLE 155-3 Duke Criteria* for Infective Endocarditis

Major Criteria
Positive blood culture for IE
Typical microorganism consistent with IE from two separate blood cultures* as noted below:
Streptococcus bovis, viridans streptococci, HACEK group
or
Community-acquired *Staphylococcus aureus* or *enterococci* in the absence of a primary focus
or
Microorganisms consistent with IE from persistently positive blood cultures defined as:
At least two positive cultures of blood samples drawn >12 h apart
or
All of three or a majority of four or more separate blood cultures (with first and last sample drawn at least 1 h apart)
Single positive blood culture for *Coxiella burnetii* or antiphase I immunoglobulin G antibody titer of >1:800
Evidence of echocardiographic involvement
Positive ECG for IE defined as:
Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation
or
Abscess
or
New partial dehiscence of prosthetic valve
New valvular regurgitation (worsening or changing of preexisting murmur not sufficient)
Minor Criteria
Predisposition: predisposing heart condition or injection drug use
Fever: temperature >38°C (100.4°F)
Vascular phenomena: major arterial emboli, septic pulmonary conjunctival hemorrhages, and Janeway lesions
Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, and rheumatoid fever
Microbiologic evidence: positive blood culture but does not meet a major criterion as noted in Table 155-4* or serologic evidence of active infection with organism consistent with IE
Echocardiographic minor findings were eliminated in the modified Duke criteria

Abbreviations: HACEK = *Haemophilus, Actinobacillus, Cardiobacterium, Eikenella, and Kingella;* IE = infective endocarditis.

*Excludes single positive cultures for coagulase-negative staphylococci and organisms that do not cause IE.

BLOOD CULTURES

Obtain blood cultures in the ED before beginning antibiotics, drawing three sets from separate sites because fewer collections may not detect bacteremia. Obtain at least 10 mL of blood for each culture bottle. Additional sets of blood cultures may be needed in patients already receiving antibiotics. Ideally, wait at least 1 hour between the first and last blood culture. In patients who are in septic shock or with systemic complications, do not withhold antibiotics to obtain delayed sets of cultures.

For patients who are at risk for culture-negative infective endocarditis, advise the laboratory of the suspected diagnosis to allow initiation of specialized testing to recover fastidious organisms. Polymerase chain reaction techniques aid pathogen detection.

OTHER DIAGNOSTIC TESTS

There are no definitive laboratory tests that diagnose endocarditis in the ED. Common findings are anemia (70% to 90% of cases), hematuria, and elevated erythrocyte sedimentation rate (>90% of cases), C-reactive protein, and procalcitonin.

ECG findings are also nonspecific but can identify conduction abnormalities resulting from infection. Prolonged PR interval, new left bundle-branch block, or new right bundle-branch block with left anterior hemiblock suggests spread of infection from the aortic valve into the conduction system. Junctional tachycardia, Wenckebach block, or complete heart block may indicate likely extension of infection from the mitral annulus into the atrioventricular node or proximal bundle of His.

Chest radiographs may demonstrate other complications, such as pulmonic emboli in patients with right-sided valvular involvement or congestive heart failure in those with left-sided valvular involvement.

ECHOCARDIOGRAPHY

Obtain echocardiography as soon as possible, because (1) echocardiographic abnormalities represent one of the two major criteria required for definitive diagnosis of endocarditis and (2) evaluation of the cardiac valves and surrounding structures provides critical information for management decisions. Bedside ED echocardiography is one tool, in addition to formal inpatient testing.

Two-dimensional transthoracic echocardiography is the first choice for those with native valves. The specificity of transthoracic echocardiography for vegetations is excellent (98%), but sensitivity varies

TABLE 155-4 Modified Duke Criteria for Infective Endocarditis

Definite Infective Endocarditis
Pathologic criteria
Microorganisms demonstrated by culture or histologic examination of a vegetation or in a vegetation that has embolized, or in an intracardiac abscess
or
Pathologic lesions: vegetation or intracardiac abscess present, confirmed by histology showing active endocarditis
Clinical Criteria, Using Specific Definitions Listed in Table 155-3
Two major criteria
or
One major and three minor criteria
or
Five minor criteria
Possible infective endocarditis
One major criterion and one minor criterion
Three minor criteria
Rejected
Firm alternate diagnosis for manifestations of endocarditis
or
Resolution of manifestations of endocarditis with antibiotic therapy for 4 d or less
or
No pathologic evidence of infective endocarditis at surgery or autopsy after antibiotic therapy for 4 d
Does not meet criteria for possible infective endocarditis

according to patient population. Sensitivity of transthoracic echocardiography is highest in injection drug users (88% to 94%), who more often have larger vegetations, a preponderance of right-sided lesions, and a favorable acoustic precordial window characteristic of younger patients. For those with chest wall deformities, obesity, or chronic obstructive pulmonary disease, echocardiography is less sensitive.

Transesophageal echocardiography has greater sensitivity and specificity for valvular abnormalities than transthoracic echocardiography due to improved image resolution, but it can be harder for an awake patient to tolerate. Use transesophageal echocardiography in (1) patients with prosthetic valves or intracardiac devices; (2) those in whom inadequate images are likely to be obtained with transthoracic echocardiography, as described above; and (3) those with intermediate or high clinical probability of endocarditis. Transesophageal echocardiography is of particular value for assessing suspected complications such as myocardial abscess and perivalvular extension.

TREATMENT

INITIAL STABILIZATION

Patients with endocarditis may present with hemodynamic instability, including hypotension, respiratory compromise due to decreased cardiac output and/or pulmonary edema, diminished pulmonary capacity, altered mental status, or acidosis. Emergency stabilization with airway management and hemodynamic monitoring and support are priority interventions. Intraaortic balloon counterpulsation aids the emergency management of unstable mitral valve rupture but is contraindicated for aortic valve rupture.

Definitive management requires a team approach and may include cardiology, infectious disease, and cardiac surgery. Systemic clot lysis or anticoagulation for treatment of endocarditis-associated stroke is controversial and best decided upon together with a stroke expert.

Anticoagulation for prosthetic valve endocarditis may reduce the risk of thromboembolism without increased risk of intracranial hemorrhage.[24] Patients with prosthetic valves already being treated with anticoagulants may be maintained on established regimens.[25]

EMPIRIC TREATMENT OF SUSPECTED ENDOCARDITIS OF NATIVE VALVES

Antibiotic selection is based on patient characteristics and local resistance patterns. **Table 155-5** lists sample empiric treatment regimens.[25-27] Although some authors recommend awaiting culture results before antibiotic therapy for patients with subacute bacterial endocarditis, we recommend ED initiation of antibiotic therapy for all patients suspected of endocarditis after obtaining appropriate cultures, targeting the most common organisms, *Staphylococcus aureus* and *Streptococcus* species. For patients with suspected native valve infection, empiric antibiotic therapy includes a penicillinase-resistant penicillin or a cephalosporin *and* an aminoglycoside. For patients with complications (including injection drug use, congenital heart disease, nosocomial infections, those who develop endocarditis while taking oral antibiotics, or those with suspected methicillin-resistant *S. aureus*), add vancomycin.

EMPIRIC TREATMENT OF SUSPECTED ENDOCARDITIS OF ARTIFICIAL VALVES

For patients with suspected artificial valve endocarditis, empiric therapy includes vancomycin, an aminoglycoside, and rifampin.

TABLE 155-5 Empiric Therapy of Suspected Bacterial Endocarditis*

Patient Characteristics	Recommended Agents, Initial Dose
Uncomplicated history	Ceftriaxone, 1–2 grams IV *or* Nafcillin, 2 grams IV *or* Oxacillin, 2 grams IV *or* Vancomycin, 15 milligrams/kg *plus* Gentamicin, 1–3 milligrams/kg IV *or* Tobramycin, 1 milligram/kg IV
Injection drug use, congenital heart disease, hospital-acquired, suspected methicillin-resistant *Staphylococcus aureus,* or already on oral antibiotics	Nafcillin, 2 grams IV *plus* Gentamicin, 1–3 milligrams/kg IV *plus* Vancomycin, 15 milligrams/kg IV
Prosthetic heart valve	Vancomycin, 15 milligrams/kg IV *plus* Gentamicin, 1–3 milligrams/kg IV *plus* Rifampin, 300 milligrams PO

*Based on American Heart Association, endorsed by the Infectious Disease Society of America, http://www.idsociety.org/Organ_System/, accessed April 1, 2014. Because of controversy in the literature regarding the optimal regimen for empiric treatment, antibiotic selection should be based on patient characteristics, local resistance patterns, and current authoritative recommendations.

DEFINITIVE TREATMENT OF ENDOCARDITIS

Definitive antibiotic treatment is based on culture and sensitivity results. Most patients will require 4 to 6 weeks of antibiotic therapy. Surgical management is indicated in patients with severe valvular dysfunction, congestive heart failure, relapsing prosthetic valve endocarditis, major embolic complications, fungal endocarditis, new conduction defects or dysrhythmias, or persistent bacteremia after appropriate antibiotic therapy.[28,29] Surgical risk increases in those older than 65 years, on inotropes, with sepsis or with cerebral emboli.[30]

ENDOCARDITIS PROPHYLAXIS

Because everyday dental activities (brushing, flossing, chewing) create bacteremia, good dental care is important. Antibiotic prophylaxis should be given to those at risk **(Table 155-6).**

Prophylaxis is *not* routinely indicated for patients with mitral valve prolapse (with or without regurgitation), pacemakers, hypertrophic cardiomyopathy, physiologic murmurs, prior coronary artery bypass surgery or angioplasty, or previous surgical repair of atrial septal defect, ventricular septal defect, or patent ductus arteriosus.

For highest risk patients, provide antibiotic prophylaxis before dental procedures that involve manipulation of gingival tissue, the periapical region of teeth, or perforation of the oral mucosa. **Prophylaxis is not needed for nondental procedures**, such as local injections, laceration suturing, IV line placement, blood drawing, endotracheal intubation, endoscopy, vaginal delivery, oral trauma and bleeding, urethral catheterization, or uterine dilation and curettage. Some experts recommend prophylaxis for body art, such as tattooing and piercing.

Recommendations for procedures that manipulate infected skin structures or musculoskeletal tissue are Class IIb (may be considered, usefulness is less well established); it is reasonable to administer antibiotics before the procedure for the highest risk groups identified in Table 155-6. The antibiotic should be active against staphylococci and β-hemolytic streptococci. Vancomycin and clindamycin are options for those unable to tolerate a β-lactam or who are known or suspected to have an infection caused by a methicillin-resistant strain of *Staphylococcus*. The incidence of bacteremia with abscess incision and drainage is very low; hence, clear data are lacking.

A simplified strategy for antibiotic prophylaxis is listed in **Table 155-7**.[32] With the endorsement of the National Institute for Health and Clinical Excellence of London,[33] the European College of Cardiology does not recommend prophylaxis before respiratory tract procedures, GI or GU procedures, or uncomplicated dermatologic or musculoskeletal procedures.[34]

With good aseptic technique, prophylactic antibiotics are not recommended prior to invasive procedures such as central lines.[35]

PRACTICE GUIDELINES

The American Heart Association has published guidelines on diagnosis and management (http://circ.ahajournals.org/cgi/reprint/111/23/e394) as well as prophylaxis (www.circ.ahajournals.org/content/lll/23/e394.full [accessed 8/17/2015])for infective endocarditis.

TABLE 155-6 Highest Risk Conditions for Endocarditis[31]

Prosthetic heart valves
Prosthetic material used for valve repair
History of previous infective endocarditis
Unrepaired cyanotic congenital heart disease
Repaired congenital heart defect with prosthetic material or device
Repaired congenital heart disease with residual defects
Cardiac transplant recipients with valve regurgitation due to a structurally abnormal valve

TABLE 155-7 Prophylaxis Against Endocarditis for Highest Risk Patients

Procedure	Patient Characteristics	Antibiotic Agent	Dose
Dental procedures involving manipulation of either gingival tissue or the periapical region of teeth or perforation of the oral mucosa	Able to take oral antibiotics	Amoxicillin	2 grams PO, 30–60 min before procedure
		or	
	Unable to take oral medication	Ampicillin	2 grams IM or IV, 30–60 min before procedure
		or	
		Cefazolin or ceftriaxone	1 gram IM or IV, 30–60 min before procedure
	Allergic to penicillins or ampicillin	Cephalexin	2 grams PO, 30–60 min before procedure
		or	
		Clindamycin	600 milligrams PO, 30–60 min before procedure
		or	
		Azithromycin or clarithromycin	500 milligrams PO, 30–60 min before procedure
	Unable to take oral medication and allergic to penicillins or ampicillin	Cefazolin or ceftriaxone	1 gram IM or IV, 30–60 min before procedure
		or	
		Clindamycin	600 milligrams IM or IV, 30–60 min before procedure
Procedures on infected skin, skin structure, or musculoskeletal tissue	Non–methicillin-resistant strain of *Staphylococcus* or β-hemolytic *Streptococcus* suspected	Dicloxacillin	2 grams PO, 30–60 min before procedure
		or	
		Cephalexin	2 grams PO, 30–60 min before procedure
	Patients unable to tolerate a β-lactam or who are known or suspected to have an infection caused by a methicillin-resistant strain of *Staphylococcus*	Vancomycin	1 gram IV, 30–60 min before procedure
		or	
		Clindamycin	600 milligrams IM or IV, 30–60 min before procedure
Other procedures (respiratory; GI; GU; noninfected dermatologic or musculoskeletal procedures)		Prophylaxis not indicated

CHAPTER 156

Tetanus

Joel L. Moll
Donna L. Carden

INTRODUCTION AND EPIDEMIOLOGY

Tetanus is uncommon in the United States but continues to have a substantial health impact in developing countries. The worldwide incidence of tetanus is approximately 1 million cases per year, with a mortality rate of 20% to 30%.[1]

The Centers for Disease Control and Prevention defines tetanus as a syndrome of acute onset of hypertonia and/or painful muscular contractions (usually of the muscles of the jaw and neck) and generalized muscle spasms without other apparent medical cause as reported by a health professional.[2] In the United States, tetanus is a reportable disease, aggregated through the National Notifiable Diseases Surveillance System.

Improved childbirth practices, widespread immunization programs for children, decennial tetanus boosters for adults, mechanization of agriculture, and use of chemical fertilizers rather than animal manure have resulted in a >95% decline in the annual incidence of tetanus in the United States since 1947.[2] From 2001 to 2008, 233 tetanus cases were reported in the United States from 45 states, with the majority of cases reported from five states: California (n = 60), Florida (n = 25), Texas (n = 12), New York (n = 12), and Pennsylvania (n = 11).[2] Most patients who develop tetanus have inadequate immunity to the disease. Due to waning immunity and failure to receive routine boosters, only 31% of Americans >70 years old have adequate tetanus immunity.[3] As a result, the average annual incidence of tetanus among those ≥65 years of age is higher (0.23 cases per 1 million population) than among those age 5 to 64 years (0.08 cases per 1 million population). Tetanus among children and neonatal tetanus are uncommon in the United States as well as in other developed countries. The case fatality rate is approximately 13%, with the elderly accounting for the majority of deaths.[2]

Most cases of tetanus in the United States are associated with an acute wound. Puncture, contaminated, infected, or devitalized wounds account for approximately 70% of tetanus cases. Although less common, chronic wounds, ulcers and other wounds in diabetics, and dental abscesses are also associated with the disease. Diabetics and injection drug users have an increased risk of contracting tetanus.[2,4]

Most patients who develop tetanus do not seek medical care for their initial wound. In those who do seek initial treatment and later develop tetanus, up to 95% do not receive appropriate therapy.[2]

PATHOPHYSIOLOGY

Clostridium tetani is a motile, nonencapsulated, anaerobic gram-positive rod, and its toxins cause tetanus. *C. tetani* exists in either a vegetative or a spore-forming state. The spores are ubiquitous in soil and in animal feces and are resistant to destruction, surviving on environmental surfaces for years. In agricultural areas, adults may harbor the organism, and spores have been found on skin or in contaminated heroin.[4,5] *C. tetani* is usually introduced into a wound in the spore-forming, noninvasive state but can germinate into a toxin-producing, vegetative form if tissue oxygen tension is reduced. **Crushed or devitalized tissue, a foreign body, or the development of infection favors the growth of the toxin-producing form of *C. tetani*.**[5,6]

C. tetani produces two exotoxins: tetanolysin, which appears to favor the expansion of the bacterial population, and tetanospasmin, a powerful neurotoxin responsible for all of the clinical manifestations of tetanus. Tetanospasmin reaches the nervous system by hematogenous spread of the exotoxin to peripheral nerves and by retrograde intraneuronal transport. Tetanospasmin does not cross the blood–brain barrier, but retrograde intraneuronal transport of the exotoxin enables tetanospasmin to gain access to the CNS.[6]

Tetanospasmin prevents the release of the inhibitory neurotransmitters glycine and γ-aminobutyric acid from presynaptic nerve terminals, releasing the nervous system from its normal inhibitory control. Loss of inhibition may also affect the preganglionic sympathetic neurons, resulting in sympathetic overactivity and high circulating catecholamine levels.[5-8]

CLINICAL FEATURES

Tetanus results in generalized muscular rigidity, violent muscular contractions, and autonomic nervous system instability.[6] Wounds that become contaminated with toxin-producing *C. tetani* are often puncture wounds, but contaminated wounds range from deep lacerations to minor abrasions.[2] **No wound is identified in up to 10% of patients with tetanus.** Tetanus can also develop after surgical procedures, otitis media, or abortion and can develop in injection drug users from contaminated heroin and in neonates through infection of the umbilical stump.[4,9]

The incubation period for tetanus ranges from <24 hours to >1 month. Short incubation periods are associated with severe disease and a poor prognosis for recovery. Clinical tetanus can be categorized into three forms: generalized, cephalic, and local. **Generalized tetanus** accounts for about 80% of cases. The most frequent presenting complaints of patients with generalized tetanus are pain and stiffness in the masseter muscles (lockjaw). Nerves with short axons are affected initially, so symptoms appear first in the facial muscles, with descending progression to the muscles of the neck, trunk, and extremities. The transition from muscle stiffness to rigidity leads to the development of trismus and the characteristic facial expression: risus sardonicus (sardonic smile). Reflex convulsive spasms and tonic muscle contractions are responsible for the development of dysphagia, opisthotonos flexing of the arms, clenching of the fists, and extension of the lower extremities. Spasms can last for 3 to 4 weeks, and recovery depends on regrowth of axonal nerve terminals and may take months.[6] Complications of tetanus include rhabdomyolysis and long-bone fractures secondary to violent muscle contractions. The mental status is normal, an important consideration in differentiating tetanus from other disorders (**Table 156-1**). Patients remain conscious and alert unless laryngospasm or contraction of respiratory muscles results in respiratory compromise. Other complications of prolonged hospitalization include pulmonary embolus, pneumonia, and sepsis. Aspiration pneumonia is present in 50% to 70% of autopsied cases.[5,6]

Autonomic changes are generally a hypersympathetic state, occurring during the second week of clinical tetanus and including tachycardia, labile hypertension, profuse sweating, hyperpyrexia, and

TABLE 156-1 Differential Diagnosis of Tetanus

Disorder	Comments
Strychnine poisoning	See chapter 201, "Pesticides."
Dystonic reaction (phenothiazines, metoclopramide)	See chapter 180, "Antipsychotics."
Hypocalcemic tetany	See chapter 17, "Fluids and Electrolytes."
Malignant neuroleptic syndrome	See chapter 180, "Antipsychotics."
Serotonin syndrome	See chapter 178, "Atypical and Serotonergic Antidepressants"
Stiff man syndrome	Centrally mediated motor hyperexcitability with persistent and intense spasms, particularly of the proximal lower limbs and lumbar paraspinal muscles.
Peritonsillar abscess	See chapter 246, "Neck and Upper Airway."
Peritonitis	See chapter 71, "Acute Abdominal Pain."
Meningeal irritation (bacterial meningitis, subarachnoid hemorrhage)	See chapters 174, "Central Nervous System and Spinal Infections" and 166, "Spontaneous Subarachnoid and Intracerebral Hemorrhage."
Rabies	See chapter 157, "Rabies."
Temporomandibular joint disease	See chapter 243, "Face and Jaw Emergencies."

increased urinary excretion of catecholamines.[6-8] **Neonatal tetanus**, a form of generalized tetanus, develops in infants born to inadequately immunized mothers, frequently after unsterile treatment of the umbilical cord stump.[9] Infants with neonatal tetanus are weak, irritable, and have an inability to suck. Symptoms are evident by the second week of life.[9]

Cephalic tetanus follows injuries to the head or occasionally otitis media and results in dysfunction of the cranial nerves, most commonly the seventh. It has a poor prognosis.

Local tetanus is manifested by rigidity of muscles in proximity to the site of injury and usually resolves completely after weeks to months. Local tetanus may progress to the generalized form of the disease. Approximately 1% of the cases are fatal.[5,6]

DIAGNOSIS

Tetanus is diagnosed clinically. In the United States, 96% of tetanus cases occur in those with unknown or inadequate immunization history.[2] Certain populations, especially the elderly, those requiring hemodialysis, and the immunocompromised, are more likely to have inadequate immunity.[10,11] There are no laboratory tests to diagnose tetanus, although serum antitoxin titers of >0.01 IU/mL (by mouse neutralization assay) are usually protective. An immunochromatographic dipstick test offers the advantage of rapid assessment of immunity, with an 88% sensitivity and 98% specificity, and may be useful in regions with high disease incidence.[12] However, tetanus has developed in patients with protective levels of antitetanus antibodies.[13] Wound culture is of limited value, because *C. tetani* may be cultured from wounds in the absence of clinical disease and may not be recovered in patients with documented tetanus.

Table 156-1 provides the differential diagnosis of tetanus. **Strychnine poisoning** most closely mimics the clinical picture of generalized tetanus.

TREATMENT

Treatment is summarized in **Table 156-2**. Admit patients with tetanus to the intensive care unit. Respiratory compromise requires immediate neuromuscular blockade and intubation. Minimize environmental stimuli to prevent the precipitation of reflex convulsive spasms.

TABLE 156-2 Treatment of Tetanus

Respiratory management	Sedation and neuromuscular blockade with succinylcholine or vecuronium for intubation and ongoing mechanical ventilation
Immunotherapy	Tetanus immunoglobulin, 3000–6000 units IM opposite side of the body from tetanus toxoid, with at least a portion around the wound site *and* Tetanus toxoid (DTaP or Td/Tdap depending on age), 0.5 mL IM at presentation, and 6 wk and 6 mo after presentation
Wound care	Wound debridement
Antibiotic therapy	Metronidazole, 500 milligrams IV every 6 h **No penicillin**
Muscle relaxation	Midazolam preferred
Management of autonomic dysfunction	Magnesium sulfate, 40 milligrams/kg IV loading, then 2 grams/h (1.5 grams/h if ≤45 kg) continuous infusion to maintain blood level of 2.0–4.0 mmol/L *or* Labetalol, 0.25–1.0 milligram/min continuous IV infusion
	Morphine sulfate, 0.5–1.0 milligram/kg/h
	Clonidine, 300 micrograms every 8 h by nasogastric tube

Abbreviations: DTaP = diphtheria and tetanus toxoids and acellular pertussis vaccine; Tdap = tetanus toxoid with lower doses of diphtheria and acellular pertussis than DTaP; Td = tetanus-diphtheria.

TETANUS IMMUNOGLOBULIN

Human tetanus immunoglobulin neutralizes circulating tetanospasmin and toxin in the wound but not toxin that is already fixed in the nervous system. Even though tetanus immunoglobulin does not ameliorate the clinical symptoms of tetanus, early reports suggest it reduces mortality.[14] The dose varies depending on the purpose. For postexposure prophylaxis, a single dose of 250 units (4 units/kg in children) IM given in the anterolateral thigh or deltoid is recommended. For the treatment of actual tetanus, the optimal dose of tetanus immunoglobulin is unknown, but 3000 to 6000 units IM is the usual recommended dose, administered in a separate syringe and opposite the site of tetanus toxoid administration. At least a portion of the dose should be administered around the wound itself.[5] **Tetanus immunoglobulin should be given before wound debridement, because exotoxin may be released during wound manipulation.** Repeated doses of tetanus immunoglobulin are unnecessary because of its long half-life of 28 days.

WOUND MANAGEMENT

Identify and debride the wound to improve the oxidation-reduction potential of infected tissue and to prevent further toxin production.

ANTIBIOTICS

Antibiotics are of limited value but are traditionally administered, and **parenteral metronidazole** is the antibiotic of choice.[15,16] **Do not give penicillin because it may potentiate the effects of tetanospasmin.**[6]

MUSCLE RELAXANTS

Tetanospasmin prevents neurotransmitter release at inhibitory interneurons, and therapy of tetanus is aimed at restoring normal inhibition. The benzodiazepines are centrally acting inhibitory agents that have been used extensively for this purpose. However, the large IV doses of benzodiazepines required in tetanus may result in metabolic acidosis secondary to the propylene glycol vehicle in IV lorazepam or diazepam. **Thus, many prefer midazolam, a water-soluble agent, for muscle relaxation.**[6] The effects of baclofen, a specific γ-aminobutyric acid agonist, vary.[6]

NEUROMUSCULAR BLOCKADE

Prolonged neuromuscular blockade aids in control of ventilation, muscular spasms, secondary fractures, and rhabdomyolysis. Succinylcholine can be given early for emergency airway control, whereas vecuronium is a good option for prolonged blockade because of minimal cardiovascular side effects.[15]

TREATMENT OF AUTONOMIC DYSFUNCTION

One randomized controlled trial in 256 patients with severe tetanus demonstrated that magnesium sulfate reduced autonomic instability and muscle spasm in the disease.[7] Furthermore, magnesium sulfate has been shown to reduce urinary catecholamine excretion in patients with severe tetanus.[8] However, a meta-analysis failed to show a benefit of magnesium sulfate on tetanus mortality, and the effect of the drug on duration of intensive care unit and hospital stay and need for ventilatory support was unclear.[17]

Adrenergic blocking agents may treat the autonomic dysfunction of severe tetanus. Choose either a short-acting β-blocker, such as esmolol, or labetalol, a combined α- and β-adrenergic blocking agent, if treating this manifestation of tetanus.

Morphine sulfate reduces sympathetic α-adrenergic tone and central sympathetic efferent discharge and produces peripheral arteriolar and venous dilatation.[6] Clonidine, a central α_2-receptor agonist, may act to reduce the sympathetic hyperactivity that causes autonomic dysfunction and thereby provide better control of crises.[18]

IMMUNIZATION

Patients who recover from tetanus must receive active immunization, because infection does not confer immunity and vaccination is the only means of disease prevention. Give adsorbed tetanus toxoid (0.5 mL) IM at the time of presentation and at 6 weeks and 6 months after injury.

In patients with tetanus-prone wounds or those with incomplete vaccinations or greater than 10 years from previous vaccination, use tetanus-diphtheria (Td) if ≥7 years old, and use diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP) for those under 7 years old.[19] DTaP contains over three times the amount of diphtheria component as Tdap and must be used for primary vaccination series in children. Because of the recent increase in the incidence of pertussis, adolescents and adults should receive a single lifetime dose of Tdap to replace one Td booster.[19] An inadvertent dose of DTaP in an adult would count as the single lifetime dose of Tdap.

The revised Advisory Committee on Immunization Practices guidelines recommend administering a dose of Tdap during each **pregnancy**, irrespective of the patient's prior history of receiving Tdap or interval since last injection, to maximize the maternal antibody response and passive antibody levels in the newborn.[20] Tdap may be given at any point during pregnancy, with optimal timing between 27 and 36 weeks of gestation unless treating a specific wound. For women who have never received Tdap, it should be given to the mother immediately postpartum and to any direct caregivers to reduce the risk of pertussis to the newborn.

Table 156-3 summarizes the guidelines for tetanus immunization and tetanus prophylaxis in wound management.[19] **Only about 60% of patients with an acute injury who seek medical care receive appropriate tetanus wound prophylaxis.**[2] Table 156-2 summarizes the management of tetanus.

Adverse reactions following tetanus immunization include erythema, induration, and pain at the injection site. Local reactions are common and usually self-limited. Exaggerated local reactions (Arthus reactions) occur occasionally after tetanus toxoid and involve extensive pain and swelling of the entire extremity. Arthus reactions occur most often in adults with high serum tetanus antitoxin levels who have received frequent doses of tetanus toxoid, the reason this therapy is limited to 10-year intervals.

Contraindications to Td or Tdap include a history of serious allergic reaction (respiratory compromise or cardiovascular collapse) to vaccine components. History of encephalopathy (e.g., coma or prolonged seizures) not attributable to an identifiable cause within 7 days of administration of a pertussis vaccine is a contraindication to Tdap. Reasons to defer Td or Tdap include Guillain-Barré syndrome ≤6 weeks after a previous dose of tetanus toxoid-containing vaccine, moderate to severe acute illness, unstable neurologic condition, or history of an Arthus hypersensitivity reaction to a tetanus toxoid–containing vaccine administered <10 years previously.[19] If tetanus toxoid is contraindicated, consider passive immunization with tetanus immunoglobulin.

TABLE 156-3 Summary Guide to Tetanus Prophylaxis in Wound Management

	Clean, Minor Wounds		All Other Wounds*	
History of Adsorbed Tetanus Toxoid (doses)	Tdap or Td† IM	TIG, 250 units IM	Tdap or Td†	TIG, 250 units IM
Unknown or less than three	Yes‡	No	Yes	Yes
Three or more#	No[f]	No	Yes**	No

*For example, wounds >6 hours old, contaminated with soil, saliva, feces, or dirt; puncture or crush wounds; avulsions; wounds from missiles, burns, or frostbite.

†DTaP for children <7 years of age (DT if pertussis vaccine is contraindicated); Td for persons ≥7 years of age. A single booster dose of Tdap is recommended for adolescents and adults to replace 1 Td booster.

‡The primary immunization series should be completed. Three doses total are required, with the second dose given at least 4 weeks after the first dose and the third dose given 6 months later.

#If only three doses of fluid toxoid have been received, then a fourth dose of *absorbed* toxoid should be given.

[f]Yes, if >10 years since last dose.

**Yes, if >5 years since last dose. Boosters more frequent than every 5 years may predispose to side effects.

Abbreviations: DTaP = diphtheria and tetanus toxoids and acellular pertussis vaccine; DT = diphtheria-tetanus toxoids; Td = tetanus-diphtheria; Tdap = tetanus toxoid with lower doses of diphtheria and acellular pertussis than DTaP; TIG = tetanus immunoglobulin.

CHAPTER 157

Rabies

David Weber

INTRODUCTION AND EPIDEMIOLOGY

This chapter reviews the epidemiology of rabies, pre- and postexposure rabies prophylaxis, and clinical presentation and treatment of rabies. Current information is available from the Centers for Disease Control and Prevention (http://www.cdc.gov/rabies/).

More than 3 billion people are at risk of rabies in over 100 countries.[1] The World Health Organization estimates that more than 15 million people receive a postexposure preventive regimen with more than 55,000 people dying of rabies annually, despite the availability of effective postexposure prophylaxis.

Rabies is primarily a disease of animals.[2-4] The epidemiology of human rabies reflects both the distribution of the disease in animals and the degree of human contact with these animals. A summary of major rabies vectors is provided in **Table 157-1**.

In the United States, rabies is endemic in many wild animal populations, with more than 6000 rabid animals reported in 2010.[5] Although human rabies is rare in the United States, postexposure rabies prophylaxis is provided to about 40,000 persons each year.[6] From 2001 to 2011, 29 cases of human rabies were reported in the United States, with eight cases contracted in other countries. About 90% of these cases were associated with **bats**. Most cases contracted outside the United States and Canada were from **dog** bites.[5,7,8]

PATHOPHYSIOLOGY

Rabies virus is the prototype member of the genus *Lyssavirus*.[9,10] All lyssaviruses are adapted to replicate in the mammalian CNS, are transmitted by direct contact, and are not associated with transmission by or natural replication in insects.

TABLE 157-1 Major World and U.S. Rabies Vectors

Vector	Region
Dogs	Asia, Latin America, Africa
Foxes	Europe, Arctic, North America
Skunks	Midwest United States, Western Canada
Coyotes	Asia, Africa, North America
Mongooses	Asia, Africa, Caribbean
Bats	North America, Latin America, Europe
No rabies	Hawaii, United Kingdom, Australasia, Antarctica

Viral infection of the salivary glands of the biting animal is responsible for the infectivity of saliva.[2-4,11] After a bite, saliva containing infectious rabies virus is deposited in muscle and subcutaneous tissues. The virus remains close to the site of exposure for the majority of the **long incubation period (typically 20 to 90 days)**. Rabies virus binds to the nicotinic acetylcholine receptor in muscle, which is expressed on the postsynaptic membrane of the neuromuscular junction. Subsequently, the virus spreads across the motor end plate and ascends and replicates along the peripheral nervous axoplasm to the dorsal root ganglia, the spinal cord, and the CNS. Following CNS replication in the gray matter, the virus spreads outward by peripheral nerves to virtually all tissues and organ systems.

Histologically, rabies is an encephalitis, resulting in infiltration of lymphocytes, polymorphonuclear leukocytes, and plasma cells, and focal hemorrhage and demyelination in the gray matter of the CNS, the basal ganglia, and the spinal cord. Negri bodies, in which CNS viral replication occurs, are eosinophilic intracellular lesions found within cerebral neurons and are highly specific for rabies. Negri bodies are found in about 75% of proven cases of animal rabies. Although their presence is pathognomonic for rabies, their absence does not exclude it.

Transmission of rabies virus usually begins when the contaminated saliva of an infected host is passed to a susceptible host, usually by the bite of a rabid animal. Other routes of documented transmission include contamination of mucous membranes (i.e., eyes, nose, mouth), aerosol transmission during spelunking (caving) in bat-infested caves, exposure while working in the laboratory with rabies virus, infected organ transplants (e.g., cornea, liver, kidney, vascular graft, lung), and iatrogenic infection through improperly inactivated vaccine.

PREEXPOSURE PROPHYLAXIS

Preexposure prophylaxis with rabies vaccine is highly recommended for persons whose recreational or occupational activities place them at risk for rabies (**Tables 157-2** and **157-3**).[12] Although the initial rabies preexposure vaccine regimen is similar for all risk groups, the need for booster doses, the timing of booster doses, and the need for and timing of serologic tests to confirm immunity differ based on the degree of individual risk for exposure to rabies. Preexposure prophylaxis may be obtained from the local health department or from a local physician or veterinarian. Preexposure vaccination does not eliminate the need for additional therapy after a rabies exposure, but simplifies postexposure prophylaxis by eliminating the need for human rabies immunoglobulin (HRIG) and by decreasing the number of doses of vaccine required (see later section, Postexposure Prophylaxis in Special Populations).

TABLE 157-3 Rabies Preexposure Prophylaxis Schedule—United States (2008)

Type of Immunization	Route	Regimen
Primary	Intramuscular*	HDCV or PCECV; 1.0 mL (deltoid area), one dose on days 0,† 7, and 21 or 28
Booster‡	Intramuscular*	HDCV or PCECV; 1.0 mL (deltoid area), one dose on day 0† only

Abbreviations: HDCV = human diploid cell vaccine; PCECV = purified chick embryo cell culture vaccine.

*Use deltoid area for adults and older children. For young children, use anterolateral thigh. Do not administer vaccine in the gluteal area.

†Day 0 is the day the first dose of vaccine is administered.

‡Persons in the continuous risk category should have a serum sample tested for rabies neutralizing antibody every 6 months, and persons in the frequent risk category should be tested every 2 years. An IM booster dose of vaccine should be administered if the serum titer falls to maintain the value of at least complete neutralization at a 1:5 serum dilution by rapid fluorescent focus inhibition test. See recommendations by the Centers for Disease Control and Prevention[12] for more details.

POSTEXPOSURE PROPHYLAXIS

RISK ASSESSMENT

The risk of developing rabies following a bite or scratch by a rabid animal depends on whether the wound was a bite, scratch, or nonbite exposure; the number of bites; the depth of the bites; and the location of the wounds (**Table 157-4**).[13]

Risk assessment for postexposure prophylaxis includes determining the epidemiology of animal rabies in the area where the contact occurred; knowing the species of animal involved; understanding the type of exposure (e.g., bite versus nonbite); clarifying the circumstances of the exposure incident; and determining if the animal can be safely captured and tested for rabies (**Table 157-5**). **The distinction between a "provoked" and "nonprovoked" attack should not be used for risk assessment.** Most animal bites are "provoked" from the standpoint of the animal (i.e., interfering with the animal's food, offspring, feeding habits, etc.). In addition, about 15% of animals with rabies do *not* exhibit aggressive behavior but are apathetic ("dumb rabies"). The local health department can provide information about the epidemiology of animal rabies in the area. **Evaluation for postexposure prophylaxis is indicated for persons bitten by, scratched by, or exposed to saliva from a wild or domestic animal that could be rabid (Figure 157-1).**

TABLE 157-2 Rabies Preexposure Risk Assessment and Recommendations

Risk Category	Nature of Risk	Typical Population	Preexposure Recommendations
Continuous	Virus present continuously, often in high concentrations; specific exposures likely to go unrecognized; bite, nonbite, or aerosol exposure	Rabies research laboratory workers,* rabies biologicals production workers	Primary course: serologic testing every 6 months; booster immunization if antibody titer is below acceptable level†
Frequent	Exposure usually episodic with source recognized, but exposure also might be unrecognized; bite, nonbite, or aerosol exposure	Rabies diagnostic laboratory workers,* cavers, veterinarians and staff, and animal-control and wildlife workers in rabies-endemic areas; all persons who regularly handle bats	Primary course: serologic testing every 2 years; booster immunization if antibody titer is below acceptable level†
Infrequent (greater than population at large)	Exposure nearly always episodic with source recognized; bite or nonbite exposure	Veterinarians and animal-control and wildlife workers working with terrestrial animals in areas where rabies is uncommon or rare, veterinary students, travelers visiting areas where rabies is endemic and immediate access to appropriate medical care, including biologicals, is limited	Primary course: no serologic testing or booster immunization
Rare (population at large)	Exposure always episodic with source recognized; bite or nonbite exposure	U.S. population at large, including persons in rabies-endemic areas	No immunization necessary

*Judgment of relative risk and extra monitoring of immunization status of laboratory workers is the responsibility of the laboratory supervisor.

†Minimum acceptable antibody level is complete virus neutralization at 1:5 serum dilution by the rapid fluorescent focus inhibition test. A booster dose should be administered if the titer falls below this level.

TABLE 157-4 Risk of Rabies in the Absence of Postexposure Prophylaxis after Exposure to a Rabid Animal

Multiple severe bites around the face: 80%–100%
Single bite: 15%–40%
Superficial bite(s) on an extremity: 5%
Contamination of a recent wound by saliva: ~0.1%
Contact with rabid saliva on a wound older than 24 hours: 0%
Transmission via fomites (e.g., tree branch): theoretical*
Indirect transmission (e.g., raccoon saliva on a dog): theoretical*

*Literature review revealed no cases due to this theoretical method of transmission.

Give postexposure prophylaxis as soon as possible after exposure to rabies-prone wildlife (**Tables 157-5** and **157-6**).

Bites For the purpose of rabies postexposure prophylaxis, **a bite exposure is defined as any penetration of the skin by the teeth of an animal**.[12] Bites to the face and hands carry the highest risk, but the site of the bite does not influence the decision to begin therapy.

Nonbite Exposures A **nonbite exposure** is contamination of scratches, abrasions, open wounds, or mucous membranes with saliva or brain tissue from a rabid animal. For example, animal licks to nonintact skin have transmitted rabies. Nonbite exposures from animals very rarely cause rabies. If the material containing the virus is dry, the virus can be considered noninfectious. Petting a rabid animal or contact with blood, urine, or feces (e.g., guano) of a rabid animal does not constitute an exposure and is not an indication for prophylaxis.[12]

Exposures to Animals Previously Vaccinated for Rabies A fully vaccinated dog or cat (i.e., two vaccinations) is unlikely to become infected with rabies. No documented vaccine failures have been reported in the United States among dogs or cats that received two vaccinations. Rare cases have been reported among animals that had received only a single dose of vaccine. In the United States, animals other than dogs, cats, and ferrets that can transmit rabies and are the source of an animal bite or scratch to a human should be euthanized and tested for rabies *even if the animals have been vaccinated*.

Exposures to Bats Any direct contact between a human and a bat should be evaluated for a rabies exposure. **Seeing a bat does not constitute an exposure.** Postexposure prophylaxis is not indicated if the person can be *certain* that a bite, scratch, or mucous membrane exposure did not occur or if the bat is available for testing and results are negative for the presence of rabies virus. All bats that might be a source of exposure, if available, should be sent to the public health department and tested for rabies, because approximately 94% of submitted bats in the United States have tested negative for rabies.[8] **The Advisory Committee on Immunization Practices recommends consideration of postexposure prophylaxis for persons who were in the same room as a bat and who were unaware if a bite or direct contact had occurred** (e.g., a sleeping person awakens to find a bat in the room, or an adult witnesses a bat in a room with an unattended child, mentally disabled person, or intoxicated person).[12,14] One article calculated the incidence of rabies following bedroom exposure with contact as 0.6 cases per billion person-years,[8] whereas another article reported that the number needed to treat to prevent a single case of rabies in this context would be 314,000 to 2.7 million persons.[15]

Bites from Healthy-Appearing Animals The Centers for Disease Control and Prevention recommends that a healthy dog, cat, or ferret that bites a person be confined and observed for 10 days.[12,14] At the first sign of illness during confinement, such animals should be evaluated by a veterinarian and a report immediately made to the local health department. If signs suggestive of rabies develop, the animal should be euthanized and its head removed and shipped under refrigeration (not frozen) for examination of the brain by a qualified laboratory designated by the local or state health department.

Bites from Stray Animals Any stray or unwanted dog, cat, or ferret that bites a person may be euthanized immediately and the head submitted for rabies examination. Animals that might have exposed a person to rabies should be reported immediately to the local health department. **An animal other than a dog, cat, or ferret that received prior vaccination** may still require euthanasia and testing if the period of virus shedding is unknown for that species.

Person-to-Person Transmission There are anecdotal reports of person-to-person transmission of rabies. Fluids from the upper and lower respiratory tracts of humans frequently test positive for rabies virus. Despite the lack of proven healthcare-associated transmission, about 30% of healthcare personnel who have had contact with a human diagnosed with rabies have received postexposure prophylaxis. Given the mechanism of disease transmission and concern among healthcare workers, contact isolation precautions should be used for patients with known or suspected rabies, and healthcare workers who care for such patients should wear either masks and eye protection or face shields.[12] **Healthcare personnel with nonintact skin or mucous membrane exposure to infective saliva from patients with rabies should receive postexposure prophylaxis.**

Patients Concerned about Rabies For unusual exposures, the state veterinarian or local public health agency can be contacted for more information. However, for patients who voice concern about rabies exposure even if the risk assessment is virtually nil (**Table 157-6**), vaccination can be offered, along with an explanation of the risks and benefits of vaccination. If the risk of rabies is virtually nil, we discourage the administration of HRIG.

WOUND CARE

First, assess wounds for the presence of a life-threatening condition, such as arterial laceration or pneumothorax.[16] Provide proper wound care, including **tetanus prophylaxis, wound cleansing with soap and water and (if available) a dilute solution of povidone-iodine (1 mL**

TABLE 157-5 Rabies Postexposure Risk Assessment and Recommendations (2012)[14]

Animal Type	Evaluation and Disposition of Animal	Postexposure Prophylaxis Recommendations
Dogs, cats, and ferrets	Healthy and available for 10 d of observations	Persons should not begin vaccination unless animal develops clinical signs of rabies.*
	Rabid or suspected rabid	Immediate immunization.
	Unknown (e.g., escaped)	Consult public health officials.
Skunks, raccoons, foxes, and most other carnivores; bats†	Regard as rabid unless animal proven negative for rabies virus by laboratory tests‡	Consider immediate immunization.
Livestock, horses, rodents, rabbits and hares, and other mammals	Consider individually	Consult public health officials; bites of squirrels, hamsters, guinea pigs, gerbils, chipmunks, mice, rats, rabbits, hares, and other small rodents almost never require rabies postexposure prophylaxis.

*During the 10-day observation period, begin postexposure prophylaxis at the first sign of rabies in a dog, cat, or ferret that has bitten someone. If the animal exhibits clinical signs of rabies, it should be euthanized immediately and tested.

†Provide postexposure prophylaxis immediately.

‡The animal should be euthanized and tested as soon as possible. Holding for observation is not recommended.

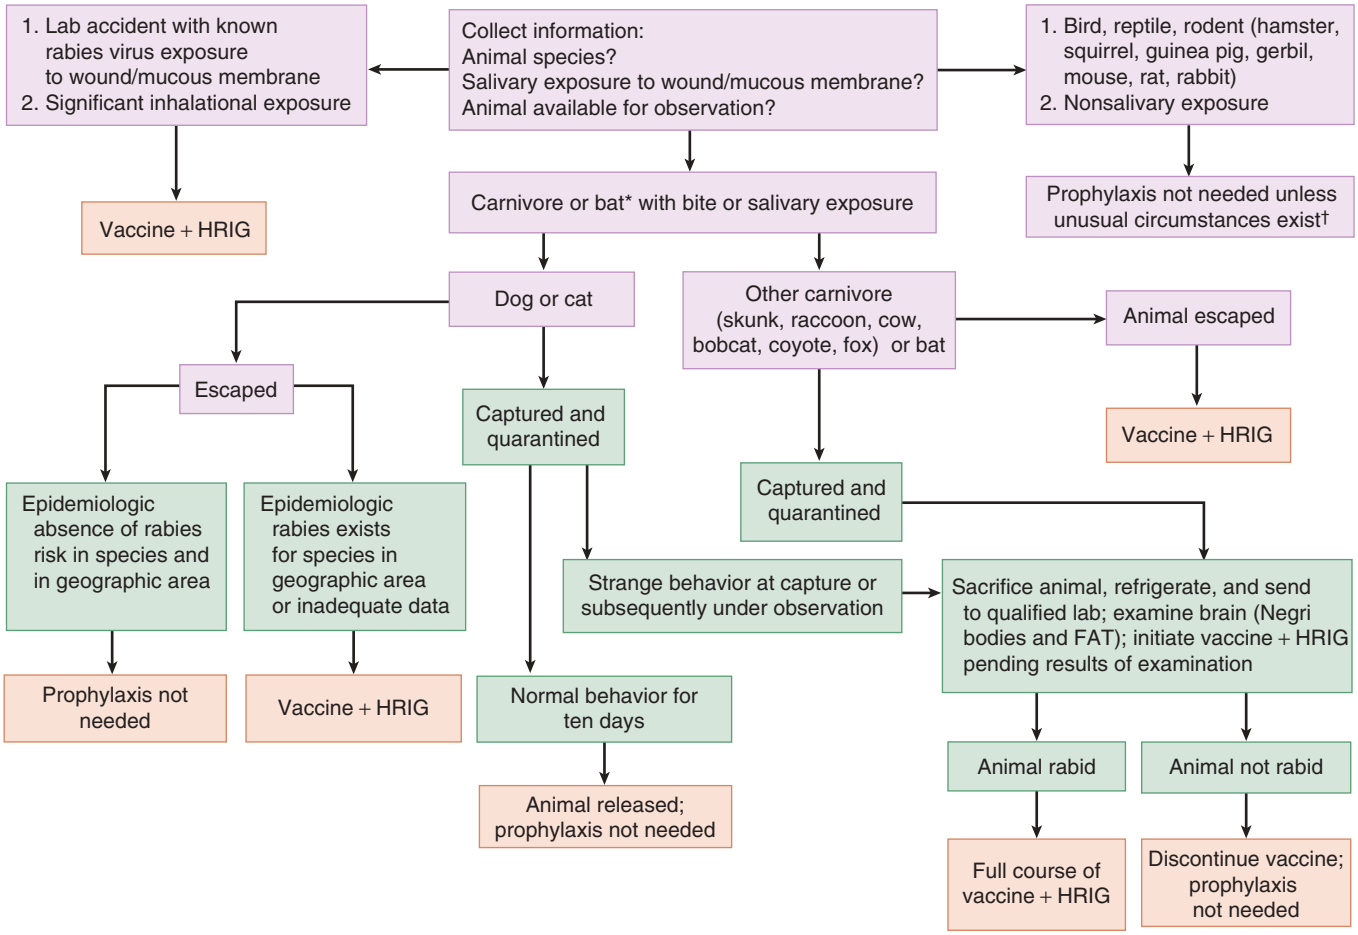

FIGURE 157-1. Clinical guidelines for administration of postexposure prophylaxis. (*) Consider postexposure prophylaxis for persons who were in the same room as a bat and who might be unaware that a bite or direct contact had occurred. (†) The small mammals listed here have never been reported to transmit rabies to humans in the United States, but theoretically, such animals could acquire and transmit rabies. Therefore, postexposure prophylaxis following a bite or scratch from one of these mammals would only be indicated if such an animal had signs typical of rabies or a positive laboratory test for rabies. Consult with local public health officials for reports of rabies in atypical animals. FAT = fluorescent antibody testing; HRIG = human rabies immune globulin.

povidone-iodine in 9 mL of water or normal saline), antibiotics (if indicated) to prevent bacterial infection (see chapter 46, Puncture Wounds and Bites), and **rabies prophylaxis** as indicated.[17]

POSTEXPOSURE PROPHYLAXIS TREATMENT

In the United States, postexposure prophylaxis consists of a regimen of one dose of HRIG and four doses of rabies vaccine over a 14-day period, except for immunocompromised persons, who should receive a five-dose series of vaccine over a 28-day period (**Table 157-7**).[14,17] The shift from a five-dose to a four-dose series of rabies vaccine occurred in 2010 and is based on rabies virus pathogenesis, experimental animal studies, clinical trials, epidemiologic surveillance, and economic analyses.[17] No other aspects of postexposure prophylaxis were altered from the 2008 recommendations (e.g., use of HRIG, site of injection, etc.). HRIG and the first dose of rabies vaccine should be given as soon as possible after exposure, preferably within 24 hours. If HRIG was not administered when vaccination was begun, it can be administered up to 7 days after administration of the first dose of the vaccine.

Follow the Centers for Disease Control and Prevention recommendations for postexposure prophylaxis *exactly* (**Table 157-7**). Although no postexposure prophylaxis vaccine failures have been reported in the United States since the licensing of human diploid cell vaccine in 1980, 13 persons outside the United States have contracted rabies after postexposure prophylaxis with tissue culture–derived vaccine.[2] Each of these cases involved deviation from the recommended protocol; wounds were not cleansed, passive immunization with HRIG was not provided, or rabies vaccine was injected into the gluteal rather than the deltoid area.

Rabies Vaccines Rabies vaccines available in the United States include human diploid cell vaccine (produced in human diploid cells; Imovax®, Sanofi Pasteur, Lyon, France) and purified chick embryo cell culture vaccine (PCECV) (produced in chick embryo cells; RabAvert®, Novartis Vaccines, Emeryville, CA). **The active antibody response requires approximately 7 to 10 days to develop, and detectable rabies virus–neutralizing antibodies generally persist for several years.** All currently used vaccines are produced in cell cultures and are significantly less toxic than older vaccines that were produced in neural tissue. Side effects of human diploid cell vaccine, including mild erythema, swelling, and pain at the injection site, have been reported in 10% to 90% of vaccine recipients. Systemic reactions, such as headache, nausea, abdominal pain, muscle aches, and dizziness, have been reported in 5% to 40% of recipients. Serum sickness–like reactions (type III hypersensitivity) have been noted in approximately 6% of persons receiving booster doses of human diploid cell vaccine and occur 2 to 21 days after administration of the booster dose. Such reactions have not been life threatening and have not been reported with purified chick embryo cell culture vaccine. Anaphylaxis and neurologic symptoms have only rarely been associated with the current rabies vaccines. **Severe egg allergy is a contraindication to the use of purified chick embryo cell culture vaccine.**

Rabies prophylaxis should not be interrupted or discontinued because of local or mild systemic adverse reactions to rabies vaccine.[16] Usually such

TABLE 157-6 Summary of Risk of Acquiring Rabies in the United States

Risk	Exposures
Moderate to high	Bite by skunk, raccoon, fox, and other wild carnivores (unless animal tested negative for rabies) Bite or direct contact with bat (unless animal tested negative for rabies) Exposure by percutaneous injury, mucous membrane exposure, or inhalation to live rabies virus in a laboratory Dog bite in a country with endemic rabies and inadequate immunization of dogs (or bite by feral dog)
Very low to low	Bite by inadequately vaccinated cat or dog that has access to the outdoors (or feral cat or dog) Contamination of open wound or abrasion (including scratches) with, or mucous membrane exposure to, saliva or other potentially infectious material (e.g., neural tissue) from a possibly rabid animal (skunk, raccoon, fox, and other wild carnivores, bat) Awakening in a room with a bat present
No risk identified	Contact of animal fluids (e.g., saliva, blood, neural tissue) with intact skin Indirect contact with saliva from a wild animal (e.g., by cleaning a dog or cat that has had contact with a wild animal)

reactions can be successfully managed with anti-inflammatory and antipyretic agents. When a person with a history of serious hypersensitivity to rabies vaccine must be revaccinated, antihistamines may be given. Epinephrine should be readily available to counteract anaphylactic reactions, and the person should be observed carefully immediately after vaccination (as after any other injection given in a healthcare setting).

Human Rabies Immunoglobulin **HRIG** is administered only once, at the beginning of antirabies prophylaxis, to provide immediate antibodies until the patient responds to rabies vaccine by producing antibodies. A passive antibody titer is evident in 24 hours. Failure to administer HRIG has led to rabies despite appropriate postexposure prophylaxis with human diploid cell vaccine. If HRIG was not given when vaccination was begun, it can be given through the seventh day after administration of the vaccine.[17] **Beyond the seventh day after vaccination is begun, HRIG is not indicated, because an antibody response is presumed to have occurred.** The Centers for Disease Control and Prevention recommends that as much as possible of the full dose be infiltrated around the wound. HRIG should never be administered in the same syringe or into the same anatomic site as the vaccine. Even if the wound has to be sutured, it should be infiltrated locally with HRIG. This practice is safe and does not create an additional risk of infection. However, caution is needed when injecting into a tissue compartment, such as the finger pulp, because excessive HRIG can increase compartment pressure and lead to necrosis.[18] Any remaining HRIG that cannot be administered into the local wound area should be injected intramuscularly at a site distant from vaccine administration. HRIG is prepared from human blood and screened for known viruses (e.g., human immunodeficiency virus, hepatitis). No cases of virus transmission from HRIG that is commercially available in the United States or Australia have been reported. HRIG should not be given to those with immunoglobulin A deficiencies and known antibodies of immunoglobulin A, because small amounts of immunoglobulin A may be present in HRIG and can cause a severe allergic reaction.

WORLD HEALTH ORGANIZATION POSTEXPOSURE PROPHYLAXIS GUIDELINES

In the United States, only regimens recommended by the Advisory Committee on Immunization Practices should be used. The World Health Organization has provided recommendations for rabies postexposure prophylaxis that also consider the cost and availability of vaccines and HRIG.[19,20] Per the World Health Organization, the indication for postexposure prophylaxis depends on the contact with the suspected rabid animal:

- Category I: touching or feeding animals, licks on intact skin (that is, no exposure)
- Category II: nibbling of uncovered skin, minor scratches or abrasions without bleeding
- Category III: single or multiple transdermal bites or scratches, contamination of mucous membrane with saliva from licks, licks on broken skin, exposure to bats

For category I exposures, no prophylaxis is required. For category II, immediate vaccination is recommended. For category III, immediate vaccination and administration of rabies immunoglobulin are recommended. Per the World Health Organization, factors that should be taken into consideration when deciding whether to initiate postexposure prophylaxis include the epidemiologic likelihood of the implicated

TABLE 157-7 Rabies Postexposure Prophylaxis Schedule—United States, 2010

Immunization Status	Treatment	Regimen*
Not previously immunized	Wound cleansing	Cleanse all wounds with soap and water; irrigate wounds with 9:1 diluted solution of povidone-iodine (if available).
	HRIG	Administer **20 IU/kg actual body weight**. If anatomically feasible, infiltrate the *full dose* around the wound(s) and give any remaining volume IM at an anatomic site distant from vaccine administration; do not give HRIG in the same syringe as vaccine. HRIG may partially suppress active production of rabies virus antibody, so **do not give more than the recommended dose**.
	Vaccine	HDCV or PCECV 1.0 mL (deltoid area†), one dose on days 0,‡ 3, 7, and 14.#
Previously immunized[f]	Wound cleansing	Cleanse all wounds with soap and water; irrigate wounds with 9:1 povidone-iodine solution.
	HRIG	HRIG should *not* be administered.
	Vaccine	HDCV or PCECV 1.0 mL (deltoid area†), one dose on days 0‡ and 3.

Abbreviations: HDCV = human diploid cell vaccine; HRIG = human rabies immunoglobulin; PCECV = purified chick embryo cell culture vaccine.

*These regimens are appropriate for all age groups, including children.

†The deltoid area is the only acceptable site of vaccination for adults and older children. For younger children, the outer aspect of the thigh (anterolateral aspect) may be used. Vaccine should never be administered in the gluteal area.

‡Day 0 is the day the first dose of vaccine is administered.

#Day 28 vaccine dose no longer recommended by the Advisory Committee on Immunization Practices, **unless the patient is immunocompromised** (see later section, Immunocompromised Persons). See http://www.cdc.gov/rabies/resources/acip_recommendations.html.

[f]Any persons with a history of preexposure prophylaxis with HDCV or PCECV; prior postexposure prophylaxis with HDCV or PCECV; or previous immunization with any other type of rabies vaccine and a documented history of antibody response to the prior immunization.

animal being rabid, the category of exposure (i.e., I, II, or III), and the clinical features of the animal, as well as its availability for observation and laboratory testing. In most situations in developing countries, the vaccination status of the implicated animal alone should not be considered when deciding whether to give or withhold prophylaxis.

For IM administration, the World Health Organization recommends the following postexposure regimens. The postexposure vaccination schedule is based on injecting 1 mL or 0.5 mL (volume depends on the type of vaccine) into the deltoid muscle (or anterolateral thigh in children <2 years of age) of patients with category II and III exposures. The recommended regimen consists of either a 5-dose or a 4-dose schedule:

- The five-dose schedule consists of one dose on each of days 0, 3, 7, 14, and 28.
- The four-dose schedule consists of two doses on day 0 (one dose in each of the two deltoid or thigh sites) followed by one dose on each of days 7 and 21.

An alternative for healthy, fully immunocompetent, exposed persons who receive wound care plus high-quality rabies immunoglobulin plus World Health Organization–prequalified rabies vaccines is a postexposure regimen consisting of four doses administered intramuscularly on days 0, 3, 7, and 14.

For intradermal administration, the World Health Organization recommends the following postexposure regimen: The two-site regimen prescribes injection of 0.1 mL at two sites (deltoid and thigh) on days 0, 3, 7, and 28. This regimen may be used for people with category II and III exposures in countries where the intradermal route has been endorsed by national health authorities.

POSTEXPOSURE PROPHYLAXIS IN SPECIAL POPULATIONS

Persons with Prior Rabies Immunization If exposed to rabies, persons previously vaccinated should receive two intramuscular doses (1 mL each) of vaccine, one immediately and one 3 days later.[14,17] "Previously vaccinated" refers to persons who have received one of the recommended preexposure or postexposure prophylaxis regimens of human diploid cell vaccine or purified chick embryo cell culture vaccine, or those who have received another vaccine and had a documented acceptable rabies antibody titer. HRIG is unnecessary and should not be given in these cases, because an anamnestic antibody response will follow the administration of a booster regardless of the prebooster antibody titer.

Immunocompromised Persons Immunization of immunocompromised persons presents special challenges. First, vaccines may represent a danger to the immunocompromised individual. Second, the immune response to vaccination may be insufficient. Higher doses or additional immunizations may be required, and even with these modifications, the immune response may be suboptimal. The severely immunocompromised are those who have congenital immunodeficiency, human immunodeficiency virus infection, leukemia or lymphoma, aplastic anemia, or generalized malignancy, or who are being treated with alkylating agents, antimetabolites, radiation, or large amounts of corticosteroids.[17]

Because rabies vaccine is formulated with inactivated virus, it does not represent a danger to immunocompromised persons and may be administered to such persons using the standard recommended doses and schedule (**Table 157-7**). However, a five-dose schedule should be used in immunocompromised persons.[17]

The recommendations for the use of HRIG are the same for immunocompromised and immunocompetent persons. However, corticosteroids, antimalarials, other immunosuppressive agents, and immunosuppressive illnesses can interfere with the development of active immunity and predispose the patient to developing rabies. **Immunosuppressive agents should not be administered during postexposure prophylaxis, unless they are essential for the treatment of other conditions.** When rabies postexposure prophylaxis is administered to persons receiving steroids or other immunosuppressive therapy, it is especially important that serum be tested for rabies antibody to ensure that an adequate response has developed.[12] To confirm the adequacy of the immune response, serum collected 1 to 24 weeks after the postexposure prophylaxis course should completely neutralize challenge virus at a 1:5 serum dilution, as measured by a rapid fluorescent focus inhibition test.[12] If no acceptable antibody response is detected, consult an infectious disease expert and appropriate public health officials.

Travelers Preexposure prophylaxis is recommended for certain international travelers based on the local incidence of rabies in the countries to be visited, the availability of appropriate antirabies biologicals, and the intended travel activity.[21,22] Such persons include veterinarians, animal handlers, field biologists, spelunkers, missionaries, and certain laboratory workers. **Chloroquine phosphate** (and possibly other structurally related antimalarials such as mefloquine, which is administered for malaria chemoprophylaxis) **may interfere with the antibody response to intradermal rabies vaccine administered for preexposure prophylaxis.** The IM route, not the intradermal route, should be used for people taking chloroquine concurrently (the intradermal route is not approved for use in the United States); ideally, the rabies preexposure vaccination series should be completed before beginning chloroquine.

Between 2001 and June 2010, six persons died in the United States from rabies after having been bitten by a dog (another died after being bitten by a fox) while visiting a foreign country. For this reason, all persons who have returned from abroad should be questioned regarding whether they received an animal bite or scratch in an area with endemic rabies. Persons bitten or scratched by an animal in an area with endemic rabies should receive appropriate postexposure prophylaxis if the injury has occurred within the known incubation period (which may rarely extend up to 5 or more years).

U.S. citizens and residents who are exposed to rabies while traveling in countries where rabies is endemic may sometimes receive postexposure prophylaxis with regimens or biologicals that are not used in the United States. If postexposure prophylaxis is begun outside the United States using a regimen or biological of nerve tissue origin not approved by the U.S. Food and Drug Administration, it may be necessary to provide additional treatment when the patient reaches the United States.[12] State and local health departments should be contacted for specific advice in such cases. The major modification used abroad, usually in an attempt to reduce cost, is the substitution of various schedules for intradermal injection or the use of vaccines not approved by the U.S. Food and Drug Administration.

Pregnant Women **Adverse pregnancy outcomes or fetal abnormalities have not been associated with rabies vaccination.** Because of the potential consequences of inadequately treated rabies exposure and because adverse events have not been associated with rabies postexposure prophylaxis during pregnancy, pregnancy is not considered a contraindication to rabies postexposure prophylaxis or HRIG.[12] If there is substantial risk of exposure to rabies, preexposure prophylaxis may also be indicated during pregnancy.

Children The dose of rabies vaccine for preexposure and postexposure prophylaxis is the same in infants and children as in adults (**Table 157-7**).[12] The dose of HRIG for postexposure prophylaxis is based on actual body weight. For small children with multiple bites, the calculated dose of HRIG may be insufficient to infiltrate all wounds. However, sterile saline can be used to dilute the volume twofold or threefold to permit thorough infiltration.[21]

CLINICAL RABIES

Rabies virus causes **acute encephalitis** in all warm-blooded hosts, including humans, and the outcome is almost always fatal. Although patients with rabies may manifest a variety of clinical symptoms and signs, the disease tends to follow a characteristic course (**Table 157-8**).

Most commonly, the incubation period after a bite ranges from 20 to 90 days.[2] However, incubation periods have been reported that are as short as 4 days and as long as 6 years. For patients who died from rabies in the United States between 1980 and 1996 and in whom a definite animal bite occurred, the median incubation period was 85 days (range, 53 to 150 days).[23] The incubation period is shorter when the site of the bite is on the head than when it is on an extremity.[2]

TABLE 157-8 Natural History of Clinical Rabies in Humans after Incubation Period

Clinical Stage	Defining Event	Usual Duration	Common Symptoms and Signs*
Prodrome	First symptom	2–10 d	Pain or paresthesia at site of bite Malaise, lethargy Headache Fever Nausea, vomiting, anorexia Anxiety, agitation, depression
Acute neurologic phase	First neurologic sign	2–7 d	Anxiety, agitation, depression Hyperventilation, hypoxia Aphasia, incoordination Paresis, paralysis Hydrophobia, pharyngeal spasms Confusion, delirium, hallucinations Marked hyperactivity
Coma	Onset of coma	0–14 d	Coma Hypotension, hypoventilation, apnea Pituitary dysfunction Cardiac arrhythmia, cardiac arrest
Death or recovery (extremely rare)	Death or initiation of recovery	Months (recovery)	Pneumothorax Intravascular thrombosis Secondary infections

*Not every symptom or sign may be present in each case.

CLINICAL FEATURES

During the prodrome, the symptoms and signs are nonspecific. Early in the course, some patients may report symptoms suggestive of rabies such as limb pain, limb weakness, and paresthesias at or near the presumed exposure site. The prodrome merges into the acute neurologic phase, which begins when the patient develops objective signs of CNS disease.

There are two clinical forms of rabies: an encephalitic form in 80% and a paralytic form in 20%.[11] In encephalitic rabies, there are often episodes of generalized arousal or hyperexcitability, disorientation, hallucinations, and bizarre behavior, often separated by lucid intervals. Autonomic dysfunction is common and includes hypersalivation, hyperthermia, tachycardia, hypertension, piloerection, cardiac arrhythmias, and priapism. Paralytic rabies generally begins with paresis in the bitten extremity with spread to quadriparesis and bilateral facial weakness. There is progression of paralytic rabies to coma and organ failure, typically with a longer clinical course than in encephalitic rabies.[11] About 50% of patients have classic hydrophobia, in which attempts to drink fluids result in severe spasms of the pharynx, larynx, and diaphragm.

Coma almost always occurs within 10 days of the onset of symptoms. Death occurs due to a variety of complications, including pituitary dysfunction, seizures, respiratory dysfunction with progressive hypoxia, cardiac dysfunction with dysrhythmias and arrest, autonomic dysfunction, renal failure, and secondary bacterial infections.

Only seven patients are known to have survived rabies. In all but one case, the patient had received either postexposure or preexposure prophylaxis with rabies vaccine (e.g., duck embryo, suckling mouse brain) before the onset of symptoms.

DIAGNOSIS AND TREATMENT

Rabies should be included in the differential diagnosis of any patient with unexplained acute, rapidly progressive encephalitis, especially in the presence of anatomic instability, dysphagia, hydrophobia, paresis, or parasthesias.[24-27] Diseases that may be confused with rabies include tetanus, poliomyelitis, Guillain-Barré syndrome, botulism, transverse myelitis, postvaccinal encephalomyelitis, intracranial mass lesions, cerebrovascular accidents, poisoning with atropine-like compounds, and infectious causes of viral encephalitis (e.g., herpes simplex, varicella zoster, arthropod-borne viral encephalitis such as eastern equine encephalitis). Emerging diseases that can be confused with rabies include West Nile virus (United States, Europe, Middle East, Africa), Toscana virus (Europe), Japanese encephalitis (Asia), enterovirus 71 (Asia), human herpes virus 6 (worldwide), chikungunya fever (Asia, Africa, Europe), Nipah virus (Asia), and Hendra virus (Asia).[28,29]

The diagnosis of rabies is frequently made postmortem. This occurs because of the rarity of the disease, the increasing number of persons without an obvious exposure, and clinical confusion with other disorders. Important clues to diagnosis include a history of an animal bite or bat exposure and the development of the pathognomonic signs of hydrophobia and aerophobia (precipitating grimacing and other signs by blowing air on the patient's face).

During the incubation period of rabies, no diagnostic test is available for animals or humans that will indicate infection. Once symptoms become evident, antigen and antibody testing of serum, cerebrospinal fluid, saliva, and tissue, such as cornea, brain biopsy, and skin from highly innervated locations (e.g., nuchal skin biopsy), can detect evidence of the disease.[4] Serum antibodies may be present as early as day 5 of clinical illness, but antibodies may be absent after 10 to 14 days or longer. CT of the brain is only useful to exclude other diseases. MRI of the brain may be normal or may show lesions in gray matter areas of the brain parenchyma, including the brainstem. Cerebrospinal fluid analysis often shows a mild mononuclear pleocytosis.

No specific therapy has been of demonstrated benefit in clinical rabies.[4] Treatment with rabies vaccine, rabies immunoglobulin, IV ribavirin, or interferon is not effective.[30] In animal models, use of corticosteroids shortens the incubation time and increases mortality, and for this reason **steroids are contraindicated**. Survival with normal neurologic function was reported for a 15-year-old girl in whom coma was induced and treatment with ketamine, midazolam, ribavirin, and amantadine was provided.[30] However, similar regimens have been used for more than 20 other patients without success.[30] Currently, treatment is directed at the clinical complications of the disease. Although rabies is not treatable, every attempt should be made to achieve rapid diagnosis, because it justifies public health measures to limit contacts with the patient and permits reconstruction of a history to identify others who may have been exposed to the same infective source.

CHAPTER 158

Malaria

Malcolm Molyneaux

INTRODUCTION

Malaria, a protozoan disease transmitted by the bite of the *Anopheles* mosquito, is one of mankind's most feared and serious afflictions. It is a leading cause of morbidity and mortality in many tropical areas of the world, especially in Africa. Approximately 55% of the world's population is exposed to the infection, which exerts its toll mainly on the young and the pregnant. Malaria is endemic or sporadic throughout most of the tropics and subtropics below an altitude of 1500 m, excluding the Mediterranean littoral, the United States, and Australia. Malaria is perhaps the most significant disease acquired through international travel to the tropics.

Five species of the genus *Plasmodium* infect humans: *Plasmodium vivax, Plasmodium ovale, Plasmodium malariae, Plasmodium falciparum*, and *Plasmodium knowlesi.* In 2012, there were an estimated 207 million cases of symptomatic malaria worldwide (80% of which occurred in Africa), with about 627,000 deaths, 90% of which occurred in Africa, and with nearly 77% of those occurring in young children.[1] The great majority of malaria deaths are due to *P. falciparum* infections, although both *P. vivax* and *P. knowlesi* can also cause fatal disease.

The incidence of malaria has decreased dramatically in some countries in recent years as a result of intensive control efforts (e.g., South Africa), but elsewhere there has been little change, and some areas have experienced increases or epidemics (e.g., Algeria, Venezuela). In the United States, more cases of imported malaria were identified in 2011 than in any year since 1971.[2] Obstacles to successful reduction of malaria worldwide include human factors (poverty, war, inadequate international cooperation), capacities of the mosquito vector (changing temperatures, insecticide resistance) and parasite characteristics (antimalarial drug resistance).

In an area of intense transmission, most malaria infections occur in children, who gradually acquire a considerable degree of immunity. In such areas, a high percentage of children may have asymptomatic parasitemia (**malaria infection**), and illness due to malaria (**malaria disease**) is commonly mild and only occasionally severe or life threatening. Nevertheless, the absolute burden of mortality is large because nearly all children are infected. Adults in such areas rarely develop severe or fatal disease.

By contrast, malaria due to *P. falciparum* is a medical emergency in a nonimmune host of any age, because the infection, if untreated, is likely to progress and to become life threatening. Once a *P. falciparum* infection has reached the stage of severe disease, there is a 5% to 30% risk of a fatal outcome, even if optimal treatment is then begun. The early clinical features of malaria are nonspecific, and malaria can mimic many other infections. A diagnosis of malaria must be considered in any person returning from the tropics with an unexplained febrile illness and must be considered in any resident in the tropics who develops a fever.

EPIDEMIOLOGY

Malaria transmission occurs in large areas of Central and South America, the Caribbean, sub-Saharan Africa, the Indian subcontinent, Southeast Asia, the Middle East, and Oceania. Certain species may predominate in a given geographic area.[3] For example, *P. vivax* is more common in the Indian subcontinent, whereas *P. falciparum* is the most prevalent form in Africa, Haiti, and New Guinea. *P. knowlesi* has been found in several countries in southeast Asia, including Malaysia, Myanmar (Burma), Thailand, the Philippines, and Singapore.[4]

The risk of contracting malaria varies considerably between regions. In 2011, the Centers for Disease Control and Prevention reported 1925 cases of malaria among persons in the United States.[2] Of 1655 imported cases where the region of acquisition was known, 1144 (69%) were acquired in Africa (63% of these in West Africa), 363 (22%) in Asia (68% of these in India), 104 (6.3%) in the Caribbean and Central America, 35 (2%) in South America, and 7 (<1%) in Oceania. *P. falciparum* accounted for 49% and *P. vivax* for 22% of all cases (although in many cases, the parasite species was not identified). Thus, almost half of all cases of malaria, including the majority of cases due to *P. falciparum,* were acquired from travels in West Africa, despite the fact that for every traveler to sub-Saharan Africa, at least 10 travelers visit potential malarious areas of Asia and South America each year. Complications developed in 14% of the reported cases of malaria identified in the United States in 2011, and five patients died (1.8% of the 275 severe cases).

P. knowlesi is a zoonosis. Macaques (old world monkeys) are the natural host. Members of the *Anopheles leucosphyrus* groups are equally attracted to humans and monkeys, which has given rise to human cases. The forest fringe habitat of this mosquito will hopefully limit the spread of this species of parasite.[5]

Resistance of *P. falciparum* to chloroquine has been widespread for many years.[6] Strains of *P. falciparum* have since become resistant to other chemotherapeutic agents, including pyrimethamine-sulfadoxine (no longer recommended as first-line treatment; can be used in pregnancy), quinine, mefloquine, and doxycycline.[7] Widespread mefloquine-resistant strains of *P. falciparum* have been seen in parts of Thailand, Myanmar (Burma), Cambodia, and China. Of greatest current concern is the observation in Cambodia and in parts of Thailand that parasites are slower to respond to artemisinin therapy than a few years ago.[8] There has not yet been evidence of impaired cure rates with artemisinin therapy, but worldwide vigilance is required to track the continuing efficacy of this important class of drugs. Resistance of *P. vivax* to chloroquine has also been identified in Southeast Asia.[9]

PATHOPHYSIOLOGY

The organism is transmitted primarily by the bite of an infected female *Anopheles* mosquito, which requires a blood meal every 3 to 4 days to nourish its eggs. This vector is most frequently found in tropical and subtropical regions below 1500 m (5000 ft) above sea level. Plasmodial sporozoites are injected into the host's bloodstream during the mosquito's blood meal and are carried through the bloodstream to the liver. Within hours, the hepatic parenchymal cells are invaded, and asexual reproduction of the parasite begins (pre-erythrocytic schizogony or exoerythrocytic stage). After thousands of daughter merozoites have been formed within a hepatocyte (amplification cycle), the cell ruptures, releasing daughter merozoites into the circulation, where they rapidly invade erythrocytes to begin the erythrocytic stage of the asexual cycle. In *P. vivax* and *P. ovale* infection, a portion of the intrahepatic forms are not released, but remain dormant as **hypnozoites**, which can reactivate after months or years to cause clinical relapses.

Once merozoites enter the erythrocytic stage, they do not reinvade the liver. A merozoite matures within the erythrocyte, feeding on hemoglobin and enlarging until it divides into about a score of daughter merozoites to form a schizont. Eventually, the infected erythrocyte lyses, merozoites are released, and these invade uninfected red blood cells, continuing and amplifying the infection.

A portion of the merozoites develop into sexual forms (gametocytes). Upon ingestion by another feeding *Anopheles* mosquito, male and female gametocytes undergo sexual reproduction within the vector's gut and migrate as infective sporozoites to her salivary glands. To maximize her blood meal, the mosquito injects her next victim with saliva containing an anticoagulant, which introduces the malarial infection. The rate at which parasites replicate and migrate in the mosquito is temperature dependent; at average environmental temperatures below about 15°C (59°F), the cycle does not complete before the death of the mosquito, and malaria transmission cannot occur.

The clinical signs of malaria first appear during the erythrocytic stage. The rupture of schizont-containing erythrocytes triggers an array of host cytokine responses, giving rise to fever and other features of the malarial illness. Because fever slows the rate of schizont formation, early-stage parasites tend to catch up with more mature stages, and therefore over time, schizont rupture may become synchronous, giving rise to the periodic fever characteristic of untreated malaria. Such periodicity rarely has time to develop when malaria is treated promptly with efficacious drugs.

Each species of *Plasmodium* has specific characteristics, including typical morphologic forms and selective red blood cell tropism (**Table 158-1**). Many of these characteristics are responsible for important pathophysiologic consequences.

Anemia can develop rapidly with *P. falciparum* infection because the percentage of erythrocytes parasitized can be overwhelming (erythrocytes of all ages are susceptible to invasion) and because the lifespan of uninfected erythrocytes is also reduced, while bone marrow erythropoiesis is slowed or halted. *P. falciparum* asexual parasites transport to the red cell surface proteins that can adhere to host endothelial receptors, resulting in the sequestration of mature parasites in the microvasculature of many tissues and organs. Sequestration may be enhanced by the impaired deformability of infected erythrocytes and consequent slowing of blood flow through microvessels. Sequestration benefits parasites by keeping them away from the spleen, but additional consequences for the host include metabolic deprivation and/or impaired perfusion of tissues, processes that are believed to contribute to many of the syndromes characteristic of

TABLE 158-1 Characteristics of Malaria-Causing *Plasmodium* Species

	P. falciparum	*P. vivax*	*P. ovale*	*P. malariae*	*P. knowlesi*
Clinical Characteristics					
Incubation period	8–25 d	8–27 d	9–17 d	15–30 d	Uncertain
Chloroquine resistance	Yes	Rare	No	No	No
Fatal attack	Yes	No	No	No	No
Relapse	No	Yes	Yes	No	No
Histologic Characteristics					
Asexual erythrocytic cycle	48 h	48 h	48 h	72 h	Uncertain
RBC preference	Reticulocytes (but can infect RBCs of all ages)	Reticulocytes	Reticulocytes	Older cells	All RBCs
Degree of parasitemia	High (multiple rings per RBC)	Low	Low	Low	Can be high
Ring forms and early trophozoites	Ring forms predominate; threadlike cytoplasm with double-chromatic dots	Amoeboid cytoplasm	Compact cytoplasm	Compact cytoplasm	Ring forms sometimes seen
Mature trophozoites	Rarely seen	Observed	Observed	Observed	Observed
Schizonts	Rarely seen	Observed	Observed	Observed	Observed
Gametocytes	Banana shaped	Round	Round	Round	Round
Circumference of infected red cell	Normal	Enlarged	Oval, with ragged (fimbriated) ends	Normal	Normal
Appearance of red cell cytoplasm	Normal	Stippled (fine Schuffner's dots)	Larger Schuffner's dots	Normal	Normal

Abbreviation: RBC = red blood cell.

severe falciparum malaria. Acidosis, for example, results from tissue hypoxia, to which sequestration, hypotension, and severe anemia may all contribute. Hypoglycemia occurs largely due to impaired hepatic gluconeogenesis, possibly enhanced by the consumption of glucose by actively metabolizing parasites and the diversion of glucose for the host's anaerobic glycolysis. Sequestration accounts for the paucity of observed mature parasites in the peripheral smear of patients infected with *P. falciparum*.

Although nearly all malaria transmission is mediated by mosquito vectors, plasmodia of any species may also be transmitted by transfusion of infected blood, by needlestick accident, or across the placenta from mother to fetus. In these cases, an exoerythrocytic phase is absent, and hypnozoites of *P. vivax* or *P. ovale* cannot develop.

Untreated, inadequately treated, or frequent malaria may lead to sequelae mediated by immunologic mechanisms, including massive splenomegaly with consequent hypersplenism, and glomerulonephritis leading to a nephrotic syndrome (attributed, without strong evidence, mainly to *P. malariae* infection). Thrombocytopenia (rarely sufficient to cause bleeding) is invariable in acute symptomatic malaria.

INCUBATION PERIOD

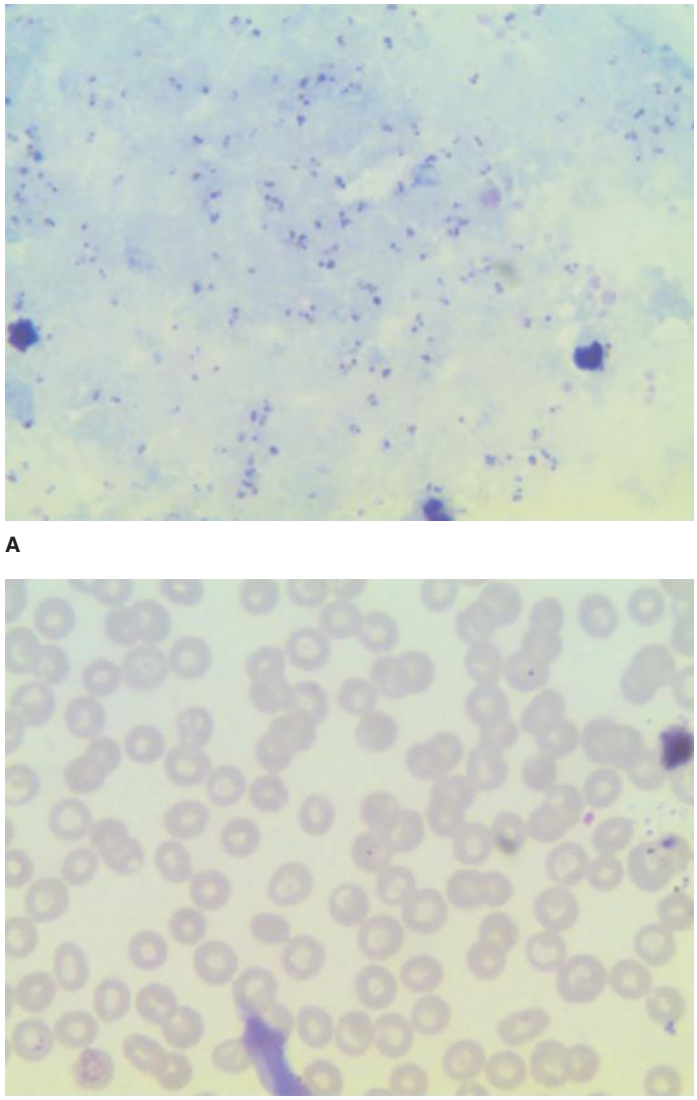
The incubation period between infection and symptoms varies with the species of parasite (Table 158-1). In the nonimmune, symptoms begin after an incubation period ranging from 7 days to several weeks or more. Incomplete suppression of disease by partially active chemoprophylaxis and partial immunity can prolong the incubation period to months or even years. For U.S. residents who developed malaria associated with travels abroad during 2011, disease became evident within 1 month after arrival home in 95% of *P. falciparum* cases, but in only 52% of *P. vivax* cases. The interval between arriving in the United States and becoming ill was between 3 and 12 months in 46% of *P. vivax* cases and 5% of *P. falciparum* cases. Six patients (0.6% overall) became ill more than 1 year after returning to the United States.[2]

CLINICAL FEATURES

UNCOMPLICATED MALARIA

The clinical hallmark of malaria is fever, with a prodrome of malaise, myalgia, headache, and chills.[10] In some patients, chest pain, cough, abdominal pain, or arthralgias may be prominent. Early symptoms are nonspecific and can easily be confused with a viral syndrome such as influenza or hepatitis or with bacterial sepsis. In a nonimmune individual, the illness usually progresses to include chills, followed by high-grade fever accompanied by nausea, orthostatic dizziness, and extreme weakness. After several hours, the fever abates and the patient develops diaphoresis and becomes exhausted. If the infection is untreated, the paroxysms of malaria—chills and fever followed by diaphoresis—may over time begin to occur at nearly regular intervals that correspond to the length of the asexual erythrocytic cycles (Table 158-1). The classic paroxysms of malaria are often lacking in malaria due to *P. falciparum* or in persons who received some form of chemoprophylaxis. The findings upon physical examination are also not specific for malaria. Most patients appear acutely ill with high fever, tachycardia, and tachypnea. Splenomegaly and abdominal tenderness are common. The liver may or may not be enlarged. Clinical signs that point to a diagnosis other than (or in addition to) malaria include lymphadenopathy and a maculopapular or petechial skin rash.

In children growing up in a malarious area, attributing an illness to malaria is particularly difficult because many children carry parasites without being unwell and because symptoms and signs of both mild and severe malaria are nonspecific.[11] In these circumstances, the higher the parasite density in the peripheral blood, the greater is the likelihood that malaria is the cause of the illness.



SEVERE (COMPLICATED) MALARIA

Malaria is described as severe or complicated when it includes one or more of the following syndromes in the context of a plasmodial infection, usually due to *P. falciparum*: coma with or without seizures ("cerebral malaria"), prostration, severe anemia, acidosis, hypoglycemia, acute renal failure, acute respiratory distress syndrome, pulmonary edema, jaundice, intravascular hemolysis, shock, and disseminated intravascular coagulation. The percentage of malaria cases imported to the United States that were classified as severe increased significantly from 18% of 1691 cases in 2010 to 22% of 1925 cases in 2011.[2]

Complications of malaria can develop rapidly in untreated *P. falciparum* infection or may supervene early in the course of treatment. Occasionally, one or more complications may constitute the presenting illness, when correct diagnosis may be both difficult and critically important. A patient with severe malaria is at risk of dying even with optimal case management. Case fatality rates range between 5% and 30% in patients receiving treatment for severe malaria according to the complications present and their intensity.

FIGURE 158-1. Retinal examination in a child with cerebral malaria. Note the patches of whitening around the fovea (dark area 2.5 disc diameters from the disc, right of field). Note also scattered white-centered hemorrhages. [Photo contributed by Ian McCormick, MD.]

A **B**

FIGURE 158-2. **A.** Thick and **B.** thin blood microscopy films from different children with malaria. The thick film shows numerous parasite nuclei, each with a faint blush of cytoplasm, seen either as a ring or as a smudge beside the nucleus. The thin film shows a single early ring stage of *P. falciparum* (center of field). The absence of dots in the erythrocyte cytoplasm and the normal size and shape of the erythrocyte distinguish this from *P. vivax* and *P. ovale*.

When cerebral malaria is suspected, meningitis or encephalitis must be either excluded or treated, and the clinician must decide whether a lumbar puncture is safe. At lumbar puncture, the opening pressure is usually raised in children and normal in adults. The fluid is normal in appearance and on routine tests. In children in *P. falciparum*–endemic areas, asymptomatic parasitemia is common, so it is difficult to be sure that an illness is due to malaria. In a child with coma and parasitemia, the presence of a recently identified retinopathy (**Figure 158-1**) greatly strengthens confidence that malaria is the cause of the syndrome.[12] Among those who recover from cerebral malaria, up to 1 in 5 children and up to 1 in 20 adults may be left with, or may later develop, neurologic sequelae.

Infections caused by any species of *Plasmodium* can result in hemolysis, some degree of anemia, splenic enlargement, and, occasionally, splenic rupture.

The very young, the elderly, and pregnant women are at greatest risk of developing complications when infected with *P. falciparum*.[13] Additional risk factors for severe malaria include an immunocompromised state, asplenia, failure to take appropriate chemoprophylaxis, refusal of or delay in seeking medical care, and late or erroneous diagnosis.[14]

DIAGNOSIS

The diagnosis of malaria rests on a history of potential exposure in a malarious area, clinical symptoms, signs, and competent microscopic examination of well-prepared thick and thin blood films (**Figure 158-2**). Diagnosis based on clinical features alone has very low specificity and results in overtreatment.[1]

The three major questions to be answered by the blood smear are as follows: (1) Is there evidence of malaria? (2) If so, what is the density of parasitemia (correlates with prognosis)? (3) What species of malaria is responsible for the infection and, in particular, is *P. falciparum* present? Clues to the diagnosis of *P. falciparum* infection include the presence of small ring forms with double-chromatin dots within the erythrocyte, multiple infected rings in individual red blood cells, a paucity (usually absence) of mature trophozoites and schizonts on smear, and infected erythrocytes that are not enlarged and that have cytoplasm without basophilic stippling. In some (but not all) cases, gametocytes may be seen; in *P. falciparum* infection, these have a diagnostic crescent shape (banana shape). Parasite densities above 4% of erythrocytes are rare in malaria due to nonfalciparum species. Obtain smears daily to assess the efficacy of drug treatment.

P. knowlesi is usually misdiagnosed as the less aggressive *P. malariae*, because the two are identical under light microscopy and require polymerase chain reaction for differentiation. Any patient coming from Asia with a high parasite burden resembling *P. malariae* should be assumed to be harboring *P. knowlesi*.[4]

THICK BLOOD FILM

Place a small drop of blood (5 µL) on a microscope slide, spread it evenly to a diameter of ~1 cm, allow it to dry, and then stain, without initial fixation, with Fields or Giemsa stain. Record the result as the number of parasites seen per oil-immersion field (for an approximate indication of density) or per 200 white cell nuclei counted (a more accurate density

of parasites can then be calculated once the WBC count is known). A thick blood film contains several layers of red cells (which are lysed by the staining procedure), allowing parasitemias down to ~40/μL to be detected by an expert microscopist.

THIN BLOOD FILM

A standard hematologic blood smear (fixed with methanol and stained with Giemsa) allows a single sheet of intact red cells to be scrutinized for the percentage of red cells parasitized, from which the number of parasites per microliter can be calculated when the red cell count is known. Because the red cells are not destroyed, a thin film allows both parasite and red cell morphology to be examined, enabling more confident identification of the species of plasmodium. A thin film may fail to detect a parasitemia with a density below ~1000/μL, but it is more useful than a thick film for counting very heavy infections.

A long and careful search for parasites is necessary before a film is declared "negative." In early infection, especially infection due to *P. falciparum*, in which mature-stage parasitized erythrocytes are sequestered from the bloodstream, parasitemia may be undetectable even in a competently read thick blood film. **In highly suspicious cases, failure to detect parasitemia is not an indication to withhold therapy.** If parasites are not seen in the stained thin smear, a thick smear must be done. If parasites are not seen on the first thick film, obtain repeat thick smears at least twice daily for as long as malaria remains a suspected diagnosis or until the patient is better. The first smear is positive in >90% of cases.[15]

ADDITIONAL DIAGNOSTIC TECHNIQUES

Newer techniques for rapid diagnosis and speciation include quantitative buffy coat fluorescent microscopy and rapid diagnostic tests (dipstick bedside tests) to detect parasite antigens (BinaxNOW®, ParaSight-F®) or to detect the parasite enzyme lactate dehydrogenase (OptiMal).[16] Sensitivity of rapid tests is excellent for *P. falciparum* malaria with high parasitemia levels, but poor for nonfalciparum malaria, and sensitively drops with lower parasitemia levels. Polymerase chain reaction–based techniques to detect parasite DNA are more sensitive than microscopy and are valuable for research studies but are rarely available for routine clinical purposes.

ADDITIONAL LABORATORY STUDIES

Nonspecific laboratory features of malaria include normochromic normocytic anemia with findings suggestive of hemolysis, a normal or mildly depressed total leukocyte count, thrombocytopenia, an elevated erythrocyte sedimentation rate, mild abnormalities in liver and renal functions, and a biologic false-positive Venereal Disease Research Laboratory test. In severe *P. falciparum* malaria, there may be hypoglycemia, severe anemia, hyperlactatemia, electrolyte disturbances, or evidence of acute renal failure or disseminated intravascular coagulation.

TREATMENT

Treatment decisions are based on the severity of the illness and the species of the infecting parasite determined by microscopic examination of thick and thin blood films.

UNCOMPLICATED (NONSEVERE) MALARIA DUE TO *P. FALCIPARUM*

Admit the patient to the hospital because severe disease can develop rapidly even after the start of specific therapy. Give analgesia if required (e.g., acetaminophen, 500 milligrams every 6 hours PO) and oral fluids. If the patient can take and retain drugs by mouth, begin a full course of oral antimalarial drugs without delay (**Table 158-2**). Artemisinin-containing combination therapies are considered the drugs of choice by the World

TABLE 158-2 Drug Options for Therapy of Uncomplicated *Plasmodium falciparum* Malaria

Treatment of choice is an artemisinin-containing combination therapy (ACT)		
Drug	**Adult Dose**	**Pediatric Dose**
Artemether-lumefantrine (CoArtem®; each tablet contains artemether 20 milligrams and lumefantrine 120 milligrams)	4 tablets twice daily for 3 d (the first 2 doses should be about 8 h apart)	5–15 kg: 1 tab initially, 1 tablet in 8 h, then 1 tablet every 12 h × 2 d 15–25 kg: 2 tablets initially, 2 tablets in 8 h, then 2 tablets every 12 h × 2 d 25–35 kg: 3 tablets initially, 3 tablets in 8 h, then 3 tablets every 12 h × 2 d >35 kg: follow adult dosing
Artesunate-amodiaquine (where available; not available in the United States; each adult tablet contains artesunate 100 milligrams and amodiaquine hydrochloride salt 270 milligrams)	2 tablets once daily for 3 d	5 to <9 kg: 1 tablet/day of artesunate (AS) 25 milligrams/amodiaquine (AQ) 67.5 milligrams 9 to <18 kg: 1 tablet/day of AS 50 milligrams/AQ 135 milligrams 18 to <36 kg: 1 tablet/day of AS 100 milligrams/AQ 270 milligrams ≥36 kg: 2 tablets/day of AS 100 milligrams/AQ 270 milligrams (adult dose)
Alternatives to ACT		
Drug	**Adult Dose**	**Pediatric Dose**
Atovaquone-proguanil (Malarone®; each adult tablet contains atovaquone 250 milligrams and proguanil 100 milligrams; each pediatric tablet contains atovaquone 62.5 milligrams and proguanil 25 milligrams)	4 tablets once daily for 3 d. Do not use for treatment if atovaquone-proguanil has been taken as chemoprophylaxis and the patient's current illness is a suspected treatment failure.	5–8 kg: 2 pediatric tablets × 3 d 9–10 kg: 3 pediatric tablets × 3 d 11–20 kg: 1 adult tablet × 3 d 21–30 kg: 2 adult tablets × 3 d 31–40 kg: 3 adult tablets × 3 d >41 kg: adult dose
Quinine sulfate (plus doxycycline or clindamycin)	650 milligrams PO every 8 h for 3–7 d	10 milligrams sulfate salt/kg, up to adult dose PO every 8 h for 3–7 d
Plus		
Doxycycline	100 milligrams PO every 12 h for 7 d	2.2 milligrams/kg (up to adult dose of 100 milligrams) PO every 12 h for 7 d
Or in children under age 8 y		
Clindamycin		7 milligrams/kg PO every 8 h for 7 d

Health Organization.[1,17] If a dose is vomited, the dose may be repeated; if it is vomited again, switch to parenteral therapy as for severe disease (see Table 158-3) until able to resume treatment by mouth. Maintain regular checks for the development of any complications (listed above under "Clinical Features"). Check blood daily for parasite density and for hemoglobin concentration. When stable, the patient may be discharged to complete the course of oral drugs at home; stress the importance of completing the course and of reporting back with any recurrence of symptoms.

The World Health Organization does not recommend chloroquine for the treatment of *P. falciparum* malaria due to changing resistance patterns and the superiority of artemisinin-containing combination therapies.[1,17] As of July of 2013, the Centers for Disease Control and Prevention recommend chloroquine for *P. falciparum* malaria imported from areas of low chloroquine resistance including Central America west of the Panama Canal, Haiti, the Dominican Republic, and parts of the Middle East.[18,19] Dose options are listed at the Centers for Disease Control and Prevention malaria Web site (http://www.cdc.gov/malaria/).

UNCOMPLICATED MALARIA DUE TO *P. VIVAX, P. MALARIAE, P. OVALE,* OR *P. KNOWLESI*

Admission to the hospital should not be necessary in most cases; however, if *P. knowlesi* is suspected, hospital admission is recommended. Dual infection with *P. falciparum* and any of the other species is possible. Make sure that the initial and subsequent slides are carefully scrutinized for evidence of *P. falciparum,* because severe disease may then develop even while on treatment. Give simple analgesia and fluids as required. Treat nonfalciparum malaria with chloroquine (each tablet contains 250 milligrams of salt = 150 milligrams of base); the adult dose is four tablets initially, then two tablets after 6 hours, then two tablets daily for 2 days. The pediatric dose is 16.7 milligrams (salt)/kg PO immediately, followed by 8.3 milligrams (salt)/kg PO at 6, 24, and 48 hours. Alternatively, an artemisinin combination therapy can be given (see Table 158-3 for dosage). *P. vivax* malaria acquired from an area with chloroquine resistance should be treated with artemisinin-containing combination therapy.[1]

Patients with *P. vivax* or *P. ovale* malaria require additional treatment to eradicate hypnozoites from the liver. This treatment can be given after full recovery from the initial illness; the most common agent used is primaquine phosphate. The adult dose is 30 milligrams of base per day for 14 days. First check the patient for glucose-6-phosphate dehydrogenase deficiency (glucose-6-phosphate dehydrogenase–deficient persons are at risk of hemolysis when treated with primaquine; an alternative management of relapsing malarias is chloroquine base 300 milligrams weekly for 6 months). Treatment with primaquine is not needed in patients with *P. falciparum* or *P. malariae* malaria because there are no dormant asexual forms in the liver. *P. vivax* or *P. ovale* infections that have been acquired by needlestick accident, blood transfusion, or transplacental infection do not need treatment with primaquine for the same reason.

SEVERE (COMPLICATED) MALARIA

Severe malaria is usually due to *P. falciparum*, but occasionally, it is due to *P. vivax* or *P. knowlesi*. The patients should be admitted to an appropriate level of intensive care. Both supportive and specific antimalarial therapies are urgent and critical to the patient's survival. Monitor the patient frequently; new complications may develop after the start of treatment.

Supportive Management Initial resuscitation may require oxygen for hypoxia, fluid replacement, IV glucose for hypoglycemia, blood transfusion for severe anemia or for disseminated intravascular coagulation, and occasionally intubation for severe respiratory distress or suspected raised intracranial pressure with altered mental status. Additional treatments for septic shock may be necessary (see chapter 151, "Sepsis"). Monitor to identify and treat seizures, hyperpyrexia, acute respiratory distress syndrome, or acute renal failure. Culture blood samples for bacterial infections, and give immediate parenteral antibiotics, because a bacterial co-infection cannot be ruled out by clinical assessment initially.

Specific Antimalarial Chemotherapy Initiate parenteral therapy with an efficacious antimalarial drug without delay. Options are listed in **Table 158-3**.

With any of the regimens in Table 158-3, continue the treatment by a parenteral route for at least 24 hours; thereafter, as soon as the patient is well enough to take drugs by mouth, switch to a complete course of the best available oral therapy (Table 158-2). If the patient remains unable to take oral therapy, the chosen parenteral therapy should be continued for a maximum of 7 days.

Do not delay treatment while awaiting laboratory confirmation, because the initial smear for *P. falciparum* may be negative, even on microscopy of a thick blood film, in a nonimmune individual. An unstable patient (abnormal vital signs, severe anemia, renal failure, pulmonary edema, acute respiratory distress syndrome, disseminated intravascular coagulation, acidosis, jaundice, hemoglobinuria, or seizures) with a clinical or travel history suggesting malaria should be started on artesunate (if available) or quinidine gluconate (Table 158-3) until a diagnosis of malaria can be ruled out.

In the United States, parenteral quinine should be reserved for individuals who develop, or who are considered to be at high risk of developing, cardiotoxicity while receiving IV quinidine.

To initiate a patient with severe malaria in the Centers for Disease Control and Prevention treatment protocol (United States only) using artesunate, contact the Centers for Disease Control and Prevention Malaria Hotline: 770-488-7788 (Monday–Friday, 9 a.m.–5 p.m., eastern time) or after hours, call 770-488-7100 and request to speak with a Centers for Disease Control and Prevention Malaria Branch clinician.[20]

IV artesunate is the drug of choice for severe malaria, according to the World Health Organization. Artesunate is rapidly effective and extremely

TABLE 158-3 Antimalarial Drug Options for Severe (Complicated) Malaria

Drug	Adult Dose	Pediatric Dose
Artesunate* (available from the CDC if quinidine fails to provide improvement; call 770-488-7788)	2.4 milligrams/kg IV at 0, 8, and 24 h, then daily. Artesunate can be given IM if necessary.	2.4 milligrams/kg IV at 0, 8, and 24 h, then daily. Artesunate can be given IM if necessary.
Quinidine gluconate (plus doxycycline or clindamycin)†	6.25 milligrams base (= 10 milligrams salt)/kg IV load over 2 h (maximum, 600 milligrams), follow with 0.0125 milligram base (= 0.02 milligram salt)/kg/min continuous infusion.	6.25 milligrams base (= 10 milligrams salt)/kg IV load over 2 h (maximum, 600 milligrams), follow with 0.0125 milligram base (= 0.02 milligram salt)/kg/min continuous infusion.
Plus		
Doxycycline	2.2 milligrams/kg IV (up to adult dose of 100 milligrams) every 12 h for 7 d.	2.2 milligrams/kg IV (up to adult dose of 100 milligrams) every 12 h for 7 d
Or in children under age 8 y		
Clindamycin		10 milligrams base/kg loading dose IV followed by 5 milligrams base/kg IV every 8 h for 7 d.

Abbreviation: CDC = Centers for Disease Control and Prevention.

*Artesunate is considered the drug of choice by World Health Organization guidelines.

†Quinine dihydrochloride is an alternative to quinidine gluconate (20 milligrams [salt]/kg infused IV over 2–4 hours, then 10 milligrams/kg every 8 hours, can be given IM if necessary, as 50 milligrams/mL solution).

potent against all erythrocyte stages. It does not cause cardiac toxicity or hypoglycemia. It is effective and is superior to IV quinine in both adults[21] and children.[22] Prompt treatment for severe malaria is critical, and artesunate's major limitation at present in the United States is its lack of timely availability.

RATES OF PARASITE CLEARANCE

With correct treatment, the parasite load in the peripheral blood should decrease rapidly during the first few days. This decrease is significantly faster with artemisinin drugs than with all other therapies, because artemisinin drugs kill early-stage as well as late-stage parasites. With artemisinin treatment, the parasite count usually decreases significantly within the first 12 hours, whereas with other drugs, this steep decrease may take 24 to 48 hours. In a patient treated with quinidine or quinine, the density of asexual parasites may be unchanged or even increased after 24 hours of therapy, but this is rarely the case in a person treated with an artemisinin therapy. Asexual forms of the parasite should not be detectable within 5 days of the start of any effective treatment course. Gametocytes, the sexual forms, which do not cause disease in the human host, may persist for several weeks after treatment and do not indicate treatment failure.

COMPLICATIONS OF TREATMENT

Complications of treatment are listed in **Table 158-4**.

Glucocorticoids are of no proven benefit for cerebral malaria and should not be used. Other unproven or harmful adjunctive therapies include heparin, iron chelators, pentoxifylline, and dichloroacetate.

Quinine and quinidine are potent inducers of insulin release and may cause severe hypoglycemia, especially during pregnancy. Sudden changes in orientation, sweating, tremor, tachycardia, or anxiety should prompt bedside glucose measurement and treatment accordingly. Cinchona alkaloids are myocardial depressants, so cardiac monitoring is needed during administration of quinidine or quinine. At least partial resistance to quinine has been reported in Southeast Asia, but it has not yet been identified in Africa.

DISPOSITION AND FOLLOW-UP

Many patients feel better after the first day or two of treatment for uncomplicated malaria. Emphasize the importance of completing the treatment, because partial therapy may fail to eliminate parasites and may be followed by recrudescence of infection. Advise the patient to report any recurrence of symptoms, because even completed treatment may fail or an unrecognized additional infection may emerge. An episode of malaria is an opportunity to advise an individual about how to prevent further infections. After severe malaria, review the patient at intervals for any sequelae. Survivors of acute kidney injury, acute respiratory distress syndrome, or severe anemia usually recover fully, but cerebral malaria may be followed by neurologic sequelae in a proportion of cases, especially in children.[23]

SPECIAL CONSIDERATIONS

PREGNANCY

Among nonimmune adults, those who are pregnant are at greater risk of developing severe disease than others. Pregnant women are at particular risk of anemia, hypoglycemia, and, especially in the third stage of labor, fluid overload. Artemisinin drugs are probably safe in pregnancy but are still subject to restriction in the first trimester. Quinidine and quinine can be used in pregnancy but carry a greater risk of causing hypoglycemia through stimulation of insulin secretion from hypertrophied pancreatic β-cells.

TABLE 158-4 Adverse Effects, Precautions, and Contraindications of Antimalarial Drugs

Drug	Minor Toxicity	Major Toxicity	Precautions/Contraindications
Chloroquine	Nausea/vomiting, diarrhea, pruritus, postural hypotension, rash, fever, headache, dizziness	Rare; hypotension and shock after parenteral therapy Retinopathy after prolonged use	Avoid in patients with severe psoriasis and some types of porphyria, caution with decreased liver function.
Quinine or quinidine	Cinchonism (nausea and vomiting, headache, tinnitus, dizziness, visual disturbance)	Hypotension, cardiac dysrhythmias, hypoglycemia, Coombs-positive hemolysis, abortions, neuromuscular paralysis (myasthenia)	Contraindicated in cardiac disease. Caution in pregnancy, myasthenia gravis.
Mefloquine	Nausea/vomiting, cramps, diarrhea, anorexia, dizziness, headaches, nightmares, and bradycardia	Rare unless underlying heart disease with bradycardia or the patient is on selected cardiotoxic medications (dysrhythmias, arrest); acute toxic confusional states may occur, as can seizures	Precaution during pregnancy and in children weighing <10 kg. Avoid if the patient is receiving quinidine. Avoid if the patient has heart conduction disturbance or if underlying seizure or major neuropsychiatric disorders.
Doxycycline	GI disturbances, phototoxicity, vaginal candidiasis	Rare; esophageal ulcerations if not taken with fluids	Contraindicated during pregnancy, in children <8 y of age. May depress prothrombin time in patients receiving anticoagulants.
Artemether-lumefantrine (Coartem®)	Headache, dizziness, anorexia, and asthenia	Rare; severe skin rash, QT prolongation	Avoidance with other drugs that may prolong QT interval. Drug interactions with cytochrome P-450 3A4 and cytochrome P-450 2D6.
Atovaquone-proguanil (Malarone®)	Nausea, vomiting, cramps, oral ulcers, headaches, dizziness	Rare serious allergic reactions and alopecia reported	Contraindicated in pregnancy and in children <5 kg (no safety data) and in patients with creatinine clearance <30.
Primaquine*	Nausea, vomiting, diarrhea, cramps, methemoglobinemia	Massive hemolysis in patients with G6PD deficiency Exacerbation of systemic lupus erythematosus or rheumatoid arthritis	Contraindicated in G6PD deficiency, pregnancy.

Abbreviation: G6PD = glucose-6-phosphate dehydrogenase.

*Terminal treatment for *Plasmodium vivax* and *Plasmodium ovale* infections only.

PREVENTION

In malaria-endemic areas, national efforts are aimed at identifying and correctly treating malaria cases while reducing transmission through widespread use of long-lasting insecticide-impregnated bednets and programs of indoor residual spraying with insecticides. Several countries have now achieved elimination of transmission within their borders, while many more are beginning to set elimination as a national target.

For nonimmune travelers, malaria is largely preventable through the use of personal protective measures and appropriate chemoprophylaxis. Travelers to malarious areas frequently do not use antimosquito measures or take antimalarial drugs.[24] Of the U.S. civilians who acquired malaria abroad during 2011, only 6% had followed a chemoprophylactic drug regimen recommended by the Centers for Disease Control and Prevention for the area to which they had traveled.[2] Persons who immigrated to the United States years ago from malarious areas often falsely assume that they are immune to disease.

Between dusk and dawn, travelers should remain in well-screened areas, use insecticide-impregnated mosquito nets, and wear long-sleeved, light-colored clothing. Nets impregnated with long-lasting insecticides are very effective, although resistance of mosquitoes to insecticides is an increasing concern. An insect repellent containing *N,N*-diethyl-*m*-toluamide (DEET) in concentrations no higher than 35% should be applied to exposed skin. DEET-based repellents are significantly more efficacious than non–DEET-based repellents.[25] Newer formulations of DEET exist with polymer encapsulation and sustained-release properties and provide long-acting protection at lower concentrations of DEET.

Appropriate chemoprophylaxis depends on the travel destination. If exposure to infected mosquitoes is likely, prophylaxis is warranted even if such exposure will be brief. Because recommendations change quite frequently and are area specific, anyone requiring advice for the prophylaxis appropriate for travel to a particular area should attend a travel clinic, or see current recommendations on the Centers for Disease Control and Prevention Web site (www.cdc.gov/malaria/travelers/drugs.html). Failure to take appropriate chemoprophylaxis is a significant risk factor for fatal infection.[26] Even with the rigorous use of antimosquito measures and chemoprophylaxis, malaria can be contracted or can recur.

Vaccines directed against various antigens and life-cycle stages of *P. falciparum* are being intensively investigated. Results of a multicountry phase III trial of the currently most developed vaccine candidate will be available by 2015 to allow a final decision about efficacy and deployment. This vaccine, which primarily aims to benefit infants and children in malarious areas, will at best have partial efficacy, so that it will complement but not replace other measures of prevention and control.[27]

PRACTICE GUIDELINES

Both the World Health Organization[17] and the Centers for Disease Control and Prevention[18,19] publish and update practice guidelines for the diagnosis and treatment of malaria.

CHAPTER 159

Food and Waterborne Illnesses

Lane M. Smith
Simon A. Mahler

FOODBORNE ILLNESSES

INTRODUCTION AND EPIDEMIOLOGY

Foodborne illness occurs after consumption of a food contaminated with bacteria, viruses, parasites, chemicals, or biotoxins. As one example, in 2008, melamine-contaminated dairy products in China affected over 50,000 children. The World Health Organization estimates that more than two million children die every year from exposure to unsafe water or food.[1] Outbreaks from contaminated food are often widespread, and foodborne disease is a public health concern. International travel contributes to foodborne illnesses as travelers are exposed to new pathogens, and migrants may introduce diseases.[1]

The Centers for Disease Control and Prevention (CDC) estimates that foodborne diseases cause 1 in 6 Americans to get sick, leading to 128,000 hospitalizations and 3000 deaths in the United States each year.[2,3] Children have the highest frequency of foodborne illness. Viruses are the most common cause of foodborne disease, with the norovirus causing more than half of all cases and 26% of all admissions.[2] Other viral sources of infection include rotavirus, astrovirus, and enteric adenovirus.

Bacterial causes tend to be more severe, with nontyphoidal *Salmonella* triggering the most cases requiring admission or resulting in fatality.[3] Other common bacterial causes of foodborne illness include *Clostridium perfringens*, *Campylobacter* spp., *Toxoplasma gondii*, *Shigella*, *Staphylococcus aureus*, and Shiga toxin–producing *Escherichia coli*. Over the past decade, there has been little change in the overall incidence of foodborne pathogens aside from *Campylobacter*, which has been steadily increasing since 2001.[3] The most common foods associated with outbreaks reported in the United States are poultry, leafy vegetables, and fruits/nuts.[2,3]

PATHOPHYSIOLOGY

There are three basic mechanisms by which microbes cause illness. First, some pathogens such as *S. aureus*, *Bacillus cereus*, and *Clostridium botulinum* (botulism) produce toxins capable of causing illness. These preformed toxins are present in the food before ingestion and result in the rapid onset (1 to 6 hours) of symptoms. Preformed toxins such as staphylococcal enterotoxin exert their effect by stimulating the host immune system to release inflammatory cytokines within the intestine.[4] These cytokines are responsible for the accompanying nausea and vomiting.

The second method involves toxin production after ingestion, which interacts with intestinal epithelium as seen with *Vibrio*, *Shigella*, and Shiga toxin–producing *E. coli*. These cause diarrhea and lower GI symptoms (cramping and sometimes bloody diarrhea), with onset at approximately 24 hours after exposure. Some toxins produced by *Vibrio* and enterotoxigenic *E. coli* alter chloride and sodium transport across intestinal mucosal surfaces without destroying cells.[5] The resulting osmotic gradient produces a large fluid shift into the intestinal lumen, which overwhelms the absorptive capacity of the colon, causing watery diarrhea. Other toxins produced after ingestion by organisms such as *Shigella* and Shiga toxin–producing *E. coli* disrupt host cell protein production, which causes death of the intestinal epithelium, resulting in bloody diarrhea and extraintestinal symptoms.[6]

Finally, direct invasion of the intestinal epithelium is a common mechanism for the enteric viruses, *Salmonella*, enteroinvasive *E. coli*, and *Campylobacter*. These pathogens enter host cells and destroy intestinal epithelium.[7] This causes diarrhea due to transient malabsorption that is frequently bloody and accompanied by systemic symptoms such as fever. These viruses require ingestion of just a few viral particles to cause disease. The upper and lower GI symptoms from invasive organisms last from 24 hours to weeks (**Table 159-1**).

TABLE 159-1 Etiologic Agents for Foodborne Diseases and Usual Incubation Periods

1–6 Hours	6–24 Hours	24–48 Hours	2–6 Days	1–2+ Weeks
Astrovirus	*Bacillus cereus* diarrhea toxin	*Clostridium botulinum*	*Campylobacter*	*Brucella*
B. cereus preformed toxin	*Clostridium perfringens*	Enterotoxigenic *Escherichia coli*	*Shigella*	*Cryptosporidium*
Ciguatoxin	*Vibrio parahaemolyticus*	*Salmonella*	Enterohemorrhagic *E. coli*	*Entamoeba*
Heavy metals		*Trichinella*	*Vibrio cholerae*	*Giardia*
Monosodium glutamate			*Yersinia*	Hepatitis A
Norovirus				*Listeria*
Scromboid toxin				*Salmonella typhi*
Staphylococcus aureus toxin				
Tetrodotoxin				

The normal human digestive tract has physiologic defenses against foodborne diseases. The low gastric pH of 1 to 3 kills many ingested pathogens, while the normal intestinal flora competitively inhibits pathogens and secretes bactericidal fatty acids and other chemicals.[8,9] Normal intestinal motility prevents pathogens from having prolonged contact with mucosal surfaces and mixes organisms with mucous-containing protective glycoproteins. Immunologic tissues are also present in the GI tract to directly attack pathogens attempting transmural migration.[9]

Alteration of these protective mechanisms can increase susceptibility to foodborne disease. For example, proton pump inhibitors, histamine-2 (H_2) blockers, and antacids reduce gastric acid production. Recent antibiotic use, chemotherapy or radiation therapy, and recent surgery alter the intestinal flora. Decreased intestinal motility from narcotics, antiperistaltic drugs, and surgery may encourage pathogen growth and migration.[9]

CLINICAL FEATURES

Suspect a foodborne disease when two or more people in a household or close association (e.g., the same workplace or communal eating arrangement) simultaneously develop GI symptoms. The most common symptoms are nausea, vomiting, diarrhea, and abdominal cramping. Systemic symptoms of fever, dehydration, and malaise are also common in patients with severe foodborne infections.

Question patients about the types of food they have recently ingested, frequency of restaurant meals, consumption of public-vended or street-vended foods, ingestion of seafood, and consumption of raw foods. Additional questions include recent travel or camping, contact with food handlers, and diaper changing. Children who attend day care centers and residents of long-term care facilities are at increased risk for foodborne diseases. People working in the food industry are also frequent victims or sources; ask them about their personal hygiene and food-handling practices. Finally, seek a history of comorbidities or influencing therapies, including human immunodeficiency virus (HIV) infection or immunosuppressive drug use.

On exam, look for dehydration and a toxic appearance. Another priority is the identification of blood in the stool and the exclusion of alternative causes of symptoms such as appendicitis. The clinical features of specific foodborne infections are summarized in **Table 159-2**.

DIAGNOSIS

Most patients with foodborne diseases do not require diagnostic testing; illnesses are often self-limited. Routine testing for stool ova and parasites or cultures is not indicated.[10] However, electrolytes and a CBC are helpful in toxic patients or those with prolonged symptoms. Stool tests are obtained in the following clinical situations[10,11]:

- Watery diarrhea with signs of hypovolemia
- Bloody diarrhea
- Fever ≥38.5°C (101.3°F)
- Prolonged duration of illness >1 week
- Severe abdominal pain or tenderness
- Hospitalized patients or recent antibiotic use

TABLE 159-2 Clinical Features of Foodborne Infections

Clinical Presentation	Foodborne Pathogens
Gastroenteritis with vomiting as the primary symptom	Viral pathogens: *Norovirus*, *Rotavirus*, and *Astrovirus*; preformed toxins: *Staphylococcus aureus* and *Bacillus cereus*
Noninflammatory diarrhea (watery, nonbloody)	Can be any enteric pathogen, but classically: ETEC *Giardia* *Vibrio cholerae* Enteric viruses *Cryptosporidium* *Cyclospora*
Inflammatory diarrhea (grossly bloody, fever)	*Shigella* *Campylobacter* *Salmonella* EIEC Shiga toxin–producing *Escherichia coli* O157:H7 and non-O157:H7 *Vibrio parahaemolyticus* *Yersinia* *Entamoeba*
Persistent diarrhea (>14 d)	Parasites: *Giardia* *Cyclospora* *Entamoeba* *Cryptosporidium*
Neurologic manifestations	Botulism (*Clostridium botulinum toxin*) Scombroid fish poisoning Ciguatera fish poisoning Tetrodotoxin Toxic mushroom ingestion Paralytic shellfish poisoning Guillain-Barré syndrome
Systemic illness	*Listeria monocytogenes* *Brucella* *Salmonella typhi* *Salmonella paratyphi* *Vibrio vulnificus* Hepatitis A, E

Abbreviations: EIEC = enteroinvasive *E. coli*; ETEC = enterotoxigenic *E. coli*.

- Elderly (≥70 years of age) or the immunocompromised
- Pregnant women or those with comorbidities such as inflammatory bowel disease

Routine stool cultures will identify *Salmonella*, *Campylobacter*, and *Shigella*. A single sample is usually sufficient, but be aware of local laboratory limitations. For example, most laboratories do not routinely culture enterotoxigenic *E. coli*, vibrios, and viruses. In 2009, the Centers for Disease Control and Prevention recommended that clinical laboratories culture all submitted stool specimens for Shiga toxin–producing *E. coli* and perform toxin assays for Shiga toxin.[12]

Testing for ova and parasites is indicated for the immunocompromised, patients with symptoms lasting longer than 2 weeks, community waterborne outbreaks, or men who have sex with men.[10,13] Because parasite excretion may not be continuous, three specimens separated by at least 24 hours may be needed to identify the causative pathogen.

Testing for fecal leukocytes has historically been performed to predict the presence of an invasive cause for acute diarrhea and increase stool culture yield. Unfortunately, several studies have shown that fecal leukocytes are neither sensitive nor specific for invasive disease, and they are a poor a predictor of response to antimicrobial therapy.[14,15] The neutrophil marker lactoferrin is a more sensitive, but less widely available, screening test for inflammatory cells in stool. If positive, fecal lactoferrin also increases the likelihood of positive stool cultures.[16,17] Direct antigen detection panels are available for specific viruses such as rotavirus, bacteria, and parasitic pathogens in many clinical laboratories.

TREATMENT

Most episodes of acute gastroenteritis require only adequate hydration and supportive care. The World Health Organization recommends initial therapy with a glucose-containing fluid (i.e., Pedialyte or equivalent) for oral rehydration.[18] Parenteral rehydration is recommended for patients with severe dehydration or continued vomiting and inability to tolerate oral fluids. Antiemetics may reduce vomiting, emergency department length of stay, and need for admission.[19,20] Antimotility medications, such as loperamide, may decrease illness duration for mild to moderate nonbloody diarrhea in adults without fever but are generally avoided in young children and patients with dysentery (fever and bloody diarrhea) due to concerns of prolonging the illness.[21]

Empiric antibiotics do not appear to dramatically alter the course of illness since most cases are viral or self-limited bacterial in origin. The 2001 Infectious Diseases Society of America guidelines recommend empiric treatment for patients with moderate to severe traveler's diarrhea, those with symptoms for more than 1 week, patients requiring hospitalization due to volume depletion, and immunocompromised hosts.[10] A common bacterial enteritis regimen is oral ciprofloxacin 500 milligrams twice daily or levofloxacin 500 milligrams once a day, each for 3 to 5 days. Azithromycin 500 milligrams once daily for 3 days is an alternative regimen.[10] Antibiotics and antimotility agents are contraindicated in patients with Shiga toxin–producing *E. coli* O157:H7 infection due to increased risk of hemolytic-uremic syndrome, especially in children and the elderly.[22] See **Tables 159-3, 159-4, 159-5, and 159-6** for more detailed treatment recommendations.

DISPOSITION AND FOLLOW-UP

Patients who appear toxic or have systemic symptoms, significant comorbidities, or severe dehydration with inability to tolerate oral fluids are admitted. Discharged patients should receive instructions on proper hygiene, notably frequent hand washing, to protect family members and contacts who are not ill. Patients discharged with pending stool culture or other studies should have a clear plan for follow-up.

SPECIAL POPULATIONS

Elderly patients, young children, and the immunocompromised are more likely to have severe illness, atypical presentations, and long-term sequelae. Patients with human immunodeficiency virus or other immunocompromised states can rapidly develop life-threatening symptoms. Thus, test more liberally and admit at a lower threshold. Pregnant patients have increased risk of complications, especially with *Listeria* infection, and may require further monitoring.[10]

SPECIAL CONSIDERATIONS

Enterohemorrhagic *E. coli* and Hemolytic-Uremic Syndrome Enterohemorrhagic *E. coli* that produces Shiga toxin is the most common cause of hemolytic-uremic syndrome in the United States.[22] The Shiga toxin–producing *E. coli* strain O157:H7 is most commonly associated with pediatric hemolytic-uremic syndrome, but other strains such as O104:H4 and O111 are associated with adult hemolytic-uremic syndrome–like illnesses. The Shiga toxin produced by these organisms halts protein synthesis in renal glomerular cells as the precipitating event in hemolytic-uremic syndrome. Toxin binding to the glomerular endothelium produces a thrombogenic environment leading to microangiopathic hemolysis through multiple cellular mechanisms.[23,24] Antibiotics may promote Shiga toxin release, which increases the incidence of hemolytic-uremic syndrome, and are avoided when this is suspected or identified. In addition, avoid antimotility agents. Treatment of hemolytic-uremic syndrome is supportive, with plasma infusion and exchange therapy showing some benefit. Approximately 50% of pediatric patients with hemolytic-uremic syndrome will require dialysis, and dehydration at the time of admission increases the frequency and duration of renal support.[25]

Scombroid and Ciguatera Poisoning **Scombroid fish poisoning** occurs after ingestion of fish of the family Scombridae (tuna, mackerel, and bonito). Other non-Scombridae fish such as mahi-mahi, bluefish, herring, and sardines are also implicated. The disease occurs when histidine is metabolized by bacteria into histamine and other bioactive amines. Improper temperature control allows high concentrations of these substances to accumulate in the fish. Symptoms usually begin 30 minutes to 24 hours after ingestion and include flushing, headache, abdominal cramping, vomiting, and diarrhea. Symptoms are usually self-limited for 12 to 48 hours. However, severe cardiac and respiratory symptoms may occur in the elderly or patients with comorbid conditions. Treatment is with antihistamines (H_1 and H_2 blockers) such as diphenhydramine and cimetidine. Laboratory testing is not needed in most cases.[26]

Ciguatera poisoning is caused by eating reef fish contaminated with the dinoflagellate *Gambierdiscus toxicus*, which produces ciguatoxin. The toxin is heat resistant and accumulates in large predatory fish such as grouper, snapper, amberjack, and barracuda. Ciguatoxin acts on sodium channels resulting in membrane depolarization. Nausea, vomiting, and diarrhea occur 1 to 24 hours after ingestion, followed by hypesthesias, paresthesias, numbness, malaise, generalized weakness, and sensitivity to temperature extremes. The latter is often described as a reversal of heat and cold sensation. Bradycardia and hypotension are also described.[27] The GI symptoms typically resolve over a few days, whereas the neurologic symptoms may persist in a waxing and waning pattern for 3 months to years.[28] Acute treatment is supportive. Mannitol has been used to treat severe cases, but the evidence is conflicting.[29,30]

Chronic Sequelae of Foodborne Illness About 2% to 3% of patients with foodborne diseases have chronic sequelae thought to be related to autoimmunity.[31,32] Protein virulence factors (superantigens) present in a number of foodborne pathogens can initiate extreme immune responses. *Salmonella, Shigella,* and *Campylobacter* have been associated with a seronegative reactive arthritis in about 2% of those infected.[33] *Campylobacter* infection is associated with Guillain-Barré syndrome with a reported rate as high as 30.4 per 100,000 cases.[32] Symptoms of Guillain-Barré syndrome typically occur 7 to 21 days after the GI symptoms resolve.[31,32] Other autoimmune disorders thought to be associated with superantigens from foodborne pathogens include multiple sclerosis, rheumatoid arthritis, psoriasis, and Graves' disease.[32] Infections with *Salmonella, Yersenia,* and *Campylobacter* may increase short- and long-term risk of death even after accounting for comorbid diseases.[33]

Prevention and Surveillance The Centers for Disease Control and Prevention tracks foodborne infections in the United States through **FoodNet**. The U.S. Food and Drug Administration and U.S. Department of Agriculture provide the Centers for Disease Control and Prevention

TABLE 159-3 Clinical Features, Diagnosis, and Management of Bacterial Foodborne Illness

Etiology	Signs and Symptoms	Duration of Illness	Associated Foods	Laboratory Testing	Treatment
Bacillus anthracis	Nausea, vomiting, bloody diarrhea, abdominal pain, malaise	Weeks	Poorly cooked meat	Blood	Ciprofloxacin or doxycycline IV + PCN, vancomycin, rifampin, or clindamycin
Bacillus cereus (preformed toxin)	Sudden onset of nausea, vomiting; can have diarrhea	24 h	—	Clinical diagnosis; assay must be ordered specifically	Supportive care
B. cereus (diarrheal toxin)	Watery diarrhea, cramping, nausea	1–2 d	Meats, gravies, stew, vanilla sauces	Not necessary	Supportive care
Brucella	Fever, chills, myalgias, arthralgias, weakness, bloody diarrhea	Weeks	Raw milk, unpasteurized goat's milk or cheese, contaminated meat	Serology, blood culture	Doxycycline 100 milligrams PO twice daily + streptomycin 1 gram IM for 14–21 d
Campylobacter	Diarrhea, cramping, nausea, vomiting, fever, often bloody diarrhea	2–10 d	Contact with raw poultry, undercooked poultry, unpasteurized milk, contaminated water	Routine stool culture; requires special media and temperature	Ciprofloxacin 750 milligrams PO twice daily or levofloxacin 500 milligrams PO daily or azithromycin 500 milligrams daily for 3–5 d
Clostridium botulinum (preformed toxin)	Vomiting, diarrhea, blurred vision, diplopia, dysphagia, descending muscle weakness, paralysis	Days to months	Canned foods, canned fish, foods kept warm in dishes, herbed oils, cheese sauce	Stool, serum, or food assay for toxin; stool culture	Supportive care (may require intubation), botulism antitoxin
C. botulinum—infants	Infants <12 mo, lethargy, weakness; poor feeding, head control, and suck	Variable	Honey, home canned vegetables, corn syrup	Stool, serum, or food for toxin; stool culture	Botulism immunoglobulin; antitoxin not recommended in infants
Clostridium perfringens	Watery diarrhea, nausea, cramping	1–2 d	Meat, poultry, dried or precooked foods, poor temperature control	Stools for enterotoxin, stool culture	Supportive care
Enterohemorrhagic *Escherichia coli* and Shiga toxin–producing *E. coli*, O157:H7	Severe, often bloody diarrhea; abdominal pain; vomiting; little or no fever	5–10 d	Undercooked beef (hamburger), unpasteurized milk, juices, raw fruits and vegetables	Stool culture; may require special media; toxin assay	Supportive; avoid antibiotics due to risk of hemolytic-uremic syndrome
Enterotoxigenic *E. coli*	Watery diarrhea, cramping, vomiting	3–7 d	Water or food contaminated with human feces	Stool culture (specific testing)	Supportive; ciprofloxacin 500 milligrams PO twice per day or levofloxacin 500 milligrams PO once daily for 3 d
Listeria monocytogenes	Fever, myalgias, nausea, diarrhea; premature delivery if pregnant; meningitis	Variable	Fresh soft cheeses, poorly pasteurized dairy products, deli meats, hot dogs	Blood or CSF fluid culture; listeriolysin O antibody assay	Supportive care; ampicillin or penicillin G; TMP-SMX for PCN allergic
Salmonella	Diarrhea, vomiting, abdominal pain, fever, myalgia	4–7 d	Eggs, poultry, unpasteurized dairy products, raw fruits and vegetables, street-vended food	Routine stool culture	Supportive care; ciprofloxacin 500 milligrams PO twice daily or levofloxacin 500 milligrams once daily for 3–5 d; ceftriaxone IV for severe disease or immunocompromised; vaccine for *S. typhi*
Shigella	Abdominal cramping, fever, diarrhea with blood and mucus	4–7 d	Fecal contamination of any food or water, person to person, prepared food	Routine culture	Supportive care; ciprofloxacin 500 milligrams PO twice per day or levofloxacin 500 milligrams once per day for 3–5 d or azithromycin 500 milligrams PO daily for 3 d
Staphylococcus aureus (preformed toxin)	Sudden-onset severe nausea, vomiting, diarrhea, fever	1–2 d	Improperly refrigerated meats, potato or egg salad; left out pastries	Clinical diagnosis; assay for toxin; culture if indicated	Supportive care only
Vibrio cholerae	Profuse watery diarrhea and vomiting; life-threatening dehydration	3–7 d	Contaminated water, fish, shellfish, street-vended foods	Specifically ordered stool culture	Aggressive PO or IV fluid replacement, azithromycin 1 gram PO once or doxycycline 300 milligrams once or ciprofloxacin 1 gram PO once

(*Continued*)

TABLE 159-3 Clinical Features, Diagnosis, and Management of Bacterial Foodborne Illness (*Continued*)

Etiology	Signs and Symptoms	Duration of Illness	Associated Foods	Laboratory Testing	Treatment
Vibrio parahaemolyticus	Watery diarrhea, cramping, vomiting	2–5 d	Undercooked or raw fish or shellfish	Stool culture (special media required)	Supportive care; antibiotics in severe illness: ciprofloxacin 500 milligrams PO twice daily or TMP-SMX-DS PO twice daily or doxycycline 100 milligrams PO twice daily for 3 d
Vibrio vulnificus	Vomiting, abdominal pain, diarrhea, skin infections; can be fatal in liver disease or immunocompromised patients	2–8 d	Undercooked or raw fish or shellfish	Specifically ordered stool, blood, or wound cultures	See Table 159-8
Yersinia	Pseudoappendicitis, fever, abdominal pain, vomiting, diarrhea, rash	1–3 wk	Undercooked pork products, tofu, contaminated water	Stool, blood, or vomitus cultures (special media)	Supportive care; antibiotics usually not required; if septic: gentamicin 5 milligrams/kg IV daily + ceftriaxone 2 grams IV daily

Abbreviations: CSF = cerebrospinal fluid; DS = double strength; PCN = penicillin; TMP-SMX = trimethoprim-sulfamethoxazole.

TABLE 159-4 Clinical Features, Diagnosis, and Management of Viral Foodborne Illness

Etiology	Signs and Symptoms	Duration of Illness	Associated Foods	Laboratory Testing	Treatment
Hepatitis A	Diarrhea, jaundice, dark urine, flu-like illness, abdominal pain	2 wk to 3 mo	Shellfish, raw produce, contaminated water, infected contacts	Liver profile, bilirubin, positive immunoglobulin, and antihepatitis A antibodies	Supportive care; prevention with immunization
Norovirus, *Rotavirus*, and other enterovirus	Nausea, vomiting, abdominal cramping, diarrhea; sometimes fever, malaise, headache	12 h to 9 d	Fecally contaminated foods; foods touched by infected workers (salads, sandwiches, produce); shellfish	Clinical diagnosis; reverse transcriptase polymerase chain reaction and electron microscopy on stool for *Norovirus* are available but rarely used; stool immunoassay, serology, or enzyme-linked immunosorbent assay kits	Supportive care, good hygiene, adequate fluid replacement

TABLE 159-5 Clinical Features, Diagnosis, and Management of Parasitic Foodborne Illness

Etiology	Signs and Symptoms	Duration of Illness	Associated Foods	Laboratory Testing	Treatment
Cryptosporidium	Watery diarrhea, cramping, fever	Weeks to months—may be relapsing	Any contaminated uncooked food, water	Specific stool examination	Supportive care and HAART in HIV infected; consider nitazoxanide 500 milligrams PO twice daily for 3 d + azithromycin in patient with HIV and severe symptoms
Cyclospora	Watery diarrhea, weight loss, cramping, vomiting, fatigue	Weeks to months, relapsing	Various types of fresh produce	Specific stool examination	TMP-SMX-DS PO twice per day or ciprofloxacin 500 milligrams twice daily for 7–10 d; nitazoxanide 500 milligrams PO twice daily for 7 d In HIV patients: TMP-SMX-DS PO four times a day for 21 d
Entamoeba histolytica	Bloody diarrhea, frequent stools, lower abdominal pain	Weeks to months	Any contaminated uncooked food, water	Examination of stool for cysts and parasites; serology	Metronidazole 750 milligrams PO three times daily for 5–10 d or paromomycin 500 milligrams PO three times daily for 7 d or tinidazole 2 grams PO for 3 d or nitazoxanide 500 milligrams PO twice daily for 3 d
Giardia	Diarrhea, cramping, copious flatus	Months	Any contaminated uncooked food	Examination of stool for ova and parasites	Metronidazole 250 milligrams PO three times daily for 7–10 d or tinidazole 2 grams PO once or nitazoxanide 500 milligrams PO twice daily for 3 d or paromomycin 500 milligrams PO three times daily for 7 d or albendazole 400 milligrams PO once daily for 5 d

Abbreviations: HAART = highly active antiretroviral therapy; HIV = human immunodeficiency virus; TMP-SMX-DS = trimethoprim-sulfamethoxazole double-strength.

TABLE 159-6 Clinical Features, Diagnosis, and Management of Toxinogenic Foodborne Illness

Etiology	Signs and Symptoms	Duration	Foods	Laboratory Testing	Treatment
Ciguatera toxin	Abdominal pain, vomiting, diarrhea, paresthesias, reversal of hot and cold sensation, weakness, hypotension, bradycardia	Days to months	Large reef fish (barracuda most common)	Clinical diagnosis	Supportive care; high-dose atropine for bradycardia; IV mannitol for severe neurologic symptoms
Tetrodotoxin (puffer fish)	Paresthesias, headache, vomiting, diarrhea, abdominal pain, ascending paralysis, respiratory failure, death	Death in 4–6 h	Puffer fish	Detection of tetrodotoxin in fish	Emergent supportive care; anticholinesterases such as neostigmine and edrophonium
Scombroid (histamine)	Flushing, rash, burning sensation, dizziness, paresthesias	3–6 h	Pelagic fish—tuna, mackerel, swordfish, mahi-mahi	Clinical diagnosis, can assay for histamine in fish	Antihistamines, supportive care
Shellfish toxins	Diarrhea, vomiting, abdominal pain, fever, numbness, dizziness, myalgias, confusion, memory loss, coma	2 h to 3 d	Shellfish, mussels, clams	Detection of toxin in shellfish	Supportive care, self-limited

with data about the origin and distribution of food products, which allows investigators to determine the source of a foodborne outbreak.

The Food Safety Modernization Act was passed into law in 2011 to address the rise in foodborne diseases by preventing, rather than responding to, outbreaks of foodborne illness. The law gives the U.S. Food and Drug Administration broad regulatory authority to oversee how food is harvested and processed.[34]

WATERBORNE ILLNESSES

INTRODUCTION AND EPIDEMIOLOGY

Waterborne illnesses occur from ingestion or contact with contaminated water found in swimming pools, hot tubs, spas, and naturally occurring fresh and salt water during recreational use.[35] Numerous species of bacteria, viruses, and protozoans are introduced into the water by fecal contamination and are capable of causing waterborne infections. However, some species of bacteria are indigenous aquatic organisms such as *Pseudomonas aeruginosa, Vibrio, Aeromonas,* nontuberculous *Mycobacterium*, and *Legionella*. Schistosomiasis is common among children in Africa, Asia, and South America, because they are likely to play in infected water. There is concern about the relationship between pediatric urogenital or intestinal schistosomiasis (often acquired in childhood) and human immunodeficiency virus risk.[36]

There were 81 recreational waterborne disease outbreaks in the United States reported to the Centers for Disease Control and Prevention in 2009–2010, which resulted in at least 1326 cases of disease and 62 hospitalizations.[35] The vast majority of these outbreaks were from treated water sources such as swimming pools and water fountains. Approximately two thirds of the waterborne illnesses were gastroenteritis, and 25% were dermatologic diseases or chemical exposures. The most common pathogen associated with these outbreaks was *Cryptosporidium*, which accounted for half of all cases.[35] The most common noninfectious source of waterborne disease was exposure to pool chemicals.

BACTERIA AND WATERBORNE ILLNESS

Implementation of water disinfection and filtration treatments has significantly reduced waterborne outbreaks from enteric bacteria.[37] Waterborne infections from *Vibrio cholerae* and *Salmonella typhi* are now extremely rare in the developed world, but both remain a major cause of illness in developing nations.[37]

Several enteric bacteria are commonly implicated in waterborne disease outbreaks in the United States. *Campylobacter* is found in virtually all surface waters due to contamination from wild bird feces and is the most common bacteria associated with recreational waterborne disease outbreaks.[35,38] Several outbreaks of human campylobacteriosis have been reported from contaminated drinking water.[39] Shiga toxin–producing *E. coli* can also be transmitted from ingestion or contact with water contaminated by farm animal feces.[40] *Shigella* species, *Salmonella* species, and *Yersinia enterocolitica* are other enteric bacteria that can cause waterborne outbreaks.[36] Most enteric bacteria, including *E. coli* O157:H7 and *Campylobacter*, are susceptible to chlorination.

Although *V. cholerae* is an enteric organism acquired from water with fecal contamination, many *Vibrio* species are endemic in marine and estuarine waters. The cholera epidemic began in Haiti in October 2010 and continues, with over 600,000 cases and nearly 8000 deaths. Environmental reservoirs have been identified in Haiti, with concern that transmission could occur to the Dominican Republic and other parts of the Caribbean.[41] *Vibrio* species can cause diarrheal illnesses or skin infections. *Vibrio vulnificus* is associated with life- and limb-threatening necrotic wound infections. The organism is found predominantly along the Gulf Coast and is acquired by patients with open wounds that are exposed to seawater. The wound infections are associated with a high rate of sepsis and amputation. Cirrhosis and high iron levels are associated with worse outcome.[42]

Found in fresh and marine waters, *Aeromonas* species can cause gastroenteritis and wound infections.[43] The majority of wound infections are simple cellulitis, but necrotizing infections and septic arthritis occur.[44,45] In addition, immunocompromised patients may progress to develop peritonitis, cholangitis, and meningitis.[43]

P. aeruginosa is an opportunistic pathogen found in fresh water. Immunocompromised patients are at risk from waterborne disease due to *Pseudomonas*. In normal hosts, *Pseudomonas* can cause otitis externa, keratitis in contact lens wearers, and folliculitis.[46] Although *Pseudomonas* can contaminate drinking water, it does not appear to cause a diarrheal illness in normal hosts.[47]

Nontuberculous *Mycobacterium* are found in salt and fresh water and can cause illness.[48] *Mycobacterium marinum* is associated with granulomatous skin infections (**Figure 159-1**).[49] *Mycobacterium avium* complex is associated with GI, pulmonary, or disseminated disease in immunocompromised patients, particularly patients with human immunodeficiency virus.[36]

Legionella is a common inhabitant of fresh water, including water that meets the standards for drinking.[36] Infection occurs from inhalation of contaminated aerosols, resulting in one of two syndromes: Legionnaires' disease or Pontiac fever. Pontiac fever is a flulike illness contracted by breathing mist that comes from a water source (such as air conditioning cooling towers, whirlpool spas, and showers) contaminated with the bacteria. For further discussion of Legionnaires' disease, refer to the chapter 65, "Pneumonia and Pulmonary Infiltrates."

PROTOZOA AND WATERBORNE ILLNESS

Giardia lamblia is a common protozoal cause of waterborne disease in the United States that accounts for 20,000 cases of diarrheal disease annually.[36,50] It is frequently found in surface waters from mountain

FIGURE 159-1. Skin infection from *Mycobacterium marinum*. A painful indurated plaque is noted on the dorsal surface of the proximal thumb. [Reproduced with permission from Wolff K, Johnson RA: *Color Atlas and Synopsis of Clinical Dermatology,* 5th ed. © 2005, McGraw-Hill, New York.]

streams to municipal reservoirs and is resistant to the levels of chlorination typically used in water treatment. Infected animals such as beavers may contribute to contamination of natural waters, which explains the term "beaver fever" used to describe giardiasis. Backpackers, campers, and travelers to disease-endemic areas are at high risk for waterborne giardiasis, as are children under 5 years of age.[50,51] Community outbreaks often start out as a waterborne disease, but subsequent transmission commonly occurs from person to person. *Giardia* is associated with acute and chronic forms of gastroenteritis, although many patients infected with *Giardia* remain asymptomatic.

Cryptosporidium is an intracellular protozoan parasite that is another common cause of waterborne illness in the United States.[52] The Centers for Disease Control and Prevention estimates that 748,000 cases of cryptosporidiosis occur each year and result in hospital admissions costing $45.8 million.[52] The inoculum required to cause infection is low, and large numbers of oocysts are excreted in the feces of infected hosts.[53] Standard doses of chlorine and zonation used in water treatment are not effective against *Cryptosporidium*, which explains its association with recreational water sources.[52] Water filtration reduces the number of oocysts, but occasionally enough remain to be infective. Infection with *Cryptosporidium* in a normal host results in a self-limited diarrheal illness, and many exposures are asymptomatic. Immunocompromised patients may experience chronic diarrhea or life-threatening complications.[51,53] *Cyclospora, Isospora,* and *Microspora* are other protozoan parasites that can cause severe disease in immunocompromised patients.[54,55]

Entamoeba histolytica is a protozoa that causes intestinal amebiasis. It is a significant waterborne pathogen in developing countries, but in the United States, it is most commonly seen in migrants, travelers to endemic areas, men who have sex with men, and institutionalized patients.[56,57] Symptoms range from asymptomatic infection to severe dysentery.[56] Fulminant colitis with bowel necrosis and perforation occurs in <1% of cases but has a mortality rate of >40%.[58] Seeding of the liver can occur, particularly in men with underlying liver disease, resulting in the formation of amoebic hepatic abscesses.[56,59]

ENTERIC VIRUSES AND WATERBORNE INFECTION

Enteric viruses are an important cause of waterborne disease. More than 100 enteric viruses pathogenic in humans have been reported, many of which can be transmitted via drinking water and recreational water.[60] Several enteric viruses, including the Norwalk virus and rotaviruses, are relatively chlorine resistant. Outbreaks have been associated with contamination of private wells and community water systems.[60]

Hepatitis A and E are associated with epidemic and sporadic infections from contaminated water. Infection from the hepatitis A virus typically results in an acute self-limited hepatitis that rarely develops into fulminant hepatic failure. The incidence of hepatitis A infections has decreased in the United States due to implementation of vaccination in high-risk adults and all children.[61] Hepatitis E is mostly confined to tropical and subtropical regions but is often complicated by cholestasis, and it causes significant morbidity and mortality in pregnant women.[62]

Noroviruses, including the Norwalk virus, are the leading cause of acute gastroenteritis across all age groups.[63] Outbreaks have been linked to contaminated drinking and recreational water, including on cruise ships.[64] Rotavirus and enteric adenoviruses are other important waterborne enteric viruses. Noroviruses, rotaviruses, and enteric adenoviruses typically cause a self-limited gastroenteritis, although dehydration from these infections can be severe in children.[36]

CLINICAL FEATURES

The majority of patients with waterborne disease present with nausea, vomiting, and diarrhea. Think of this cause in symptomatic patients with recent travel, outdoor activities such as camping or backpacking, recent recreational water use, or those using a private drinking water supply rather than municipal drinking water or bottled water. Patients with severe or chronic gastroenteritis symptoms may have immune deficiency such as human immunodeficiency virus or immunosuppressive drugs. In patients with bloody diarrhea, suspect invasive enteric bacteria as the cause.[11] Giardia and other protozoan parasites are suspected in patients with diarrhea lasting 2 or more weeks.[10]

Physical examination should focus on identifying signs of dehydration and any open skin wounds acquired in fresh or marine waters. Waterborne skin infections can range in severity from simple cellulitis to necrotizing fasciitis. Patients with *V. vulnificus* present after recent exposure to salt water and hemorrhagic bullae or signs of necrotizing infection (**Figure 159-2**).[43] Clinical features of waterborne pathogens are summarized in **Table 159-7**.

DIAGNOSIS

Diagnostic testing is usually not needed. Viral antigen tests for rotavirus may be helpful in children with severe or persistent symptoms to distinguish viral from bacterial pathogens. Testing of stool for ova and parasites is indicated in patients with recent travel to endemic countries, immunocompromised status, or diarrheal illness of 2 or more weeks; during community-wide waterborne outbreaks; or in men who have sex with men.[10,13] Because parasite excretion may not be continuous, three specimens separated by at least 24 hours may be needed to identify the causative pathogen.

The diagnosis of waterborne skin infections is based primarily on the patient's physical examination findings and history of water exposure. Identification of the causative agent can be attempted by Gram stain and

FIGURE 159-2. Skin infection from *Vibrio vulnificus. V. vulnificus* was cultured from the bulla aspirates from this patient with hemorrhagic and bullous skin lesions of the lower legs. TABLE 159-7 Type of Transmission and Clinical Features Associated with Waterborne Pathogens

Pathogen	Drinking Water	Recreational Water	Clinical Features
Campylobacter	+	+	Gastroenteritis; can be associated with Guillain-Barré syndrome
Escherichia coli O157: H7	+	+	Gastroenteritis; can be associated with hemolytic-uremic syndrome
Salmonella species	+	+	Gastroenteritis, typhoid fever
Shigella species	+	+	Gastroenteritis
Yersinia species	+	+	Gastroenteritis
Vibrio species	+	+	Gastroenteritis; skin infections
Aeromonas species	+	+	Gastroenteritis; skin infections
Pseudomonas	–	+	Skin infections, nosocomial infections
Nontuberculous *Mycobacterium*	+/–	+	Skin infections, disseminated disease in immunocompromised
Giardia	+	+	Acute and chronic gastroenteritis, asymptomatic carriage
Cryptosporidium	+	+	Acute and chronic gastroenteritis, severe among immunocompromised
Entamoeba	+	+	Acute and chronic gastroenteritis, rare fulminant colitis, liver abscess
Hepatitis A	+	+	Acute hepatitis; rare liver failure
Hepatitis E	+	+	Acute hepatitis; fulminant and severe in pregnancy
Enteric viruses	+	+	Gastroenteritis

+, potential source of infection; –, not potential source of infection

wound culture (acid-fast staining if *M. marinum* is suspected). Blood cultures are best reserved for systemically ill patients.

TREATMENT

In most cases of acute gastroenteritis from waterborne pathogens, treatment is limited to rehydration. Empiric antibiotic therapy is used for patients with moderate to severe disease, recent travel history, or symptoms lasting more than 1 week; those needing hospitalization; and immunocompromised hosts.[10] **Avoid antibiotics in cases of suspected *E. coli* O157:H7 due to an increased risk of development of hemolytic-uremic syndrome.** Appropriate antibiotics include 3 to 5 days of oral ciprofloxacin 500 milligrams twice daily, levofloxacin 500 milligrams once daily, or double-strength trimethoprim-sulfamethoxazole twice daily.[10] Azithromycin 500 milligrams orally once daily for 3 to 5 days is recommended for pregnant women, children, and patients with travel to areas with fluoroquinolone-resistant *Campylobacter* (Thailand).[10]

Antimotility agents can be given to patients or children >3 years old without signs of invasive bacterial infection (bloody stools or fever).[21,22] Probiotics, such as lactobacilli, may shorten the duration of diarrheal illnesses in adults and children.[65]

Infections from *Giardia* and *Entamoeba* are typically treated with metronidazole (Table 159-5). Paromomycin is an alternative to metronidazole in pregnant women.[66] Other alternatives for *Giardia* and *Entamoeba* treatment include tinidazole and nitazoxanide.[66] Albendazole is also effective for giardiasis, but not amebiasis. Infections from *Cryptosporidium* are generally self-limited and usually do not require specific treatment in immunocompetent patients. However, antimicrobial treatment with nitazoxanide or paromomycin is used in patients with prolonged infections, children, and the immunocompromised.[67] For immunocompromised patients with *Cryptosporidium*, nitazoxanide or paromomycin alone or in combination with azithromycin is used. Initiation of highly active antiretroviral therapy is the first priority for *Cryptosporidium* treatment in patients with human immunodeficiency virus.[68]

Treatment of waterborne skin infections includes empiric antibiotic administration (**Table 159-8**) and tetanus vaccination if needed. Consensus is that initial empiric antibiotic therapy should be broad spectrum, including clindamycin in combination with a fourth-generation cephalosporin, an extended-spectrum fluoroquinolone (i.e., moxifloxacin), or an antipseudomonal penicillin (i.e., piperacillin-tazobactam).[69,70] If *V. vulnificus* is suspected, treat with doxycycline and a fourth-generation cephalosporin.[42] Clarithromycin or doxycycline is indicated for most *M. marinum* infections, but severe cases require added rifampin or ethambutol.[49] Patients with evidence of necrotizing infections need immediate surgical consultation for operative debridement.[69]

DISPOSITION AND FOLLOW-UP

Most episodes of acute gastroenteritis secondary to waterborne pathogens are benign and self-limited. Patients with systemic symptoms, severe dehydration, significant comorbidities, or inability to tolerate oral fluids should be considered for admission. Patients with waterborne skin infections should be admitted for systemic illness, suspected necrotizing infections, or comorbidities such as immunocompromised states.

TABLE 159-8 Treatment of Waterborne Skin Infections

Pathogen	Clinical Features of Skin Infection	Treatment
Vibrio vulnificus	Cellulitis with hemorrhagic bullae, septicemia	Doxycycline 100 milligrams IV twice per day plus fourth-generation cephalosporin; necrotizing infections require emergent surgical debridement
Aeromonas species	Cellulitis, necrotizing wound infections	Mild infections: ciprofloxacin 500 milligrams PO twice per day; severe infections: ciprofloxacin 400 milligrams IV twice per day plus an IV antipseudomonal penicillin or fourth-generation cephalosporin; necrotizing infections require emergent surgical debridement
Pseudomonas aeruginosa	Hot-tub folliculitis, cellulitis in immunocompromised/diabetics	Hot-tub folliculitis is usually self-limited. Severe infection: ciprofloxacin 400 milligrams IV twice per day plus an IV antipseudomonal penicillin or fourth-generation cephalosporin
Mycobacterium marinum	Granulomatous skin infections	Clarithromycin 500 milligrams PO twice per day or doxycycline 100 milligrams PO twice per day for 3 mo; severe cases: combine with rifampin or ethambutol

PREVENTION AND SURVEILLANCE

The U.S. Safe Water Drinking Act of 1974 authorizes the Environmental Protection Agency to set national standards for U.S. public drinking water systems. The agency has set standards for 90 chemical, microbiologic, radiologic, and physical contaminants.[71] These include coliform counts, the presence of human enteric viruses, *Cryptosporidium*, and *Giardia*.

All public drinking water is required to be disinfected, which typically involves treatment with chlorine and ozone.[71] Enteric bacteria such as *E. coli* and *Campylobacter* are susceptible to these disinfection measures. However, pathogens such as protozoans and some enteric viruses are less susceptible to chlorine, and despite filtration, these pathogens may be present in sufficient quantities to cause disease.

Several recently developed vaccines are available to prevent waterborne infection from hepatitis A virus. An aggressive vaccination campaign in high-risk adults and all children has resulted in a decline in cases in the United States.[61]

CHAPTER 160

Zoonotic Infections

Bryan B. Kitch
John T. Meredith

INTRODUCTION

The World Health Organization defines zoonotic infections as those diseases and infections that are naturally transmitted from vertebrate animals to or from humans. Zoonotic infections are often encountered in emergency care. Ticks are one of the most important vectors of human infectious diseases in the world.

A zoonotic infection has presenting symptoms similar to many acute infections: fever, headache, myalgias, malaise, and weakness. Given this, a specific diagnosis is often difficult. Particular exposures or occupations that involve animal contact carry an increased risk of disease (**Table 160-1**). Recent travel, particularly in spring, summer, and early fall, or history of habitation in an underdeveloped country, are also risk factors. Zoonoses can occur at any time of the year, but in temperate climates, most zoonoses happen in the spring and summer.

Zoonoses that can present as an undifferentiated febrile illness are listed in **Table 160-2**.

TABLE 160-1 Risk Factors for Zoonotic Infection

Risk Category	Examples
Agricultural workers	Farmers, cattle ranchers, sheep ranchers, and migrant workers
Animal processing workers	Slaughterhouse workers, animal hide processors, and workers in manufacturing who deal with animal products
Outdoor enthusiasts	Forestry workers, lumbermen, surveyors, park rangers, hunters, spelunkers, and fishermen
Pet owners	Those living alongside a dog, cat, bird, rodent, rabbit, reptile, or fish
Professionals	Veterinarians, animal researchers, and animal handlers
Immunocompromised patients	Those with congenital immunodeficiencies, diabetes mellitus, alcoholism, renal failure, liver failure, cancer, splenectomy, or human immunodeficiency virus

TICKBORNE ZOONOTIC INFECTIONS

Ticks parasitize vertebrates in virtually every part of the world. Saliva of some tick species contains an anesthetic, as well as several inflammatory factors, and some species contain a toxin that paralyzes the host. Ticks feed for several days on the host, and their presence often goes unnoticed for a time, and many affected patients do not recall a history of a tick bite.[1] Tickborne diseases are often accompanied by a rash. Tickborne zoonoses have a geographic distribution (**Table 160-3**) and seasonal variation.

TICK REMOVAL, PROPHYLACTIC TREATMENT, AND PREVENTION OF TICK BITES

The most effective way to remove an embedded tick is manual extraction with tweezers or blunt angled forceps to grasp the tick as close to the skin surface as possible. Avoid puncturing or grasping the body of the tick, because this can lead to rupture of the tick and release of an infectious pathogen. Pull perpendicular to the skin with gentle traction, avoiding twisting or breaking the tick. Remove all portions of the tick because residual body parts can stimulate a granulomatous reaction and persistent infection. After complete removal of the tick, cleanse and disinfect the skin surface. Do not handle the extracted tick with bare hands. Do not use topical or injected lidocaine or pass sutures through the tick, and avoid the use of gasoline, kerosene, petroleum jelly, or fingernail polish, which all can increase infection or impair complete tick removal. Commercially available tick removal devices exist, with certain models having improved outcomes over the use of tweezers.[2] Save the removed tick in alcohol to aid in identification, especially if illness occurs.

Prophylactic treatment of a tick bite can be given only in select, not all, circumstances.[3] Recommended settings for prophylactic treatment include the ability to easily identify the tick as *Ixodes scapularis*, tick attachment for greater than 36 hours or with obvious tick engorgement, and a local tick bite in an area with *Borrelia burgdorferi* carrier rate of greater than 20%.[4] In these cases, use a *one-time dose* of doxycycline 200 milligrams for adults or 4 milligrams/kg in children for Lyme prophylaxis.

The best method to avoid tick bites is the application of topical DEET (N,N-diethyl-m-toluamide) to exposed skin and treatment of clothing with permethrin. Optimal DEET concentration is 15% to 33%, with less effectiveness if the DEET concentration is >35%. Apply to skin according to label directions.

ROCKY MOUNTAIN SPOTTED FEVER

The human disease-causing rickettsioses—the spotted fevers—include a number of different species identified in the Americas, Europe, Southwest Asia, Africa, Siberia, western Russia, and Australia. Disease names are based on species and geography: Mediterranean spotted fever, Israel spotted fever, Astrakhan fever, Siberian tick typhus, Queensland tick typhus, African tick bite fever, and so on.

Rocky Mountain spotted fever (RMSF) is one of the most severe of the tickborne illnesses in the United States, with peak occurrence occurring in June and July. The fatality rate for RMSF is currently less than 0.5%. Geographically, although reported widely and in both rural and urban settings any time of the year, more than 60% of reported cases originate from five states: North Carolina, Tennessee, Oklahoma, Missouri, and Arkansas.[5] The causative organism of RMSF is *Rickettsia rickettsii*, a pleomorphic, obligate intracellular organism, and the vectors in the United States are the very small *Dermacentor* (*D. variabilis* and *D. andersoni*, the American dog tick) and *Rhipicephalus sanguineus* ticks (the brown dog tick, found in the American southwest). Deer, rodents, horses, cattle, cats, and dogs are zoonotic hosts, with higher incidence in communities with free-roaming dog presence.[5] *Rickettsia parkeri* and

TABLE 160-2 Common Systemic Zoonotic Infections

Agent	Animal Reservoir	Physical Findings	Diagnostic Tests	Treatment
Aeromonas species	Fish, reptiles	Nonspecific fever, severe crepitant cellulitis with systemic toxicity, gastroenteritis	—	See chapter 159, "Food and Waterborne Illnesses"
Brucella canis	Dogs	Nonspecific fever	Serologic testing, blood culture	Doxycycline plus gentamicin or rifampin. TMP-SMX plus gentamicin in children
Capnocytophaga	Dogs and cats	Fever, septic shock, and meningitis from infected bite	Culture of bite wound	Amoxicillin-clavulanate or clindamycin. Pip-Tazo or a carbapenem plus clindamycin/vancomycin for shock
Chlamydophila psittaci	Birds	Fever, flulike illness, pneumonia, endocarditis, sepsis	Serologic testing and sputum culture	Doxycycline. Azithromycin and levofloxacin are alternatives
Coxiella burnetii	Cattle, sheep, goats. Occasionally cats	Fever, pneumonia, hepatitis, meningitis, endocarditis	Serologic testing, PCR	Doxycycline, with the possible alternative of a fluoroquinolone or macrolide
Ehrlichia species	Ticks	Nonspecific fever, sepsis, meningitis, hepatitis	Clinical diagnosis, serologic testing, peripheral blood smear, immunocytologic testing, PCR	Doxycycline recommended for all patients (even children and pregnancy). Rifampin is alternative.
Leptospira species	Birds, dogs, rodents	Fever, pneumonia, conjunctivitis, lymphadenopathy	Darkfield microscopic examination of body fluids, serologic testing	Penicillin G IV. Ceftriaxone IV alternative. Mild disease: oral doxycycline or amoxicillin or azithromycin
Francisella tularensis	Rabbits, cats, wild animals, biting insects	Fever, sepsis, meningitis, pneumonia, hepatitis, rash	Serologic testing (poses hazards to laboratory staff)	IV aminoglycosides. Alternative: Doxycycline or ciprofloxacin
Rickettsia rickettsii	Ticks	Fever, diarrhea, or typical presentation of Rocky Mountain spotted fever	Clinical diagnosis, rise in antibody titer between acute and convalescent serum, skin biopsy	Doxycycline or chloramphenicol
Salmonella enterica	Dogs, cats (rarely), reptiles (turtles)	Fever, abdominal pain, sepsis, cellulitis, meningitis, endocarditis, septic arthritis	Blood or stool culture	Fluoroquinolones or third-generation cephalosporins
Streptococcus iniae cellulitis	Fish, seafood	Fever, cellulitis	Wound culture, blood culture	β-Lactams except aztreonam. Alternatives: azithromycin, clindamycin, fluoroquinolones
Yersinia pestis	Dogs, cats, rodents	Bubonic: fever, headache, buboes, or pneumonic: cough, chills, dyspnea, shock	Blood culture, culture of suspected sites	Doxycycline, fluoroquinolone, gentamicin, streptomycin, or chloramphenicol

Abbreviations: PCR = polymerase chain reaction; Pip-Tazo = piperacillin-tazobactam; TMP-SMX = trimethoprim-sulfamethoxazole.

other members of the family are implicated in causing cases of possible RMSF and may be responsible for an increase in incidence as more cases are reported.

Clinical Features The diagnosis relies on epidemiologic features and the clinical exclusion of other diseases. Early signs and symptoms of RMSF are fever, headache, myalgia, and malaise. Additionally, other nonspecific findings include lymphadenopathy, abdominal pain, nausea, vomiting, diarrhea, and headache. Late in the disease course, confusion, meningismus, renal failure, respiratory failure, and myocarditis may occur. The classic clinical picture is the triad of fever, rash, and tick bite, but only about half of the patients can recall a tick bite.

The rash occurs on days 2 to 4 after the onset of fever but is absent in about 20% of patients. Most patients do not have a petechial rash when they seek initial medical care.[1] The rash occurs earlier in children than in adults and begins as small blanching erythematous to pink macules and becomes petechial later. This characteristic maculopapular rash begins on the hands, feet, wrists, and ankles, and then spreads centripetally up the trunk (see chapter 249, "Generalized Skin Disorders"). The *rash is not pathognomonic* and may occur in other illnesses. Additionally, the rash is easily overlooked early in infection and in those with dark skin. Another feature to recognize is the possibility of a nonexudative conjunctival injection with bilateral periorbital edema, resembling that found in toxic shock syndrome or Kawasaki's disease. Abdominal distention and organomegaly may exist on physical exam.[6]

Diagnosis and Treatment Immunoglobulin G– or immunoglobulin M–specific antibodies are not detectable in acute-phase serum. Laboratory abnormalities are usually nonspecific, but the **combination of normal white and red cell counts, thrombocytopenia, mild elevation of liver enzymes (aspartate aminotransferase and alanine aminotransferase), and hyponatremia suggests RMSF**, especially if the disease is advanced. Hypoalbuminemia may be present and is the cause of edema.[6] In addition to clinical patterns, diagnosis can be confirmed with a rise in antibody titer between acute and convalescent serum, skin biopsy with immunofluorescent testing, or culture, although none of these are useful for ED diagnosis.

Preferred treatment is doxycycline (**Table 160-4**). Given the relatively long half-life of doxycycline (18 to 21 hours), several days of a higher dose regimen may be required to achieve rapid therapeutic response in the critically ill patient. The risk of cosmetically perceptible tooth staining is small for a single course of treatment. **Doxycycline therapy is recommended by the American Academy of Pediatrics and by the Centers for Disease Control and Prevention as the treatment of choice for all rickettsial diseases, including RMSF, in children of all ages.**[1]

TICK PARALYSIS

Many tick species secrete neurotoxic substances from salivary glands of attached ticks. Tick paralysis occurs worldwide, in Australia, Africa, Europe, and North America, and is more common in children than adults. Prolonged tick attachment (5 to 7 days) can result in host paralysis. Symptoms are ascending weakness, beginning in the lower extremities, and moving upward to the trunk, upper extremities, and

TABLE 160-3 Tickborne Zoonotic Infections

Disease	Primary Vector	Animal Reservoir	Clinical Features	Geographic Distribution
Babesiosis	*Ixodes dammini, I. scapularis,* and *I. pacificus*	Cattle, horses, dogs, cats, rodents, deer	Fatigue, malaise, anorexia, nausea, headache, sweats, rigors, abdominal pain, emotional lability, depression, dark urine, hepatomegaly, fever, petechiae, ecchymosis, occasional rash, and occasionally, pulmonary edema	Northeast and north-central United States
Colorado tick fever	*Dermacentor andersoni* (wood tick)	Deer, marmots, porcupines	Fever, chills, headache, myalgias, nausea, vomiting, photophobia, abdominal pain, and occasional sore throat; also may have conjunctivitis, lymphadenopathy, hepatosplenomegaly, stiff neck, retro-orbital pain, weakness, and lethargy	Western and northwestern United States and southwestern Canada
Anaplasmosis	*I. scapularis, I. pacificus*	Dogs, deer, other mammals	Fevers, chills, malaise, headache, nausea, muscle aches, cough, sore throat, and pulmonary infiltrates (especially in children)	Japan, Malaysia, and the eastern, northeastern, and north-central United States
Ehrlichiosis	*Amblyomma americanum* (lone star tick)	Dogs, deer, other mammals	Fevers, chills, malaise, headache, nausea, muscle aches, cough, sore throat, and pulmonary infiltrates (especially in children)	Japan, Malaysia, Europe, and southeastern and south-central United States
Lyme disease (*Borrelia burgdorferi*)	*I. dammini*	Deer, sheep, deer mice	Erythema migrans, meningitis, encephalitis, neuropathy, and joint and heart symptoms	Atlantic central and north-central United States, Europe
Rocky Mountain spotted fever (*Rickettsia rickettsii*)	*D. andersoni* and *D. variabilis* (dog tick)	North American mammals	Petechiae, purpura, pulmonary infiltrates, jaundice, myocarditis, hepatosplenomegaly, meningitis, encephalitis, and lymphadenopathy	Most of the continental United States, although more prevalent in the southeast and south-central United States
Relapsing fever (*Borrelia* species)	*Ornithodoros* species	Human body lice, wild rodents, humans	Fever, chills, headache, myalgias, and arthralgias; pain, nausea, vomiting, and hypotension	Worldwide
Tularemia (*Francisella tularensis*)	*Dermacentor* spp. and *Amblyomma* spp.	Rabbits, deer, dogs	Pneumonia, regional lymphadenopathy and headache, cough, myalgias, arthralgias, nausea, vomiting, ulceration at inoculation site, and ocular findings	Northern hemisphere, North America, northern Asia, Europe

TABLE 160-4 Tickborne Zoonotic Infections and Specific Treatment

Tickborne Zoonotic Infection	Specific Treatment
Rocky Mountain spotted fever	Doxycycline 100 milligrams PO or IV twice a day for 7 d, or for 2 d after temperature normalizes. Some recommendations exist for an initial loading dose of 200 milligrams. For children weighing <45 kg, the dose is 2.2 milligrams/kg twice daily. Although doxycycline is contraindicated for use in pregnancy, it may be warranted in life-threatening situations. Chloramphenicol is an alternative; however, it has multiple toxic effects and contraindications, and may be difficult to obtain. Dosing is 50 milligrams/kg/d divided into 4 doses for 7 d.
Lyme disease	Primary stage or mild secondary: 14–21 d of doxycycline (100 milligrams PO twice a day), amoxicillin (500 milligrams PO 3 times a day in adults, 50 milligrams/kg/d divided 3 times a day in children), or cefuroxime (500 milligrams PO twice a day in adults, 30 milligrams/kg/d divided 3 times a day in children). Macrolides possible but less effective. Severe illness, CNS positive, or high-degree heart block: ceftriaxone 2 grams IV for 14–30 d. A single 200-milligram oral dose of doxycycline given within 72 h of a high-risk deer tick bite is effective in preventing Lyme disease.
Tickborne relapsing fever	Doxycycline (100 milligrams PO/IV twice a day for 7–10 d). Alternative: erythromycin (500 milligrams PO/IV 4 times a day for 7–10 d). Chloramphenicol is an alternate.
Colorado tick fever	Treatment is supportive.
Tularemia	Adults: streptomycin, 1 gram IM/IV twice a day, or gentamicin/tobramycin, 5 milligrams/kg IV divided every 8 h. Treat for 10 d. Children: streptomycin, 15 milligrams/kg IM twice daily (should not exceed 2 grams/d). Mild disease: ciprofloxacin 750 milligrams PO twice a day or doxycycline 100 milligrams PO twice a day. Treat for 21 d. Prophylaxis for lab exposures: doxycycline 100 milligrams PO twice a day or ciprofloxacin 500 milligrams PO twice a day. Treat for 14 d.
Babesiosis	Atovaquone (750 milligrams PO every 12 h) plus azithromycin (500 milligrams PO on day 1, then 250–1000 milligrams daily). Treat for 10 d. If relapse occurs, treat for the longer duration: 6 weeks or 2 weeks after negative blood smear. Severe disease in adults: clindamycin (1200 milligrams IV twice a day or 600 milligrams PO 3 times a day) + quinine (650 milligrams PO 3 times a day). Treat for 7–10 d.
Ehrlichiosis and anaplasmosis	Doxycycline, 100 milligrams PO twice a day for 7–14 d. For children weighing <45 kg, the dose is 2.2 milligrams/kg twice a day.

head over hours to days. Cerebrospinal fluid analysis is normal. Diagnosis is made upon finding a tick on the body. Tick removal leads to recovery in 24 hours.

LYME DISEASE

Lyme disease was probably first noted in Europe about 100 years ago, based on descriptions of the rash, erythema chronicum migrans. Lyme disease is the most common vectorborne zoonotic infection in the United States, with approximately 30,000 cases reported annually. Based on public health data and insurance information, the actual number of patients diagnosed with Lyme disease may be closer to 300,000 per year.[7] Lyme disease is reported in Europe, China, Japan, Australia, parts of Russia, and in all U.S. continental states, with 95% of the reported cases originating from just 13 states clustered in the northeast and upper midwest. Peak transmission occurs in May through August. The responsible organism is *B. burgdorferi*, a spirochete, and the vector is the *Ixodes* deer tick, also known as *black-legged tick*. The overall risk of Lyme disease after a deer tick bite is low, about 3% in endemic areas. However, the risk of infection is proportional to the length of time the tick feeds on the host, with minimal to no risk associated with tick attachment duration less than 36 hours.[4,8]

Clinical Features Lyme disease has three stages. The **first stage** is local and often characterized by **erythema migrans**: an erythematous plaque with central clearing. Erythema migrans develops in approximately 60% to 80% of cases.[1] It develops within 2 to 30 days at the site of the tick bite and is a result of a vasculitis. There may also be nonspecific symptoms of fever, chills, fatigue, myalgias, arthralgias, and lymphadenopathy. The rash may persist for up to 1 month and recur in the secondary stage of Lyme disease. Untreated erythema migrans resolves spontaneously in 3 to 4 weeks. This rash causes few symptoms and, depending on skin location, may go unnoticed by the patient.

The **second stage**, early disseminated disease, develops with the reproduction and spread of the *Borrelia* spirochete and occurs within a few days to months of the initial infection. This stage is characterized by fever, adenopathy, neuropathies, cardiac abnormalities, arthritic complaints, and skin lesions. Multiple annular/target-shaped skin findings occur in up to 50% of the patients infected and are the most characteristic component of the secondary stage of illness.

The most common neurologic symptom in the secondary stage of illness is the development of cranial neuritis, most often **unilateral or bilateral facial nerve palsy**. Facial palsy can also occur along with the initial rash of erythema migrans. Neuroborreliosis occurs in 15% of the untreated cases and can consist of periodic headache, neck stiffness, difficulty in mentation, cerebellar ataxia, myelitis, encephalitis, motor or sensory radiculoneuritis, mononeuritis multiplex, and facial palsy.[9] Asymmetric oligoarticular arthritis of the large joints, with a particular predilection for the knees, is another complication. Brief attacks of asymmetric oligoarticular arthritis are common in the untreated patient in the secondary stage of illness. Attacks are characteristically separated by months of remission. Cardiac abnormalities occur in up to 8% of patients and present as varying degrees of atrioventricular block, sometimes requiring the insertion of a temporary pacemaker for stabilization. Additionally, myopericarditis may also be a manifestation on initial presentation.

The **late disseminated stage** of illness occurs months to years after the initial infection and is characterized by chronic arthritis, myocarditis, subacute encephalopathy, axonal polyneuropathy, and leukoencephalopathy.[9] The advanced, chronic neurologic forms of Lyme disease can persist for over 10 years. Additionally, between 10% and 20% of patients treated with antibiotics can have persistent symptoms of disease, usually muscle and joint aches with fatigue. This entity is currently being studied but seems to be an autoimmune response persistent from the initial infection.

Diagnosis and Treatment Diagnosis is clinical early in disease when erythema migrans is present; testing is required to diagnose later stages of Lyme disease.[8] For the latter, use polymerase chain reaction testing, polyvalent fluorescence immunoassay, or Western immunoblot testing,[9] because *B. burgdorferi* is difficult to culture.

Treatment of Lyme disease is with doxycycline (preferred agent) or amoxicillin. Neurologic symptoms or persistent other manifestations require ceftriaxone therapy (Table 160-4). A previously marketed vaccine no longer exists, because it conferred no ongoing immunity.

EHRLICHIOSIS

Ehrlichiosis is a group of zoonotic diseases caused by the *Ehrlichia* genus, gram-negative pleomorphic coccobacilli that infect circulating leukocytes.[1] Infection due to *Ehrlichia chaffeensis* is also called *human monocytic ehrlichiosis*. The disease vector is the lone star tick, *Amblyomma americanum*. The major animal reservoir in North America is the white-tailed deer in the southeastern United States, with dogs and mice carrying several less common species of the pathogen.[10] Disease incidence has been on the rise, increasing from 0.8 to 3 cases/million in the United States in 2000 to 2007, partly attributed to increased recognition. It has also been described in Europe. The mortality rate in confirmed cases varies between 1% and 3% depending on causative agent.[10]

Symptoms usually develop within 1 to 2 weeks of a tick bite.[11] Clinical signs and symptoms are fever, headache, malaise, nausea, vomiting, diarrhea, abdominal pain, and arthralgias. Fever is present in the vast majority of cases (97%). Rash is present in 30% of adults and has no pathognomonic features, making it a nonspecific diagnostic clue.[12] With disease progression, a minority of patients go on to develop severe complications of renal failure, respiratory failure, and encephalitis. The acute phase of illness lasts less than 4 weeks, with the majority of patients recovering and proceeding on to a convalescent phase.

Laboratory studies can demonstrate leukocytopenia, thrombocytopenia, and elevation of hepatic enzymes. Diagnosis is made clinically but can be confirmed by laboratory testing once treatment has begun. Peripheral blood smear may show colonies of ehrlichiae in the white blood cells in 20% of infected patients. Polymerase chain reaction is specific but not sensitive and is best in the first week of illness. Antibody tests are expected to be negative in 85% of patients during initial infection. The gold standard test is immunofluorescence assay.[11]

Treatment is with doxycycline until 3 to 5 days after fever resolution or 10 to 14 days after resolution of CNS symptoms in severe disease. Rifampin is used in those with contraindications to doxycycline.[12]

ANAPLASMOSIS

Anaplasmosis is a tickborne disease caused by the bacteria *Anaplasma phagocytophilum*.[13] Older terms for the disease are *human granulocytic ehrlichiosis* and *human granulocytic anaplasmosis*. The vector is the black-legged tick, *I. scapularis*, as well as the western black-legged tick, *Ixodes pacificus*. The zoonotic reservoirs are deer, elk, and rodents, and the disease is prevalent in the upper midwestern and northeastern United States in the same areas where Lyme disease is present, with 90% of all reported anaplasmosis cases from only six states. Peak transmission occurs in the summer, specifically June and July. Incidence of reported cases has risen from 1.4 to 6.1 cases per million in the United States from 2000 to 2010. Case mortality rate has remained less than 1%.[14] Symptoms, developing within 1 to 2 weeks of the initial bite, are nonspecific and similar to those of ehrlichiosis or influenza—fever, chills, headache, and myalgias. Rash is rare in anaplasmosis and should clue the clinician to consider an alternative diagnosis.[14] Laboratory findings are nonspecific and should not alter the clinical decision to treat but may consist of leukocytopenia, thrombocytopenia, and elevation of hepatic enzymes. Confirmatory testing modalities are similar to those for ehrlichiosis. Treatment is with doxycycline, as noted in other tick infections (Table 160-4).

TICKBORNE RELAPSING FEVER

Relapsing fever is caused by several varieties of gram-negative *Borrelia* spirochetes. It was first described in West Africa and is now recognized worldwide. Within the United States, it is rarely found east of Texas.[15] *Ornithodoros* ticks (soft ticks that can survive for years between meals) are the vectors, and the principal zoonotic reservoirs are wild rodents, specifically tree squirrels and chipmunks.[16] The classic risk factor is

sleeping in rustic mice-infested structures in the wilderness of the western United States. The initial presentation may be that of a rash or a 2- to 3-mm pruritic eschar at the site of a tick bite. An average incubation period of 7 days precedes the onset of fever, chills, cephalgia, myalgia, arthralgia, abdominal pain, and general malaise. Headache and myalgia occur in over 90% of cases.[16] Characteristically, the roughly 3-day-long febrile episodes are interspersed with 7-day-long afebrile periods, which may cycle one to four times before resolution.[16] Untreated, the disease is usually self-limited, with deaths occurring mostly at the extremes of age.

Leukocytosis and thrombocytopenia are the typical laboratory findings. Diagnosis is confirmed with the appearance of spirochetes on darkfield microscopy or Wright-Giemsa–stained peripheral blood smears, with a 70% sensitivity if obtained during a febrile period. Patients with relapsing fever may test false positive on Lyme disease assays due to protein cross-reactivity.[16]

The recommended treatment is with tetracycline or erythromycin. Use IV ceftriaxone for 10 to 14 days if any CNS involvement is seen.[16] Similar to Lyme disease, patients in an endemic area with a confirmed tick bite can receive postexposure doxycycline as effective prophylaxis.[17]

COLORADO TICK FEVER

Colorado tick fever is caused by an RNA virus of the genus *Coltivirus* in the family Reoviridae.[18] The principal vector is the wood tick, *D. andersoni*, and the zoonotic reservoirs are deer, marmots, and porcupines. The disease is endemic to the western mountainous regions of the United States and is limited to elevations between 4000 and 10,000 ft. Transmission to humans can occur with short periods of tick attachment. The incubation period is 3 to 5 days, and the onset of illness is characterized by fever, chills, headache, myalgias, and photophobia. There may be a macular or petechial rash in a minority of patients. The disease is self-limited, and complications are rare, although some patients may experience recurrent fever after 1 to 2 days of improvement. Diagnosis is most often based on history, clinical findings, and geography. Treatment is supportive.[18]

TULAREMIA

Tularemia is caused by a small gram-negative, nonmotile intracellular coccobacillus, *Francisella tularensis*. The disease is found in North America, northern Asia, and Europe. The zoonotic vectors are ticks of the *Dermacentor species* (wood tick, dog tick) and the *Amblyomma* species (lone star tick), as well as various flies. The principal zoonotic reservoirs are rabbits, hares, and deer.[18] Tularemia is contracted through tick/fly bites, by inhalation, or through open wounds while in contact with an infected zoonotic host. Incubation is often between 3 and 6 days but may range from 2 hours to 3 weeks. The clinical presentation depends on the method of inoculation, and the clinical forms are called *ulceroglandular, glandular, typhoidal, pneumonic, oculoglandular,* and *oropharyngeal*. The **ulceroglandular form** is the most common, occurring in 80% of cases,[18] and is characterized by a maculopapular skin lesion that ulcerates, followed by painful regional adenopathy and systemic symptoms. The **glandular form** consists of painful adenopathy without ulcerations. The **typhoidal form**, occurring in 20% to 30% of cases, consists of high fever, chills, cephalgia, and abdominal pain with an absence of skin and lymph involvement. Typhoidal tularemia is noted to have a slower tachycardia than would be expected given the fever magnitude. It is the form of the disease with highest morbidity, complications, and organ failure. The **oculoglandular form** and **pneumonic form** are the result of deposition into the eyes or inhalation of the *F. tularensis* bacterium. Pneumonic tularemia has up to a 50% mortality rate and is the most lethal form of disease.

Laboratory findings are nonspecific; confirmatory testing is difficult and poses health risks to laboratory staff. First-line treatment is with streptomycin; gentamicin, ciprofloxacin, imipenem, doxycycline, and chloramphenicol are alternative therapies. Prevention of exposure and early treatment are key measures to prevent adverse outcomes. Clinical suspicion should be high for this disease in endemic areas. Due to the ease of transmission and lethality, *F. tularensis* is a possible agent of biologic warfare/terrorism (Table 160-4).

BABESIOSIS

Babesiosis is a malaria-like disease transmitted by ticks, with the etiologic agents being protozoan parasites. *Babesia microti* is the most common causative organism in the United States, with sporadic cases caused by *Babesia duncani* on the Pacific coast.[19] The major zoonotic reservoirs are domesticated mammals, rodents, and deer. Ixodes ticks function as the principal vector globally. Babesiosis has been transmitted through blood transfusions and is the most common transmitted pathogen reported to the Food and Drug Association, with about 160 cases reported since 1979.[19] Clinically, the presentation occurs 1 to 4 weeks after exposure with generalized malaise, anorexia, fever, and chills that can progress to intermittent sweats, myalgia, headache, and hemolytic anemia. Splenectomy and immunosuppression are risk factors. Laboratory tests demonstrate hemolysis, liver dysfunction, anemia, thrombocytopenia, and renal failure. Co-infection with Lyme disease or anaplasmosis/ehrlichiosis is common; patients with severe disease or disease refractory to treatment should be considered for alternative etiologies of illness. Diagnosis is made by finding intraerythrocytic ring forms resembling malaria on a Giemsa- or Wright-stained peripheral blood smear, although false-negative results can occur when the level of parasitism is low. Treatment duration is typically for 7 to 10 days with atovaquone plus azithromycin or clindamycin, with quinine added for severely ill patients (Table 160-4).

ZOONOTIC ENCEPHALITIS AND MENINGITIS

Zoonotic encephalitis is most often an arboviral infection transmitted hematologically by an arthropod or insect vector from an animal host.[20] There are multiple distinct arboviruses that cause zoonotic encephalitis in the United States and Canada. Furthermore, encephalitis may be seen in the nonviral zoonotic infections of *Bartonella henselae, Brucella canis*, borreliosis, *Coxiella burnetii, Ehrlichia* species, listeriosis, leptospirosis, Lyme disease, RMSF, psittacosis, and toxoplasmosis.[20]

Often, the vector is a mosquito or tick, and the animal host is a small animal or bird. Rabies is an exception (see chapter 157, "Rabies"), as a virus that ascends peripheral nerve tracts after inoculation from an infected animal's bite.

The first clinical signs and symptoms are nonspecific: malaise, myalgia, and fever. These findings are followed by headache and a sudden decline in mental status. Head CT scan is usually normal. The cerebrospinal fluid is often abnormal, showing a slightly elevated opening pressure, normal to slightly elevated protein concentration, normal glucose levels, and predominance of lymphocytes. The electroencephalogram is abnormal, with diffuse bilateral slowing interrupted by occasional spike activity. Cerebrospinal fluid viral cultures are frequently sterile, and the infectious agent is rarely isolated from the cerebrospinal fluid. Enzyme-linked immunosorbent assay of serum can be used to detect most arboviral infections causing encephalitis.

Treatment is supportive and directed toward decreasing elevated intracranial pressure. Consider treatable causes of encephalitis, such as herpes simplex or varicella, in the differential diagnosis.

The West Nile virus is an arbovirus that can cause a flulike illness, West Nile fever or **West Nile virus encephalitis**. Infected mosquitoes transmit the virus to humans and other animals through bites. Approximately 20% of patients infected will develop symptomatic illness. Of those who do, less than 1% develop severe or potentially fatal infection.[21] West Nile is the most common arboviral infection in the United States. Although antibody responses can be measured to confirm disease, lab testing is usually not specific. Treatment for West Nile virus is supportive, with attention to the need for mechanical ventilation and management of elevated intracranial pressure or seizures (**Table 160-5**; see chapter 153, "Serious Viral Infections").

Zoonotic meningitis can be caused by brucellosis, listeriosis, plague, salmonellosis, tularemia, leptospirosis, Lyme disease, ehrlichiosis, Q fever, RMSF, or psittacosis. Cerebrospinal fluid is almost always abnormal, showing a slightly elevated opening pressure, normal to slightly elevated protein concentration, normal glucose levels, and predominance of lymphocytes. Treatment is directed toward the specific organism cultured from the cerebrospinal fluid. However, empiric antibiotic coverage should be administered immediately in

TABLE 160-5 Selected Zoonotic Infections and Specific Treatment

Selective Zoonotic Infections	Specific Treatment
West Nile virus encephalitis	Supportive care.
Brucellosis (*Brucella* species)	Mild disease: doxycycline, 100 milligrams PO twice a day for 6 weeks, + gentamicin, 5 milligrams/kg IV daily for 7 d. Alternative: doxycycline, 100 milligrams PO twice a day, + rifampin, 600–900 milligrams PO daily for 6 weeks. Joint involvement: doxycycline, 100 milligrams PO twice a day, + rifampin, 600–900 milligrams PO daily for 3 months, + gentamicin, 5 milligrams/kg IV once daily for first 7 d. Neurologic involvement: doxycycline, 100 milligrams IV/PO twice a day, + rifampin, 600–900 milligrams PO daily, + ceftriaxone, 2 grams IV twice a day. Treat until cerebrospinal fluid normalizes.
Psittacosis (*Chlamydophila psittaci*)	Doxycycline, 100 milligrams PO for 5–7 d. Alternative: azithromycin dose pack or levofloxacin, 750 milligrams PO for 5–7 d.
Q fever (*Coxiella burnetii*)	Doxycycline, 100 milligrams PO twice a day for 2–3 weeks. Alternative: consider 2–3 weeks of a fluoroquinolone or a macrolide.
Pasteurellosis (*Pasteurella multocida*)	Amoxicillin-clavulanate, 875/125 milligrams PO twice a day for 7–10 d. Alternative therapies based on culture data and presence of *Staphylococcus* co-infection. Often resistant to cephalexin, clindamycin, and macrolides.
Plague (*Yersinia pestis*)	Gentamicin, 5 milligrams/kg IV daily for 10 d. Alternative: streptomycin, 15 milligrams/kg IV/IM twice a day for 10 d. Postexposure prophylaxis: Doxycycline, 100 milligrams PO twice a day, or ciprofloxacin, 500 milligrams PO twice a day. Treat for 7 d.
Hantavirus	Treatment consists of supportive care with attention to adequate oxygenation.
Toxocariasis (*Toxocara canis*)	Moderate to severe disease: albendazole, 400 milligrams PO twice a day, with/without prednisone, 60 milligrams/d for allergic response. Treat for 5 days. Alternative: mebendazole, 100–200 milligrams PO twice a day for 21 d.
Dipylidiasis (dog tapeworm)	Praziquantel, 5–10 milligrams/kg PO, one-time dose. Alternative: niclosamide, 2 grams PO, one-time dose
Leptospirosis	Mild disease: doxycycline, 100 milligrams PO twice a day for 5–7 d. Alternative: azithromycin, 500 milligrams PO daily for 3 d. Severe disease: penicillin G, 1.5 million units IV every 6 h for 7 d, or ceftriaxone, 1–2 grams IV daily for 7 d. Alternative: doxycycline, 100 milligrams IV for 7 d.

any presumptive case of meningitis in an effort to reduce mortality and morbidity (see chapter 174, "Central Nervous System and Spinal Infections").

UPPER RESPIRATORY ZOONOTIC INFECTIONS

Recurrent pharyngitis in a household member can have a zoonotic source, sometimes the household pet. Case reports exist where domestic animals in cohabitation with humans were associated with group A streptococcal pharyngitis recurrence; however, current practice guidelines on infection can find no causal link.[22] **Prolonged exudative pharyngitis raises the suspicion of a zoonotic origin or atypical pharyngitis, particularly if the exudative pharyngitis includes systemic symptoms and leukocytosis, and is refractory to standard antistreptococcal therapy.** Dogs and domesticated farm animals can be the source of *Streptococcus* species, *Corynebacterium ulcerans, Yersinia* species, and viral vesicular stomatitis. All of these zoonoses can present as an exudative pharyngitis. Nondomesticated animals can be a source of exudative pharyngitis as a result of *Bordetella* species, *F. tularensis, Streptobacillus moniliformis,* and *Yersinia pestis*. Birds carry *Chlamydophila psittaci*, which can cause an atypical exudative pharyngitis in humans.

LOWER RESPIRATORY ZOONOTIC INFECTIONS

Zoonotic pneumonia presents as an atypical, community-acquired pneumonia with systemic symptoms. Most often, the presentation consists of productive or nonproductive cough, fever, chills, headache, myalgias, and a nonspecific rash. Symptoms can progress very rapidly. A detailed history is an important tool for the consideration of zoonotic pneumonia. Ask about animal exposure, occupation, and recent travel. Consider zoonotic pneumonia as a source of gram-negative community-acquired pneumonia and in any case of atypical pneumonia with systemic symptoms (**Table 160-6**).

ANTHRAX

Inhalation anthrax (*Bacillus anthracis*) is acquired most often from handling unsterilized, imported animal hides or imported raw wool; anthrax is generally fatal. Inhalation anthrax is a mediastinitis without alveolar involvement rather than pneumonia. Initial symptoms are similar to influenza with a slightly higher propensity for dyspnea. Illness can progress to respiratory failure in 2 to 3 days, with marked mediastinal and hilar edema. Anthrax vaccine is available primarily for populations at high risk of exposure to aerosolized *B. anthracis* spores such as military personnel and laboratory workers.[23] The protocol for **anthrax vaccination** consists of five intramuscular injections, three injections on day 0 and one each at weeks 2 and 4.[24] The vaccination is well tolerated by most patients.

A 60-day antibiotic course combined with a three-dose vaccination course used in postexposure prophylaxis could be effective in preventing anthrax postexposure, although this regimen is not presently approved by the Food and Drug Administration for this purpose.[24] Antibiotics typically used in inhalation anthrax are doxycycline or ciprofloxacin, plus an additional one or two agents for synergy, including penicillin G, vancomycin, rifampin, or other agents for which the strain is suspected to be sensitive. Cephalosporins are contraindicated due to resistance.[24]

TABLE 160-6 Zoonotic Pneumonias

Disease	Organism	Reservoirs	Treatment
Inhalation anthrax	*Bacillus anthracis*	Imported animal hides, raw wool, sick domestic animals	Adult initial treatment: ciprofloxacin, 400 milligrams IV every 12 h (alternative: doxycycline, 100 milligrams IV every 12 h or levofloxacin, 500 milligrams every 24 h), + clindamycin, 900 milligrams IV every 8 h, + rifampin, 300 milligrams IV every 12 h Plus one-time infusion raxibacumab, 40 milligrams/kg diluted over 2.25 h When clinically stable: ciprofloxacin, 500 milligrams PO twice a day, + clindamycin, 450 milligrams PO every 8 h, + rifampin, 300 milligrams PO twice a day Treat for 60 d
Brucellosis	*Brucella* species	Food animals and product handling, ingestion, inhalation	See Table 160-5
Psittacosis, ornithosis	*Chlamydophila psittaci*	Bird exposure—pet and pet shop, veterinarians, turkey farms	See Table 160-5
Q fever	*Coxiella burnetii*	Inhaled endospores from animal-contaminated soil; cat afterbirth, ticks	See Table 160-5
Tularemia	*Francisella tularensis*	Aerosol from dead birds, animals; bacteremic spread from bubo; ticks and biting flies	See Table 160-4
Leptospirosis	*Leptospira interrogans*	Domestic and wild animals, contaminated water, veterinarians, farmers	See Table 160-5
Pasteurellosis	*Pasteurella multocida*	Underlying respiratory disease; contact with cat, dog in home	See Table 160-5
Rocky Mountain spotted fever	*Rickettsia rickettsii*	Tick-associated, typical rash	See Table 160-4
Toxoplasmosis	*Toxoplasma gondii*	Contact with domestic food animals and pets, ingestion of cysts, pneumonia in immunocompromised persons	Severe disease: Pyrimethamine, 200 milligrams PO on d 1, followed by 50–75 milligrams PO every 24 h, + sulfadiazine, 1–1.5 grams PO every 6 h, + leucovorin, 5–20 milligrams 3 times weekly If ocular involvement, treat as above and add prednisone, 0.5 milligrams/kg PO twice a day Treat until 1–2 weeks after symptoms resolve, continue leucovorin for 1 week past that
Plague	*Yersinia pestis*	Contact with mammals and fleas; veterinarians; outdoor activities in endemic area; cats	See Table 160-5
Viral pneumonias			
Hantavirus pulmonary syndrome	Bunyaviridae	Rodent feces, urine, and saliva	Ventilator oxygenation or consideration of ribavirin
Influenza pneumonia	Influenza A	Aquatic fowl, pigs, horses, marine mammals	Supportive care; amantadine or rimantadine; oseltamivir if benefits outweigh risks

BRUCELLOSIS

Brucellosis (*Brucella* species) occurs most often from the consumption of unpasteurized dairy products. Another way of acquiring brucellosis is found in slaughterhouse workers exposed to aerosols containing *Brucella* bacteria.[25] In reference to the inhalation form of *Brucellosis*, this rare presentation is one of an upper respiratory infection with a cough, productive sputum, hoarseness of voice, dyspnea, and wheezing. There are no pathognomonic signs on chest x-ray, and a variety of findings may be present including pneumonia, adenopathy, effusion, granulomas, and effusion. With long-standing resolution, calcified granulomas may remain.[26] Doxycycline combined with rifampin is effective therapy; the recommended duration is 6 weeks to prevent recurrence[25] (Table 160-5).

PSITTACOSIS

Psittacosis (parrot fever, parrot disease, or ornithosis) is caused by *Chlamydophila psittaci*, an organism common to most birds and domesticated fowl. This disease is rare, with only a handful of cases reported annually in the United States, although underreporting is likely due to the often mild unrecognized form of disease.[27] Human acquisition is from the inhalation of dust from dried bird feces, feather dust, aerosolized avian respiratory secretions, or direct bird contact.[27] Psittacosis is characterized by an incubation period of 5 to 14 days followed by abrupt onset of fever, chills, cephalgia, myalgia, and generalized malaise. Pneumonia is atypical, with a nonproductive cough and lobar or interstitial infiltrates on chest radiograph. Extrapulmonary manifestations including endocarditis, hepatitis, cranial nerve palsies, and acute interstitial nephritis are possible. Diagnosis is made based on clinical suspicion for the disease and confirmation of isolation of *C. psittaci* from respiratory secretions or by IgM immunoassay. Doxycycline is the mainstay of treatment, with most patients responding rapidly to therapy. Tetracycline is also an option along with macrolides[27] (Table 160-5).

Q FEVER

Q fever (*Coxiella burnetii*) is a rickettsial infection acquired by aerosol inhalation primarily; however, arthropod vector transmission is possible.[28] The primary reservoirs are cattle, sheep, and goats, with bacterial shedding in urine, afterbirth products, and feces. The organism is highly resistant to environmental degradation. The disease is often self-limiting, with variable pulmonary manifestations and extrapulmonary findings. In addition to

pulmonary infiltrates, severe headache, pericarditis, myocarditis, endocarditis, and a nonjaundiced hepatitis can occur. The majority of patients will have nonspecific infiltrates on chest x-ray.[28] Doxycycline is the treatment of choice for acute Q fever and is most effective in reducing duration of symptoms and risk of complications when initiated within the first 3 days of illness. Q fever may rarely progress to a chronic infective state with fatigue and extrapulmonary manifestations being predominant findings[28] (Table 160-5).

PASTEURELLOSIS

Pasteurellosis (*Pasteurella multocida*) is endemic to the normal oral flora of cats and most dogs. Classically, infection is associated with necrotizing cellulitis from bite wounds. Rarely bronchitis, bronchopneumonia, and suppurative pleural effusion occur as a result of pulmonary infection. Treatment is with amoxicillin-clavulanate, doxycycline, penicillin, or a third-generation cephalosporin (Table 160-5).

PULMONIC PLAGUE

Between 1000 and 2000 cases of plague are reported to the World Health Organization each year, with mortality rates reported as approximately 10%. Most human cases today are reported from sub-Saharan Africa. In the United States, plague (pulmonary form) (*Yersinia pestis*) is most often found in rock squirrels and ground rodents of the Southwest. Cats can be carriers of plague, whereas dogs are resistant to the disease. The principal vector is the rodent flea, with the majority of infected fleas globally found on black rats or brown sewer rats.[29] Humans and household pets can become infected when bitten by an infected flea or consuming other infected animals. Humans may also be infected by inhalation of animal secretions. Incubation period from a flea bite to disease ranges from 2 to 10 days. Often an eschar is found at the site of the flea bite, followed by the development of a bubo, an enlarged, suppurative, proximal lymph node. Sepsis and pneumonia from hematologic spread occur following the bubo appearance. The disease is rapidly fatal if not aggressively treated.

Start treatment at the time plague is suspected with parenteral streptomycin or gentamicin. Transition to oral therapy with doxycycline, ciprofloxacin, or chloramphenicol occurs when clinically improved. These agents can be used as initial therapy in those who cannot tolerate the preferred choice. Continue any therapy for at least 10 days or 2 days after resolution of fever[29] (Table 160-5).

HANTAVIRUS

Hantavirus, identified in 1977, is from the Sin Nombre virus, which belongs to the Bunyaviridae family of viruses. The deer mouse (*Peromyscus maniculatus*) is the primary vector in the southwestern United States.[30] Infected rodents excrete hantavirus in feces, urine, and saliva. Human infection occurs with the inhalation of dried, particulate feces, by contact with urine, or by a rodent bite. Clusters of hantavirus pulmonary syndrome have been reported in South America. In Asia, hantaviruses can cause hemorrhagic fever with renal syndrome—acute renal failure with concurrent thrombocytopenia, ocular abnormalities, and flulike symptoms. In the United States, the presentation of this zoonosis is that of hantavirus cardiopulmonary syndrome,[30] which consists of an initial flulike prodromal illness of 3 to 4 days in duration, rapidly followed by pulmonary edema, hypoxia, hypotension, tachycardia, and metabolic acidosis. Dizziness, nausea, vomiting, absence of cough, and thrombocytopenia are common and may help to differentiate hantavirus pulmonary syndrome from acute respiratory distress syndrome, bacterial pneumonia, and influenza pneumonia. Hantavirus pulmonary syndrome carries a very high mortality rate, which was previously estimated around 60% but has now improved to 30% with efforts toward prevention, recognition, and early aggressive care.[31] Diagnosis is with an immunofluorescent or immunoblot assay. Treatment is supportive.[32]

GI ZOONOTIC INFECTIONS

Many of the parasitic, bacterial, and viral organisms responsible for gastroenteritis share a zoonotic source in addition to a human source. These are discussed elsewhere.

HEPATITIS E

Hepatitis E virus is a nonenveloped virus with a single-strand RNA genome. Hepatitis E virus is global in distribution and is characterized by zoonotic as well as other means of transmission. When transmitted from animals, the origin is suspected to be boar, deer, and domestic pigs, cattle, sheep, goats, and ducks. Domesticated pigs are particularly susceptible to hepatitis E virus and provide a major source of exposure to humans, particularly in Japan. Further specifics of the disease can be found elsewhere in this text.

DERMATOLOGIC ZOONOTIC INFECTIONS

Dermatologic findings are common in zoonotic infections, because the skin is often the site of inoculation and may display focal findings. The common dermatologic infections of impetigo, ecthyma, and cellulitis can be transmitted zoonotically, as can human infestations with mites and lice. The dermatophytoses *Trichophyton verrucosum* and *Microsporum canis* account for the majority of zoonotic dermatophyte infections, with *M. canis* accounting for 15% of all human dermatophytoses. Chancriform lesions (ulcerations at the site of inoculation) can result from zoonotic infection of bacterial, mycobacterial, fungal, or viral etiology.

BACTERIAL ZOONOTIC SKIN INFECTIONS

The most well-described bacterial chancriform zoonotic lesions are *B. anthracis* (anthrax), *B. henselae* (cat-scratch disease), *Erysipelothrix rhusiopathiae* (erysipeloid), *F. tularensis* (tularemia), *Listeria monocytogenes* (listeriosis), *Mycobacterium marinum* (aquarium granuloma), and *Burkholderia mallei* (glanders).[33] The majority of these chancriform zoonotic infections occur in livestock workers, cattle ranchers, veterinarians, stable workers, horse trainers, slaughterhouse workers, poultry workers, and farmers. Significant zoonotic fungal infection is principally from *Blastomyces dermatitidis* (cutaneous blastomycosis) and *Sporothrix schenckii* (sporotrichosis). Dog and cat owners, along with veterinarians, are most at risk of contracting these two fungal zoonoses. All of the chancriform zoonotic infections most commonly appear at the site of inoculation, often the hands or forearms.

CUTANEOUS ANTHRAX

Cutaneous anthrax, also known as *woolsorter's disease*, accounts for 95% of all anthrax infections.[34] Cutaneous anthrax is most common in societies dependent on and in close contact with livestock and agriculture-based societies. Recently, localized outbreaks have been seen among injection drug users.[34] The hands and fingers are the most commonly infected areas of the body, but arms, lower legs, and feet can also be involved. Anthrax spores are deposited in a skin wound; in 1 to 5 days, a painless or pruritic macule develops at the inoculum site. The macule evolves into an ulcerative site with multiple serosanguineous vesicles. Vesicles contain the anthrax bacillus and are infectious. Gram stain or culture of the vesicular fluid is often diagnostic. The ulcer eventually progresses to a painless black eschar and falls off within 2 weeks. If purulence is present, suspect secondary bacterial superinfection. Untreated, mortality is between 5% and 20% with progression to shock possible. If the disease is thought to have been acquired naturally (i.e., bioterrorism not a concern), penicillin or amoxicillin for 3 to 7 days is the primary treatment.[35] Other patients are treated with oral ciprofloxacin for 60 days, with doxycycline as an alternative option.

VIRAL ZOONOTIC SKIN INFECTIONS

Zoonotic dermatoses of viral etiology include *Vaccinia* species (cowpox), *Paravaccinia* species (pseudocowpox), and bovine papular stomatitis. These cutaneous viral zoonoses often occur on the hands and forearms of patients who work closely with cattle, sheep, goats, or horses. Systemic zoonoses can be accompanied by dermatologic findings, usually a generalized maculopapular rash, which is common in bartonellosis, lymphocytic choriomeningitis, Colorado tick fever, leptospirosis, psittacosis, and

TABLE 160-7 Specific Zoonotic Dermatologic Findings

Zoonoses	Characteristic Rash
Aeromonas species	Crepitant cellulitis with systemic toxicity
Lyme disease	Erythema migrans at the focus of the tick bite
Rocky Mountain spotted fever	Maculopapular rash on soles and palms with centripetal spread, advanced characteristics of petechial hemorrhage and necrosis
Viral hemorrhagic fever	Petechial and purpuric rash

rickettsial infections. However, the maculopapular rash associated with most zoonotic infections is nonspecific and does not facilitate the diagnosis. Those zoonotic infections with specific dermatologic findings that can aid in diagnosis are infections from *Aeromonas* species, Lyme disease, RMSF, *Vibrio* species, and viral hemorrhagic fevers (**Table 160-7**).

ZOONOSES ACQUIRED FROM HOUSEHOLD PETS

Dogs and cats are the two most common household pets in North America and account for the majority of these zoonotic infections. Small rodents, pet birds, reptiles, and aquarium fish account for only a fraction of the zoonotic infections in the United States[36] (**Table 160-8**). Although pet owners often have close contact with their pets, pet-acquired zoonoses are rare and not often recognized.

HELMINTHS (WORMS)

Up to 50% of dogs are infected with at least one intestinal parasite, and 15% of adult dogs actively excrete *Toxocara canis*, the source of **toxocariasis** and visceral larva migrans.[36] Despite its prevalence in dogs, human toxocariasis is infrequently diagnosed, probably because infection is often subclinical. Typically, the only indication of infection is eosinophilia. Children may display fever, cough, nonspecific rash, and failure to thrive. Rarely, pulmonary infiltrates, hepatosplenomegaly, and seizures may occur. Diagnosis is by either biopsy of infected tissue or by enzyme-linked immunosorbent assay. Treatment in the symptomatic patient consists of albendazole or mebendazole (Table 160-5). Corticosteroids can be used to control the allergic component.

Other intestinal parasites that may be transmitted to humans from household pets include *Ancylostoma caninum* or *braziliense* (cutaneous larva migrans), *Echinococcus granulosus* (echinococcosis), and *Dipylidium caninum* (dipylidiasis or dog and cat tapeworm).[36]

Cutaneous larva migrans is often a self-limiting, pruritic, erythematous serpiginous rash caused by a migrating hookworm larva in the skin and is often acquired from fecally contaminated soil. Single-dose ivermectin is the preferred treatment in patients over 5 years of age. Multiple-dose albendazole is another option, as is topical thiabendazole. Although dogs and other carnivores are the definitive hosts for *E. granulosus*, echinococcosis is most common in areas of cattle and sheep ranching. This zoonosis involves multiple organ systems: liver, lung, muscle, bone, kidney, and brain. Typically, there is a unilocular cyst containing multiple larvae that enlarge over time. Definitive treatment is surgical; however, leakage of the cystic fluid can spread the infection and cause an anaphylactic reaction. Should the lesion not be anatomically favorable for unruptured excision, pharmacotherapy with benzimidazoles can be used, but recurrence is high.[37]

Dipylidiasis, caused by a tapeworm common to both dogs and cats, is found worldwide. Human infection is rare, requiring a human to swallow an infected flea. When infection does occur, it is often in children and presents with the nonspecific symptoms of diarrhea and pruritus ani. Occasionally, the cucumber-shaped proglottides are seen moving in the child's stool. Treatment is with praziquantel or niclosamide[36] (Table 160-5).

PROTOZOA

Cats are the host of the intracellular protozoan *Toxoplasma gondii*, which causes **toxoplasmosis**. Human toxoplasmosis can occur in three ways: by ingestion of uncooked or raw meat, especially pork or mutton containing the *Toxoplasma* cysts; by ingestion of the oocysts from cat and wild-animal feces; and transplacentally.[36] Transplacental transmission can result in congenital abnormalities of retinochoroiditis, hydrocephalus, hepatosplenomegaly, and thrombocytopenia in 10% of the children infected. The majority of children transplacentally infected with toxoplasmosis display no significant abnormalities. Nevertheless, pregnant women should limit their contact to only indoor cats and avoid contact with cat feces. The encysted trophozoite can become reactivated in a previously infected host if the host becomes immunocompromised. Treatment of acute chorioretinitis, of severely symptomatic patients, or in certain pregnancy conditions is with pyrimethamine (25 to 100 milligrams/d PO for 3 to 4 weeks) plus sulfadiazine (1.0 to 1.5 grams PO four times a day for 3 to 4 weeks) and folinic acid.[36,38]

SPECIAL POPULATION: IMMUNOCOMPROMISED PATIENTS

Immunocompromised patients include those with congenital immunodeficiencies, diabetes mellitus, chronic renal failure, or liver failure; splenectomized patients; chronic alcoholics; cancer patients; transplanted patients; and human immunodeficiency virus–positive

TABLE 160-8 Pet-Associated Zoonotic Infections

Dog	Cat	Bird	Rodent	Fish and Reptiles

TABLE 160-9 Zoonotic Infections in Immunocompromised Patients

Infection	Source	Clinical Findings	Antibiotic Treatment
Cat-scratch disease *Bartonella henselae*	Cats	Pyogenic granulomas, regional lymphadenopathy, and fever	Doxycycline or a macrolide
Bordetella *Bordetella bronchiseptica*	Dogs	Fever, pharyngitis, and cough	Azithromycin Alternatives: clarithromycin, TMP-SMX
Campylobacter *Campylobacter* species	Dogs, cats	Gastroenteritis and diarrhea	See chapter 159, "Food and Waterborne Illnesses."
Cryptococcus *Cryptococcus neoformans*	Bird droppings and cats	Flulike symptoms early, photophobia, headache, cranial nerve symptoms, and meningeal irritation later	Mild disease: fluconazole Severe: amphotericin B + flucytosine followed by fluconazole
Cryptosporidium	Dogs	Diarrhea	Immunocompetent host: nitazoxanide HIV positive: HAART only
Giardia *Giardia lamblia*	Dogs, cats	Gastroenteritis and diarrhea	See chapter 159.
Listeria *Listeria monocytogenes*	Livestock and dairy products	Sepsis and meningitis	Severe disease: ampicillin + gentamicin Gastroenteritis in at-risk population: amoxicillin or TMP-SMX
Mycobacterium			
M. avium	Pet birds	Pneumonia and gastroenteritis	Clarithromycin or azithromycin + ethambutol + rifampin
M. marinum	Fish	Cutaneous granulomas, skin ulcerations at distal extremities	Clarithromycin, minocycline, doxycycline, TMP-SMX, or rifampin + ethambutol
Rhodococcus *Rhodococcus equi*	Farm animals	Pneumonia and cavitating lung lesions	Two of the following agents: levofloxacin, rifampin, azithromycin, ciprofloxacin, imipenem, vancomycin
Salmonella *Salmonella* species	Dogs, cats, reptiles, and farm animals	Gastroenteritis, diarrhea, and sepsis	See chapter 159.
Toxoplasmosis *Toxoplasma gondii*	Cats	Pneumonia, brain abscesses, encephalitis, and ocular disease	Pyrimethamine + sulfadiazine + folinic acid

Abbreviations: HAART = highly active antiretroviral therapy; HIV = human immunodeficiency virus; TMP-SMX = trimethoprim-sulfamethoxazole.

patients. Of all of these patients, those undergoing chemotherapy and those with acquired immunodeficiency syndrome have the greatest risk of acquiring a zoonotic infection.[38] *Salmonella* and *Campylobacter* are the two most common infections acquired by immunocompromised patients from their pets, but the overall risk of transmission of *Salmonella* and *Campylobacter* from contact with pets is low. Additionally, *M. marinum* from aquatic pets and *Bartonella* from cats are also commonly acquired by immunocompromised patients. Other acquired zoonotic infections that immunocompromised patients are susceptible to include *T. gondii, Cryptosporidium, Giardia, Rhodococcus equi,* and *Bordetella bronchiseptica* (**Table 160-9**). With the exception of *Bartonella* (cat-scratch disease), most of these zoonotic infections are acquired by immunocompromised patients from sources other than exposure to animals.[38]

CHAPTER 161

Global Travelers

Raghu Venugopal
Shawn D'Andrea

INTRODUCTION

Of returning travelers who become ill, many have neither serious nor exotic illnesses.[1] The most likely causes of acute symptoms are common problems such as upper respiratory infections, diarrheal illnesses, or reactions to stress, fatigue, or new medications. The ED physician often does not confirm the final diagnosis, but rather protects the health of the public from potentially communicable diseases, begins diagnostic and therapeutic interventions, and provides appropriate referral. Local or regional international health clinics are good resources for referral of patients who need more advanced evaluation, serologic testing, and long-term follow-up (see http://www.travelersvaccines.com/).

Key points for the initiation of ED care are the following:

1. Isolate and use personal protective precautions early when evaluating patients with suspected travel-related infections.
2. Most travelers do not have exotic diseases; think of common causes.
3. Malaria lurks in the febrile patient returning from travel, even in the presence of prophylaxis.

INITIAL EVALUATION OF THE RETURNING TRAVELER

RISK ASSESSMENT

Of travelers, 64% report one or more illnesses during travel, 26% are ill upon return, and 56% of those ill upon return develop symptoms after arrival in the United States.[2] Many disease incubation times are longer than the transit times.

Most travelers on vacation or business are abroad for <20 days, and <5% spend extended time overseas. Some travelers originate from disease-endemic nations, as tourists or newly arrived immigrants; these people are at risk of illness due to transit and exposure to areas with high rates of endemic infectious disease. Others at risk include nonvoluntary travelers, such as refugees and displaced persons, as well as landed immigrants returning from visiting their homeland. In all extended-duration travelers, consider endemic illnesses, even if they lived in the area previously. Travelers also have a risk of tropical illness due to increasing adventure-type travel to areas that were previously inaccessible (**Table 161-1**).

Diseases such as malaria are uncommon in the United States but are leading causes of mortality overseas. Other parasitic agents, such as helminths and rickettsia, also occur with increased frequency and severity in the tropics (see chapters 158 and 160, "Malaria" and "Zoonotic Infections"). Diagnosis of a tropical infection requires a unique set of tests, and therapy is organism specific.

Think of a potential bioterrorist agent as a cause of disease when factors suggest intentional release, such as divergence of the disease presentation from the typical epidemiology of the community and an atypical number of patients presenting with similar clinical syndromes. Examples of diseases that could be weaponized include anthrax, plague, viral hemorrhagic fevers, and tularemia (see chapters 9, "Bioterrorism" and 160).

INCUBATION PERIOD

The approximate incubation period (the time between exposure and signs and symptoms) can be helpful in assessing illness risk. For example, if fever begins >21 days after return or infected patient contact, yellow fever, viral hemorrhagic fevers (including Ebola, covered elsewhere), and other arboviruses (e.g., dengue fever) are unlikely, irrespective of the exposure history (**Table 161-2**). In comparison, schistosomiasis may cause symptoms 5 weeks after exposure. Many diseases have variable incubation depending on factors such as host immunity and the use of chemoprophylaxis and antipyretics.

HISTORY

Suspect imported disease in recent world travelers, and direct the history appropriately (Table 161-2 and **Table 161-3**). Note previous medical conditions because immunosuppression, age <5 years, advanced age, pregnancy, and diabetes often render the patient less tolerant of tropical infections.

Ask about the duration of travel (suggesting specific disease incubation periods) and destination or origin (suggesting possible cause), which can focus the differential diagnosis (**Table 161-4**). Other important considerations are the living conditions and locale of the traveler (rural areas have greater infectious risks of certain diseases), type of accommodation, and travel-related activities (suggesting possible exposure, **Table 161-5**).

Review any pretravel immunizations and preventive medications, high-risk behaviors, and prior medical conditions. Immunization history is relevant because proper vaccination against hepatitis A, hepatitis B, and yellow fever can effectively rule these out as causes of illness. Adherence to appropriate chemoprophylaxis reduces the risk of acquiring malaria—which is the most important tropical emergency—yet it cannot eliminate the possibility. Because of increasing malaria resistance, assume that the febrile returning traveler has malaria even if chemoprophylaxis was correctly taken.

A history of medications, herbs, and traditional medicines consumed is also useful information, because these may contain antipyretics that can alter disease presentation. If altered mental status exists, suspect cerebral malaria or meningitis and consider early empirical treatment for both until the diagnosis is confirmed.

PHYSICAL EXAMINATION

When assessing vital signs, consider that antipyretics can mask fever. Evaluate the abdomen for hepatosplenomegaly or focal abdominal

TABLE 161-1 Risk of Infectious Exposure

High risk (1 in 10 travelers): diarrhea, upper respiratory illness, and noninfectious illnesses such as injuries and exacerbation of preexisting chronic diseases
Moderate risk (1 in 200 travelers): dengue fever, Chikungunya, enteroviral infection, gastroenteritis, giardiasis, hepatitis A, malaria, salmonellosis, sexually transmitted diseases, shigellosis
Low risk (1 in 1000 travelers): amebiasis, ascariasis, measles, mumps, enterobiasis, scabies, tuberculosis, typhoid, hepatitis B
Very low risk (1 in >1000 travelers): human immunodeficiency virus, anthrax, Chagas' disease, hemorrhagic fevers, pertussis, plague, typhus, hookworm

TABLE 161-2 Typical Incubation Periods for Selected Tropical Infections

Incubation Period	Infections Likely
<10 d (short incubation)	Traveler's diarrhea Dengue fever and arboviral infections Yellow fever Spotted fevers Anthrax Diphtheria Malaria Rabies Typhoid fever Meningococcal infections Plague Tularemia Typhus (louse- and flea-borne)
<21 d (intermediate incubation)	Leptospirosis Viral hemorrhagic fevers Malaria Enteric fevers (typhoid, paratyphoid) Typhus African trypanosomiasis
>21 d	Viral hepatitis (A, B, C, D, E) Malaria Acute HIV infection Amebic liver abscess Schistosomiasis (Katayama fever) Visceral leishmaniasis Filariasis
>Months	Tuberculosis Malaria Filariasis Viral hepatitis B, C HIV Visceral leishmaniasis Rabies Syphilis African and American (Chagas' disease) trypanosomiasis

Abbreviation: HIV = human immunodeficiency virus.

TABLE 161-3 Travel-Specific Aspects of the Medical History

Pretravel information
Previous medical condition
Pediatric patient, diabetes, pregnancy, immunosuppression (especially human immunodeficiency virus [HIV]/acquired immunodeficiency syndrome or steroid use)
Pretravel consultation and preparation (self-treatment medications, vaccination history, prophylaxis, etc.)
Type and compliance with chemoprophylaxis, particularly malaria
History of routine childhood immunization (DPT, polio, MMR, HiB, etc.)
Nation of birth and citizenship
Travel information
Exact itinerary of departure and arrival (within the last 3–5 y may be relevant)
Season of travel (monsoon, dry season)
Destinations visited (including locations of transit or stopovers)
Urban or rural, altitude
Purpose of travel and activities in country
General purpose of visit or travel (e.g., "adventure travel" with high exposure to remote, natural elements)
Contacts and their health
Habitat and location of lodging (bednets, window screens, thatched roof, mud walls)
Crowded living or sleeping conditions
High-risk activities (e.g., medical care of displaced populations, spelunking in caves)
Opioid use or injection drug use
Sexual intercourse with high-risk sexual contacts (unprotected with anyone; with high-risk populations, e.g., commercial sex workers, in areas with high prevalence of HIV); dates and nature of sexual contact
Exposure to environment (swimming in fresh or salt water, hiking, trekking, digging, or soil contact, e.g., open-toed shoes or bare feet)
Consumption of high-risk foods (wild game or bush meat, raw or undercooked meats or fish, unpasteurized milk products, food from street vendors, natural sources of water, salads)
Exposure to dogs, birds, or rodents
Adverse incidents
Insect or animal bites
Saliva from animals to open wounds
Assault or trauma
Status and health of fellow travelers
Possible ill contacts
In-country medical consultations sought, remedies used, and procedures (injections, acupuncture, transfusions, dental procedures, body piercing, or tattooing)

Abbreviations: DPT = diphtheria, pertussis, and tetanus; HiB = *Haemophilus influenzae* type b; MMR = measles, mumps, and rubella.

discomfort. Examine for lymphadenopathy and inspect the skin for rashes, lesions, or pallor. Ophthalmologic examination for scleral icterus, conjunctival injection, or petechiae helps detect causes. Imported diseases should be suspected in the presence of high fever, signs of hemorrhage, diarrhea, shortness of breath, skin lesions, and neurologic disturbances. **Table 161-6** lists other signs of tropical illness.[3]

Usually one or more hallmark symptoms or signs are associated with specific infections, allowing categorization. These include fever, CNS complaints, abdominal pain, diarrhea, skin and eye complaints, and respiratory symptoms. It is important to identify diseases that may be rapidly fatal, easily treatable, and/or potentially contagious.

LABORATORY TESTING

Initial studies include a CBC with differential and platelet count, hepatic function tests, and urinalysis; thick and thin blood smears for malaria (and rapid antigen detection test); blood cultures, urine cultures, stool cultures, and stool analysis for WBCs, ova, and parasites; and a chest radiograph for fever and cough. The absolute eosinophil count is often elevated to >500/mm^3 in parasitic diseases caused by worms. In a clinically well-appearing patient in whom malaria treatment is not begun but malaria is suspected, obtain blood for smear every 12 to 24 hours. Specific serologic tests are deployed selectively, such as erythrocyte sedimentation rate, purified protein derivative, syphilis test, human immunodeficiency virus test, and serology for arboviruses or rickettsiae.

Consult an infectious disease specialist early in the evaluation to optimize testing and follow-up. It is also wise to obtain an extra vial of serum in a red-top tube (for serology and immunology) during the initial evaluation. This specimen can be used later for comparison with convalescent-stage specimens.

TABLE 161-4 Regional Tropical Illnesses

Africa: malaria, human immunodeficiency virus, TB, hookworm, tapeworm, roundworm, brucellosis, yellow fever (and other hemorrhagic fevers such as Lassa fever or Ebola), relapsing fever, schistosomiasis, tick typhus, filariasis, strongyloidiasis
Central and South America: malaria, relapsing fever, dengue fever, filariasis, TB, schistosomiasis, Chagas' disease, typhus
Mexico and the Caribbean: dengue fever, hookworm, malaria, cysticercosis, amebiasis
Australia, New Zealand: dengue fever, Q fever, Murray Valley encephalitis, Japanese encephalitis
Middle East: hookworm, malaria, anthrax, brucellosis
Europe: giardiasis, Lyme disease, tickborne encephalitis, babesiosis
China and East Asia: dengue fever, hookworm, malaria, strongyloidiasis, hemorrhagic fever, Japanese encephalitis

Abbreviation: TB = tuberculosis.

DISEASES COMMONLY ASSOCIATED WITH FEVER

Although fever is nonspecific, it raises the suspicion for a serious infection (**Table 161-7**).[4,5] **Patients with fever after tropical travel have malaria until proven otherwise.** Other common serious infections are listed in **Table 161-8**.[6,7]

MALARIA

The classic clinical triad for all species of malaria is fever, splenomegaly, and thrombocytopenia.[8,9] Fever is typically irregular for the first week and later may demonstrate periodicity. Patients usually have continuous symptoms initially followed by episodic pyrexia every 2 to 3 days, depending on the infecting species. Periodicity is unusual with falciparum malaria. Serious malaria infections occur primarily in young children, pregnant women, the elderly, individuals never previously infected, and patients with comorbid medical problems. Because associated symptoms such as headache, cough, and GI problems mimic other conditions, malaria is a consideration in all febrile travelers.

Diagnosis is based on clinical presentation and confirmed with laboratory evidence of bloodborne protozoa. Patients with fever >38.5°C (101.4°F) of unclear origin and recent or past travel to an endemic area should be screened by blood smears and rapid antigen detection tests when available. Refer to chapter 158 for a detailed discussion of malaria diagnosis and treatment.

DENGUE FEVER

Dengue is the most serious febrile tropical disease after malaria. The World Health Organization reported a 30-fold increase in incidence of dengue in from the 1960s to the 2010s, with up to 50 million cases occurring annually worldwide.[10] Suspect dengue fever among travelers with fever developing within 2 weeks of travel. Dengue may be contracted more than once because each of the four strains offers no cross-protective immunity. Many cases are self-limiting, and the illness is not reportable in the United States.[11]

Dengue fever occurs in urban environments in most tropical nations and is transmitted by the peridomestic day-biting *Aedes aegypti* mosquito.

TABLE 161-5 Specific Exposures and Associated Tropical Infections

Contact/Exposure	Possible Infections
Untreated water, unpasteurized dairy products	Salmonellosis, shigellosis, hepatitis, amebiasis, brucellosis, listeriosis, TB
Raw or undercooked shellfish	Clonorchiasis, paragonimiasis, *Vibrio*, hepatitis A
Raw or undercooked animal flesh	Trichinosis (e.g., pig, horse, bear), *Salmonella*, enterohemorrhagic *Escherichia coli*
Raw vegetables, water plants (e.g., watercress)	Fascioliasis
Animal contact (and animal products)	Rabies, Q fever, tularemia, brucellosis, echinococcosis, anthrax, plague, Nipah virus, toxoplasmosis, herpes B encephalitis
Rodent contact	Hantavirus, viral hemorrhagic fevers, murine (endemic) typhus, Lassa fever, plague, leptospirosis
Arthropod vectors	
Mosquitoes	Malaria, dengue fever, Chikungunya, filariasis, yellow fever, and other arboviral infections
Ticks or mites	Rickettsioses, tularemia, scrub typhus, Crimean-Congo hemorrhagic fever, African tick bite fever
Reduviid (kissing) bugs	American trypanosomiasis (Chagas' disease)
Tsetse flies	African trypanosomiasis (African sleeping sickness)
Fleas	Typhus, plague
Sandflies	Leishmaniasis, sandfly fever
Freshwater exposure	Schistosomiasis, leptospirosis
Barefoot exposure	Strongyloidiasis, cutaneous larva migrans, hookworm
Sexual contacts	Human immunodeficiency virus, hepatitis B, syphilis, gonorrhea, chlamydia, herpes simplex
Infected persons contact	Viral hemorrhagic fever, enteric fever, meningococcal infection, TB

Abbreviation: TB = tuberculosis.

Urban dengue in the Americas, Africa, and the Indian subcontinent is usually classical dengue fever, whereas in Southeast Asia, it manifests as hemorrhagic fever and shock. Classic dengue fever presents after a typically short incubation period of 4 to 7 days with sudden high fever, headache, nausea, vomiting, myalgias, and rash usually lasting several days. Facial flushing, conjunctival injection (although uncommon), and retro-orbital pain can occur. After defervescence, a fine, pale, morbilliform rash develops on the trunk and spreads to the extremities and face. Small children may only present with a mild upper respiratory infection, and classic dengue may be confused with influenza, measles, or rubella. Although other causes of fever can present with a similar clinical picture, such as West Nile fever (transmitted by the *Culex* mosquito), West Nile fever causes lymphadenopathy, which is usually absent in dengue. **Dengue can also cause petechial hemorrhages indistinguishable from meningococcemia.**

Dengue hemorrhagic fever preferentially occurs among infants of immune mothers, children >1 year old, and those with second and subsequent infections. It begins as classical dengue with fever and myalgias. After 2 to 7 days, as pyrexia improves, lassitude, fatigue, and shock develop with an ensuing mortality that is >10%. Clinical features include pleural effusions and bleeding diathesis with epistaxis, purpura, petechia, and marked thrombocytopenia with elevated hematocrit because of vascular permeability. Dengue hemorrhagic fever may rapidly evolve into dengue septic shock, which is often fatal. Dengue septic shock is heralded by abdominal pain, severe emesis, mental status changes, and alternating severe pyrexia and hypothermia.

Diagnosis of dengue is based on clinical findings; although serology is confirmatory, cross-reactivity often occurs with other flaviviruses. Enzyme-linked immunosorbent assay provides rapid confirmation of infection by day 6 of the illness. Laboratory abnormalities include leukopenia, thrombocytopenia, and hepatic dysfunction. In uncomplicated dengue fever, treatment is supportive and consists of fluids and analgesics. Only acetaminophen is recommended for managing pain and fever because **aspirin and other nonsteroidal anti-inflammatory drugs are contraindicated** due to anticoagulant properties.

TABLE 161-6 Physical Findings in Selected Tropical Infections

Physical Finding	Likely Infection or Disease
Rash	Dengue fever, typhus, syphilis, gonorrhea, Ebola fever, brucellosis, Chikungunya, HIV seroconversion
Jaundice	Hepatitis, malaria, yellow fever, leptospirosis, relapsing fever
Lymphadenopathy	Rickettsial infections, brucellosis, HIV, Lassa fever, leishmaniasis, Epstein-Barr virus, cytomegalovirus, toxoplasmosis, trypanosomiasis
Hepatomegaly	Amebiasis, malaria, typhoid, hepatitis, leptospirosis
Splenomegaly	Malaria, relapsing fever, trypanosomiasis, typhoid, brucellosis, kala-azar, typhus, dengue fever, schistosomiasis
Eschar	Typhus, borreliosis, Crimean-Congo hemorrhagic fever, anthrax
Hemorrhage	Lassa, Marburg, or Ebola viruses; Crimean-Congo hemorrhagic fever; meningococcemia, epidemic louse-borne typhus

Abbreviation: HIV = human immunodeficiency virus.

TYPHOID FEVER

Enteric fever, or typhoid fever, is a serious infection diagnosed in roughly 400 travelers annually returning to the United States, with an additional 100 cases of paratyphoid. Typhoid and paratyphoid are caused by *Salmonella typhi* and *Salmonella paratyphi*, respectively.[12] **Once malaria is excluded, typhoid fever is commonly the cause of a febrile illness lasting >10 days.**[13] Imported cases occur in visiting friends and relatives and travelers from Mexico, Indonesia, Peru, and the Indian subcontinent. Vaccination before travel helps thwart acquisition, although protection wanes with time and revaccination is required.

The disease is transmitted in a dose-related fashion after food contamination by feces or urine from actively infected cases or healthy disease carriers. Incubation times and disease severity vary from 1 to 3 weeks. After ingestion, bacteria adhere to the small bowel mucosa, invade lymphoid tissues, and disseminate by lymphatics to the bone marrow, gallbladder, and spleen to reproduce in macrophages. Most pathology occurs in the gut as a consequence of inflammation, necrosis, and ulceration. Typhoid fever classically begins with fever and headache, and then progresses to high fever with chills, headache, cough, abdominal distention, myalgias, constipation, and prostration. The differential diagnosis includes malaria, typhus, viral hepatitis, amebic liver abscess, and other types of infective enteritis. In epidemics, patients can present with acute diarrhea and vomiting, headache, and meningeal signs. Most patients, however, present with constipation rather than diarrhea.

TABLE 161-7 Tropical Infectious Diseases Causing Fever among International Travelers

Disease	Distribution	Mode of Transmission
INCUBATION <2 WEEKS		
Undifferentiated fever		
Malaria	Most tropical and subtropical areas	Infected mosquito bite
Dengue	Tropics and subtropics, including urban areas	Infected mosquito bite
Chikungunya	Africa, Asia, and Caribbean	Infected mosquito bite
Spotted fever	Worldwide	Infected tick or mite bite
Scrub typhus	Asia, Australia	Infected mite bite
Leptospirosis	Widespread, mostly tropics	Percutaneous contact with animal urine or contaminated soil and water; ingestion
Typhoid fever	Developing countries, especially Indian subcontinent	Contaminated food/water ingestion
Acute HIV infection	Worldwide	Permucosal or percutaneous exposure to infective blood or fluids
African trypanosomiasis	East African form found in East and South Africa. West African form found in central and West Africa	Infective tsetse fly bite
Shigellosis	Widespread, most common in developing countries	Contaminated food/water ingestion
Salmonellosis	Widespread, most common in developing countries	Contaminated food/water ingestion
Campylobacteriosis	Widespread, most common in developing countries	Contaminated food/water ingestion
Fever with hemorrhage		
Meningococcemia	Widespread, highly prevalent in sub-Saharan meningitis belt in dry season from December to June	Via respiratory and oral secretions
Leptospirosis	Widespread, most common in tropical climate	Freshwater exposure
Crimean-Congo hemorrhagic fever	East and West Africa, Eurasia	Infected tick bite
Viral hemorrhagic fever	Worldwide	Contact with an infected patient, rodent, bat, tick, or mosquito
Other bacterial infection		
Fever with CNS involvement		
Meningococcemia	See listing above	See listing above
Rabies	Common in Africa, Asia, and Latin America	Infected animal saliva exposure
Malaria	See listing above	See listing above
Many viral and bacterial forms		
Arboviral encephalitis (Japanese encephalitis, tickborne encephalitis, dengue, West Nile, Murray Valley)	Worldwide	Infected mosquito or tick bite
Angiostrongyliasis	Widely scattered, most common in East Asia and Southeast Asia	Ingestion of contaminated food/water with snail or slug slime
Poliomyelitis	Primarily Africa and parts of Asia	Ingestion of feces-contaminated food/water
Fever with respiratory findings		
Influenza	Widespread; outbreaks on cruise ships	Direct or airborne droplet transmission
Severe acute respiratory syndrome	China, Hong Kong, other regions in East Asia	Direct or airborne droplet transmission
Legionellosis (legionnaires' disease)	Widespread; outbreaks in hotels and cruise ships	Inhalation or aspiration of infected droplets
Q fever	Worldwide	Inhalation of infective aerosol from animal source
INCUBATION 2–6 WEEKS		
Malaria	See listing above	See listing above
Typhoid fever	See listing above	See listing above
Hepatitis A and E	Widespread; most common in developing countries	Contaminated food/water ingestion
Acute schistosomiasis	Africa, Middle East, Southeast Asia, and Brazil	Penetration of skin by larval cercaria during freshwater exposure
Amebic liver disease	Widespread; developing countries	Ingestion of cysts usually in feces-contaminated food/water
Leptospirosis	See listing above	See listing above
African trypanosomiasis	See listing above	See listing above
Q fever	See listing above	See listing above
Acute HIV infection	Worldwide, increased risk in developing countries	Sexual exposure

(*continued*)

TABLE 161-7 Tropical Infectious Diseases Causing Fever among International Travelers (*Continued*)

Disease	Distribution	Mode of Transmission
INCUBATION >6 WEEKS		
Malaria	See listing above	See listing above
Tuberculosis	Worldwide	Inhalation
Hepatitis B	Widespread	Permucosal or percutaneous exposure to infective blood or fluids
Visceral leishmaniasis	Many parts of Africa, Asia, South America, and Mediterranean basin	Infective sand fly bite
Lymphatic filariasis	Widespread in tropical areas	Infected mosquito bite
Schistosomiasis	See listing above	See listing above
Amebic liver abscess	See listing above	See listing above
Rabies	Worldwide	Infected animal saliva exposure
African trypanosomiasis	See listing above	See listing above

Abbreviation: HIV = human immunodeficiency virus.

Bradycardia relative to fever is classic (but may be absent); after several days of fever, a pale red macular rash may appear on the trunk (**rose spots**) among fair-skinned individuals. As the disease progresses, splenomegaly develops. Patients may develop leukopenia and elevated liver enzymes, although most cases have nonspecific laboratory values. Complications include small bowel ulceration, anemia, disseminated intravascular coagulopathy, pneumonia, meningitis, myocarditis, cholecystitis, and renal failure. Sequelae include deafness, and neurologic involvement including psychosis, ataxia, and seizures can occur.[14]

Diagnosis is clinical and confirmed by culturing blood, urine, or stool (during the second week) or by rapid antigen testing. Although most cultures have a moderate yield, bone marrow culture is most sensitive, and organism identification is possible after antibiotic treatment.

Current treatment recommendations for typhoid fever include **fluoroquinolones** (ciprofloxacin), **cephalosporins** (cefixime and ceftriaxone), or **azithromycin**, with duration of treatment dependent on severity of illness. Currently, ampicillin, trimethoprim-sulfamethoxazole, and chloramphenicol are unreliable due to resistance. Nalidixic acid–resistant *S. typhi* strains are also associated with fluoroquinolone resistance; these organisms are found in both India and Southeast Asia. If typhoid meningitis is suspected, administer dexamethasone, 3 milligrams/kg IV loading dose over 30 minutes, followed by 1 milligram/kg IV every 6 hours for eight doses in addition to antibiotics. Supportive treatment includes IV rehydration and blood transfusion (if needed from GI losses). Untreated, mortality is 10% to 15%, mostly in young children.

RICKETTSIAL SPOTTED FEVERS

Rickettsial spotted fevers are transmitted by the bite, body fluid, or feces of ixodid arthropod ticks, and the ticks are widely globally distributed. Fleas and mites also transmit rickettsial infections. Among the eight major rickettsial infections, there is great variation in severity. Mortality without treatment approaches 25%, which is lowered to 5% with treatment (see chapter 160). Suspect scrub typhus (*Rickettsia orientalis*) after rural travel in the Asia-Pacific region and maritime Russia and African tick typhus (*Rickettsia conorii* var. *pijperi*) after travel to sub-Saharan Africa or the West Indies.

TABLE 161-8 Most Common Causes of Fever after Travel to Tropical Regions

Malaria
Respiratory tract infections (upper respiratory tract infections, pneumonia, legionnaires' disease, and influenza)
Diarrheal disease
Urinary tract infection
Dengue fever
Enteric fever (typhoid, paratyphoid fever)
Rickettsial infection
Infectious mononucleosis
Pharyngitis

Scrub Typhus and African Tick Typhus The mite bite, in the case of scrub typhus, or tick bite, with African tick typhus, may go unnoticed. After 3 to 14 days of incubation, patients develop fever, malaise, myalgias, severe headache, rash, nausea, and vomiting. The rash may be absent. Scrub typhus is characterized by a papule at the bite site. The papule later becomes necrotic and forms a crusted black "tache noire" eschar. As organisms disseminate, patients develop fever, malaise, headache, lymphadenopathy, and splenomegaly. African tick typhus presents like scrub typhus, but with much less severe symptoms and localized lymphadenopathy associated with an eschar. Diagnosis is clinical, and serologic tests are confirmatory. **Doxycycline**, 100 milligrams PO twice daily for 7 to 10 days, is the empirical treatment of choice, and chloramphenicol is an alternative. African tick typhus requires only 3 days of therapy and is often self-limited even without treatment. In severe cases of scrub typhus, death occurs from a multiorgan toxemia within 1 to 2 weeks of illness onset if untreated. Continue treatment for at least 5 days and for 48 hours after defervescence.

Typhus (Epidemic Louse-Borne Typhus) Typhus is a rickettsial louse-borne disease caused by *Rickettsia prowazekii*. Typhus is a different disease from the bacterial disease due to *S. typhi*, typhoid fever (see above). Epidemic louse-borne typhus is transmitted by the arthropod body louse. Typhus is widespread and found in Central Africa, Asia, and Central, North, and South America. It is also common in cold mountainous regions affected by famine, war, or mass population movement, where adequate clothing exists to harbor the louse or lice. Louse-borne disease occurs after louse body fluids and feces are rubbed into abrasions or after bites. Infection results in high fevers after an 8- to 12-day incubation period. Severe headache is common, and a maculopapular rash appears between days 4 and 7, generally sparing palms and soles. The rash may be hemorrhagic. Diagnosis starts on clinical grounds and is confirmed with serologic testing. Treatment is **doxycycline** (100 milligrams PO twice daily) or chloramphenicol (50 milligrams/kg/d PO in four divided doses) for 7 days and until 48 hours after defervescence. Untreated, mortality is as high as 60%.

LEPTOSPIROSIS (WEIL'S DISEASE)

Leptospirosis, or Weil's disease, follows mucous membrane or percutaneous exposure to freshwater contaminated by *Leptospira interrogans*. Infected animals excrete the spirochete in their urine. Infected patients typically have had contact with dogs; swam, rafted, or waded in contaminated surface water; or farmed or gardened in contaminated areas. Outbreaks commonly occur after flooding. Although the risk to most routine travelers is low, recent ecotourists and adventure travelers have become infected after intense water exposure.

The clinical course can be asymptomatic, but often symptoms illustrate a biphasic pattern. After an incubation of 2 to 20 days, high fever, severe headache, chills, myalgias, hepatitis (with or without jaundice), and nonspecific influenza-like symptoms develop. **Notable is conjunctival injection without purulent discharge.** Symptoms resolve in 4 to 7 days, followed several days later by the severe, icteric Weil's disease caused by circulating antibodies. The second phase lasts for up to 4 weeks and can include aseptic meningitis, renal failure, uveitis, rash, and, rarely, circulatory collapse. Isolation of leptospires from blood, urine, or cerebrospinal fluid is diagnostic, although sensitivity varies with duration of symptoms. Serology is most often used to confirm the diagnosis. Treatment reduces the severity and duration of symptoms and may prevent the second disease phase. Mild disease can be treated within the first 3 days of illness with PO **amoxicillin**, 500 milligrams four times daily, or **doxycycline**, 100 milligrams twice daily, whereas more severe cases require IV penicillin (1.5 million units every 6 hours), ceftriaxone (1 gram daily), or ampicillin (1 gram every 6 hours). Treatment duration is 7 to 14 days total. Consider empiric therapy with PO doxycycline or IV penicillin (or ampicillin) if leptospirosis is suspected.

RELAPSING FEVER

Relapsing fever is a bacterial infection caused by the spiral-shaped *Borrelia* species (*Borrelia recurrentis*) transmitted by lice or tick bites. It is rare among travelers, yet should be suspected in those who have contact with refugee and displaced populations. After being introduced by a louse or tick bite, *Borrelia* reproduce in body fluids and produce endotoxins affecting the liver, spleen, and capillaries. After incubation of 3 to 10 days, patients develop fever, chills, headache, myalgias, abdominal pain, and jaundice. In severe cases, mental status changes, meningoencephalitis, myocarditis, hepatic failure, and disseminated intravascular coagulopathy occur. After 5 to 7 days, fever may spontaneously abate, accompanied by hypotension, and, near day 14, fever may recur. The number of relapses varies, with 1 to 2 relapses in louse-borne fever, 3 to 6 relapses in tickborne fever, and up to 11 relapses in African varieties. Diagnosis is made by clinical suspicion and confirmed by identifying spirochetes blood peripheral smear, cerebrospinal fluid, or bone marrow. Spirochetes are best observed in blood when taken during the febrile period. Louse-borne and tickborne relapsing fever is treated with tetracycline, 500 milligrams PO every 6 hours for 10 days; doxycycline, 100 milligrams PO every 12 hours for 7 to 10 days; or erythromycin, 500 milligrams PO every 6 hours for 10 days. When CNS involvement is suspected, ceftriaxone, 2 grams IV, should be given every 24 hours.

DISEASES COMMONLY ASSOCIATED WITH FEVER AND HEMORRHAGE

Among the most feared tropical diseases are viral hemorrhagic fevers. However, viral hemorrhagic fevers are rare when compared with other febrile hemorrhagic infections such as malaria, dengue fever, meningococcemia, leptospirosis, plague, bacterial sepsis, and rickettsial fevers. ***Neisseria meningitidis* is the most common cause of acute hemorrhagic fever in temperate climates.** Among travelers, several treatable infections, including Lassa fever, meningococcemia, leptospirosis, and rickettsial infection, can cause fever associated with hemorrhage. Most people with viral hemorrhagic fevers, such as dengue, hantavirus (see chapter 160), Lassa, Ebola, Marburg, and Rift Valley, develop fever within 3 weeks after exposure. Establish a precise travel itinerary to estimate the incubation time. Viral hemorrhagic fever usually follows the bite of infected mosquitoes and ticks, close contact with rodent/bat excreta, or direct contact with infected, symptomatic individuals (the latter notably for Ebola).

In the event of a suspected viral hemorrhagic fever of tropical origin, institute control measures, including isolation in a negative-pressure room, the use of high-efficiency particulate-arresting respirators, and the use of gloves and gowns. **Immediately notify local public health officials for suspected contagious viral hemorrhagic fevers such as Marburg, Lassa, Ebola, or Crimean-Congo hemorrhagic fever.** If intentional bioterrorism is suspected, notify local law enforcement officials, the Federal Bureau of Investigation, and the Centers for Disease Control and Prevention (1-770-488-7100).

CRIMEAN-CONGO HEMORRHAGIC FEVER

This tickborne viral disease is common in Africa, eastern Europe, Asia, and the Middle East, especially in Turkey.[15] Agriculture workers are at greatest risk, but healthcare workers are the second most affected group. Mortality ranges from 3% to 30%.[15] The prehemorrhagic period is characterized by the sudden onset of fever, headache, myalgia, dizziness, and, possibly, mental confusion. The hemorrhagic period is short (2 to 3 days), develops rapidly, usually begins between the third to fifth day of disease, and may be accompanied by tender hepatomegaly. The most common bleeding sites are the nose, GI system (hematemesis, melena, and intra-abdominal), uterus (menometrorrhagia) and urinary tract (hematuria), and the respiratory tract (hemoptysis). Thrombocytopenia is common. Patients may have leukopenia and elevated liver enzymes, lactate dehydrogenase, and creatinine. Prothrombin time and activated PTT can be prolonged.

Diagnosis is clinical and confirmed with serology. Treatment is primarily supportive, including treatment of coagulopathy and respiratory support in severe cases.[15] Oral or IV forms of **ribavirin** are available and used in more severe cases; treat for 10 days (30 milligrams/kg as an initial loading dose, then 15 milligrams/kg every 6 hours for 4 days, and then 7.5 milligrams/kg every 8 hours for 6 days).[15]

YELLOW FEVER

Yellow fever, an acute zoonotic flavivirus, has a jungle monkey reservoir, and its equatorial belt lies in South/Central America and Africa. Recent outbreaks in Bolivia, Kenya, and Nigeria indicate that it could reappear in the southern United States, where the day-biting mosquito vector *A. aegypti* (also transmitting dengue) is endemic. Yellow fever vaccination is mandatory in endemic areas. Outbreaks are common near tourist areas and may occur among nonimmunized adventure travelers who travel to endemic areas.

Yellow fever ranges in severity from an undifferentiated self-limited flulike illness to a hemorrhagic fever that is fatal in 20% of cases. After an incubation of 3 to 6 days, patients develop fever, headache, myalgias, conjunctival injection, abdominal pain, prostration, facial flushing, and relative bradycardia. In most cases, patients recover, but in others, fever remission lasts a few hours to several days, followed by renewed high fever, vomiting, headache, back pain, shock, multiorgan failure, and bleeding diathesis. **The classic presentation is a triad of jaundice, black emesis, and albuminuria.** In severe cases, hypotension, shock, and metabolic acidosis develop, complicated by myocardial dysfunction and arrhythmias. Confusion, seizures, and coma are common in the late stages of the illness, and death can occur within 7 to 10 days after onset. The diagnosis is primarily clinical, although confirmation is possible through virus identification or rising antibody titers in recovering patients. Leukopenia and albuminuria are typical, direct bilirubin levels rise, and liver enzymes are elevated for several days during which time azotemia and oliguria ensue. Treatment is supportive, with fluid replacement and management of hematologic complications.

LASSA FEVER

Lassa fever, an arenavirus, was first detected in Lassa, Nigeria, and is spread by contact with bush rat excreta. Epidemics were noted with civil unrest and forced migration of populations. The likelihood of travelers becoming infected is low because it is primarily a disease of rural communities where bush rats thrive. Although Lassa fever is mostly found in rural West Africa, it has been exported to Europe and North America by infected patients. The disease is highly contagious through close contact with blood and body fluids.

After an incubation period of 3 to 16 days, the disease presents as a viral syndrome with insidious onset of fever, malaise, headache, sore throat, retrosternal chest pain, back pain, abdominal pain, and myalgias. Varied and nonspecific symptoms persist for 4 to 6 days, at which time the patient suddenly deteriorates and becomes gravely ill. Among those infected, 80% have few symptoms and 20% have severe multiorgan

disease. The main features are high fever, severe prostration out of proportion to the fever, severe sore throat with dysphagia and yellow-white exudates, abdominal pain, diarrhea, and vomiting. Only one third of patients experience bleeding, which may include oozing from the gums, hematemesis, melena, hematochezia, hemoptysis, hematinuria, or brain hemorrhage. Diagnosis is made by enzyme-linked immunosorbent assay serology, culture, or immunohistochemistry. Strict patient isolation and use of personal protection by healthcare workers are necessary. Treatment is largely supportive, but patients with severe disease may benefit from early treatment with **ribavirin** IV or PO (see dose for Crimean-Congo hemorrhagic fever above in "Crimean-Congo Hemorrhagic Fever"). Survivors will defervesce within 10 days of disease onset and, except for sensorineural deafness, can make a complete recovery.

EBOLA

Periodic outbreaks of Ebola virus disease have been reported since 1976, when an outbreak occurred in the Democratic Republic of the Congo (Zaire). Since then, outbreaks have occurred in Gabon and Uganda, with the most recent large outbreak in multiple West African countries. Four Ebola species cause disease in humans. Symptoms begin 2 to 21 days after exposure with fever, myalgia, malaise, diarrhea, abdominal pain, and vomiting, and progress to hemorrhage, shock, and end-organ failure. Mortality is high, but those who recover have an antibody response that lasts about 10 years. Disease transmission is by direct contact with infected blood or body fluids, contaminated needles or syringes, or infected bats or primates. The virus is stable, with little mutation in current species compared to that in the epidemic of 1976. Diagnosis is by enzyme-linked immunosorbent assay serology, polymerase chain reaction, culture, or immunochemistry. Treatment is supportive, but vaccines are currently under development. Epidemic containment focuses on avoidance of exposure, and for healthcare workers, use of personal protective equipment. Hospital preparedness consists of the identification of potential exposed contacts by identifying travel and direct exposure history, determining disease signs and symptoms, and then isolating individuals with possible disease.

DISEASES COMMONLY ASSOCIATED WITH FEVER AND CENTRAL NERVOUS SYSTEM INVOLVEMENT

Fever with acute mental status changes, headache (**Table 161-9**), nuchal rigidity, and focal neurologic signs is associated with a number of serious infections. **CNS involvement with fever in travelers returning from malaria-endemic regions requires emergency presumptive treatment for both malaria and bacterial meningitis (see chapters 158 and 174, "Malaria" and "Central Nervous System and Spinal Infections").** The differential diagnosis for fever with CNS involvement includes malaria, bacterial meningitis, tuberculosis, typhoid fever, rickettsial infections, and rabies. Other causes are viral encephalitides, including Japanese and West Nile encephalitis, which often present similarly.

Patients with altered mental status suspected of tropical illness may demonstrate coma, decreased level of consciousness, meningeal signs, or seizures. Although seizures should arouse suspicion of cerebral malaria, suspect **cysticercosis** in those with long-term residence in Latin America and a first-time seizure. **Meningococcal meningitis** occurs with regularity in sub-Saharan Africa along the "meningitis belt" running from Ethiopia in the east to Senegal in the west, and pilgrims attending the Hajj in Saudi Arabia are also at risk of *Neisseria* meningitis. Aseptic meningitis may be caused by enteroviruses or, less commonly, typhoid fever, leptospirosis, or rickettsiae. Encephalitis may be caused by an arboviral infection, such as Japanese B encephalitis.

TABLE 161-9 Tropical Infectious Diseases Causing Severe Headache and Fever

Malaria
Rickettsial disease
Dengue fever
Typhoid fever
Human African trypanosomiasis

JAPANESE ENCEPHALITIS

Japanese encephalitis is a *Culex* mosquito-borne flavivirus infection that occurs in an epidemic or sporadic pattern over large areas of Asia and the western Pacific. It is rarely transmitted to U.S.-bound travelers because the vector breeds primarily in rural rice fields. Infected patients present with a sudden high fever, headache, nuchal rigidity, vomiting, and seizures (especially infants) after the incubation time of 5 to 15 days. A variety of pyramidal and extrapyramidal signs may develop soon after fever. If the outcome is fatal, it usually occurs in the first 10 days. Diagnosis is based on clinical suspicion, although virus can be isolated from cerebrospinal fluid, and antibody titers can rise. Treatment is supportive with IV fluid and electrolyte management, assisted respiration if necessary, anticonvulsants, and neuropsychiatric consultation during convalescence. Recovery may take months, and varying degrees of residual neurologic damage may persist indefinitely. Immunization is recommended for travelers to rural, endemic regions in Asia.

CYSTICERCOSIS

Cysticercosis is a systemic illness caused by dissemination of the larval form of the pork tapeworm, *Taenia solium*. The disease affects an estimated 50 million people worldwide. Endemic areas include Mexico, Latin America, sub-Saharan Africa, India, and East Asia. The incidence in the United States is increasing due to increased immigration from endemic areas and increased travel to endemic areas. Humans are definitive *T. solium* hosts and can carry the intestinal adult tapeworm. An intermediate host, usually a pig, ingests fecally shed egg-containing proglottids or *T. solium* eggs. Humans develop cysticercosis when they inadvertently ingest eggs from contaminated food or soil or eat undercooked pork.

Infestation can occur in almost any tissue. Involvement of the CNS, *neurocysticercosis*, is the most clinically important manifestation of the disease. Neurocysticercosis is a leading cause of new adult-onset seizures worldwide. Other symptoms of neurocysticercosis include obstructive hydrocephalus, meningoencephalitis, stroke-like focal deficits, headache, and visual or mental status changes. Noncontrast CT scan shows calcifications of inactive disease and can reveal mass effect or hydrocephalus. Antihelminthic agents are the mainstay of treatment (**praziquantel**, 50 milligrams/kg/d PO divided three times daily for 15 days). Use steroids in those with encephalitis, hydrocephalus, or vasculitis to avoid inflammation as cysts involute.

DISEASES COMMONLY ASSOCIATED WITH CHRONIC FEVER

Evaluate patients with chronic or relapsing fever lasting beyond 3 weeks after travel initially for non–travel-related infections, inflammatory diseases, and noninfectious disorders. Tropical illnesses that cause chronic fever include protozoal infections (such as trypanosomiasis, leishmaniasis, amebiasis, and malaria), typhoid or paratyphoid fever, and tuberculosis (**Table 161-10**).

HUMAN AFRICAN TRYPANOSOMIASIS (AFRICAN SLEEPING SICKNESS)

Sleeping sickness is caused by the two identical endemic protozoan subspecies, *Trypanosoma brucei gambiense* (responsible for most clinical cases) and *Trypanosoma brucei rhodesiense*, transmitted by the aggressive tsetse fly found in rural Africa. The tsetse fly is indigenous to vegetation near rivers, lakes, forests, and wooded savannah. After a bite, a localized inflammatory reaction occurs, followed in 2 to 3 days by a painless chancre that increases in size for 2 to 3 weeks and then gradually regresses. Trypomastigotes mature and divide in the blood and lymph after the development of the chancre and cause intermittent fever unresponsive to antimalarials. Malaise, rash, wasting, and eventual CNS involvement occur, causing behavioral and neurologic changes, encephalitis, coma, and death. Disease categorization depends on whether the

TABLE 161-10 Selected Causes of Chronic and Relapsing Fevers

Etiologic Organism	Organism Species
Bacterial	Bartonellosis
	Brucellosis
	Leptospirosis
	Q fever
	Relapsing fever
	Syphilis
	Tuberculosis
	Tularemia
	Typhoid fever
Fungal	Blastomycosis
	Coccidioidomycosis
	Cryptococcosis
	Histoplasmosis
Protozoan	Amebic liver disease
	Visceral leishmaniasis
	Malaria

Viral	Human immunodeficiency virus
Helminthic	Angiostrongyliasis
	Fascioliasis
	Schistosomiasis
	Toxocariasis
	Trichinosis

CNS has been invaded or not. Other complications include hemolysis, anemia, pancarditis, and meningoencephalitis.

Diagnosis is made by rapid evaluation of blood smears for the mobile parasite. Organisms can also be identified by aspiration of lymph nodes, chancres, or bone marrow or by CSF examination. The treatment of sleeping sickness varies according to the stage of illness. If the disease has not invaded the CNS, treat with pentamidine or suramin. If the CNS is invaded, treatment requires melarsoprol, eflornithine, or a combination of nifurtimox and eflornithine. Diagnosis and treatment need infectious disease consultation.

AMERICAN TRYPANOSOMIASIS (CHAGAS' DISEASE)

The protozoan *Trypanosoma cruzi* is found in up to 5% of emigrants from endemic parts of Latin America and is reported as far north as Texas. It is spread by the reduviid "kissing bug" or "assassin" bug. The bites typically happen nocturnally after the bug emerges from rural adobe walls or thatched roofs. Among travelers, it is rare; it causes an acute illness and, commonly, an asymptomatic infection with complications arising years later in the heart and GI tract. It is transmitted during a blood meal when the bug defecates trypanosome-infected feces around the meal site, causing a local inflammatory reaction and trypanosome inoculation after the host rubs the organism into the bite wound or into adjacent mucous membranes or conjunctiva. Infection can also be acquired by blood transfusion, by laboratory accidents, and congenitally.

Unilateral periorbital edema (Romaña sign) or painful cutaneous edema at the site of skin penetration (chagoma) is followed by a toxemic phase with parasitemia causing lymphadenopathy and hepatosplenomegaly. The acute phase generally lasts 2 to 4 weeks but may last up to 3 months. Next is a long, asymptomatic, latent phase when nerve ganglion cells are gradually destroyed, leading to depressed cardiac and GI function. Cardiac complications include myocarditis, dysrhythmias, cardiomyopathy, and sudden death. Chagas-induced heart disease is the leading form of congestive heart failure in much of Latin America. GI complications are megaesophagus or megacolon.

The acute phase diagnosis is made by examination of peripheral blood smears demonstrating motile parasites or by blood culture or muscle biopsy. In the chronic phase, serologic tests and tissue biopsy are useful. Treatment is available for acute, reactivated, or chronic cases. The two medications used are nifurtimox and benznidazole, which are available in the United States through the Centers for Disease Control and Prevention.

TABLE 161-11 Clinical Syndromes of Leishmaniasis

Visceral leishmaniasis (kala-azar or black fever): The most devastating and fatal form caused by *Leishmania donovani*. A progressive, chronic, and systemic disease with high mortality if untreated, but with a good prognosis if provided adequate care. Fatality is a result of secondary infections such as tuberculosis, pneumonia, and dysentery. It is typified by the pentad of fever, weight loss, hepatosplenomegaly, pancytopenia, and hypergammaglobulinemia.

Cutaneous leishmaniasis: Characterized by skin sores initially appearing as papules or nodules. These later ulcerate, especially on exposed skin surfaces, later leaving scars.

Mucocutaneous leishmaniasis (espundia): Chronic and relentless disease affecting the mucous membranes of the nose, mouth, and throat.

Diffuse cutaneous leishmaniasis: Typically chronic diffuse plaques or nodules, difficult to treat, and with few resulting deaths.

LEISHMANIASIS (VISCERAL)

Leishmania is an intracellular protozoan transmitted by *Lutzomyia* or *Phlebotomus* sandflies. The disease occurs sporadically in rural Africa, Asia, the Mediterranean basin, and Central/South America, and outbreaks occasionally occur, such as in Brazil, India, and the Sudan, which places resident expatriates and travelers at risk. The disease is a low risk to most travelers, although European travelers to nonendemic Mediterranean nations occasionally export cases. Suspect *Leishmania* in the military and their families living proximal to jungles, adventure travelers, field biologists, and emigrants from endemic zones.

The infecting species determines the pathology, ranging from a localized self-healing lesion to widespread, persistent, and potentially destructive disease. Four major clinical syndromes are recognized (**Table 161-11**).

The most important diagnostic information is patient origin and travel itinerary because endemic areas suggest the infection type. Definitive diagnosis requires reference laboratory expertise to isolate motile extracellular parasites aspirated from bone marrow, spleen, or lymph nodes, or on smears or sections taken from the ulcer edge by punch biopsy.

Treatment of visceral leishmaniasis by infectious disease consultants relies on factors such as the origin of the disease, type of disease, parasite species, and patient comorbidities. Treatment for visceral leishmaniasis is with agents such as **amphotericin B**, **pentavalent antimonials, or miltefosine**. Treatment of cutaneous leishmaniasis is either by local therapy, oral systemic therapy, or parenteral systemic therapy.

DISEASES COMMONLY ASSOCIATED WITH ABDOMINAL AND URINARY COMPLAINTS

Illnesses causing abdominal pain and diarrhea are common among world travelers because of infecting bacteria, viruses, soil-transmitted helminths, and other parasites. Most infections are caused by the consumption of undercooked or fecal-contaminated foods and are preventable by adequate hygiene, potable water, and careful food preparation.

SCHISTOSOMIASIS (BILHARZIA OR SNAIL FEVER)

Schistosomiasis, infection with a blood fluke found in Africa, the Middle East, South America, and Asia, infects >200 million people worldwide, with 20 million people suffering severe consequences. Suspect schistosomiasis in travelers with GI symptoms following exposure to freshwater in endemic zones. For most short-term travelers, the risk is low, although significant outbreaks now occur among adventure tourists, Peace Corps workers, and those who swim in infested streams and lakes. The larvae are released into freshwater by snails, which are intermediate hosts. Infection occurs by tiny, free-swimming cercariae that penetrate

wet, unbroken skin or are ingested from slow-moving freshwater. Brief or even single exposures like washing or wading can cause infection in previously unexposed asymptomatic individuals. After inoculation, an immediate cercarial allergic and pruritic dermatitis occurs that can last days. In the following 4 to 8 weeks, fever occurs, accompanied by headache, cough, urticaria, diarrhea, hepatosplenomegaly, and hypereosinophilia (Katayama fever). Worms mature into adults in the venous blood and, for the next 30 to 40 years, deposit eggs into selective body tissues (*Schistosoma haematobium* in the bladder and *S. mansoni* and *S. japonicum* in the GI tract). Eggs are deposited throughout the brain, skin, liver, and GI tract. Eggs stimulate a vigorous immune response that results in clinical symptoms.

CNS symptoms include seizures, paralysis, and acute transverse myelitis. *S. haematobium* infection causes dysuria, frequency, and terminal hematuria, and can cause bladder scarring, calcification, and squamous cell carcinoma. *S. japonicum* and *S. mansoni* infections lead to hepatosplenomegaly, hepatic granulomas, and periportal fibrosis. *S. japonicum* and *S. mansoni* also can cause diarrhea, abdominal cramps, acute abdominal pain, and, late in the disease course, portal hypertension. *S. dermatitis*, a non–human-infecting schistosome, has cercariae that only penetrate the superficial skin, causing an irritation known as *swimmer's itch*.

Diagnosis is by detecting eosinophilia and is made primarily by microscopic identification of ova in mid-day urines or stool or in a biopsy specimen. Serologic antibody detection methods are highly accurate and are usually positive in light infections missed by egg detection. Offer treatment to symptomatic patients and seropositive travelers using **praziquantel**; some may require a second treatment. For swimmer's itch, no treatment is required.

CLONORCHIASIS (CHINESE OR ORIENTAL LIVER FLUKE)

Clonorchiasis, a trematoidal disease of the bile ducts, is caused by *Clonorchis sinensis* and follows ingestion of poorly cooked freshwater fish containing encysted larvae. Travelers are at low risk despite the tremendous prevalence among those living in endemic zones such as Southeast Asia. Once ingested, larvae mature into adults, migrate to bile ducts, survive for 30 or more years, and cause fibrosis. The extent of pathology is related to parasite burden, and among the millions infected, only few are symptomatic. Acute symptoms include anorexia and diarrhea and may progress in heavy infections to chronic bile duct obstruction, liver tenderness, and/or jaundice and, in advanced cases, biliary cirrhosis and cholangiocarcinoma. Diagnosis is made by detecting the characteristic embryonated eggs in stool or duodenal aspirate, and eosinophilia is common. Serologic tests using enzyme-linked immunosorbent assay have 70% sensitivity, and CT, abdominal ultrasonography, and upper endoscopy examinations are useful. Treatment is with praziquantel or albendazole.

DISEASES COMMONLY ASSOCIATED WITH ABDOMINAL PAIN AND DIARRHEA

Diarrhea and gastroenteritis are the most common travel ailments, affecting up to one half of travelers (**Table 161-12**). Traveler's diarrhea is especially common after travel to Africa, Asia, the Middle East, South and Central America, and Mexico. Diarrhea is typically accompanied by fever, flatulence, nausea, emesis, and abdominal pain, which is usually spasmodic and colicky. *Campylobacter jejuni* may cause severe and constant pain, and cholera may cause somatic muscle cramps. Nonbloody gastroenteritis and diarrhea are usually caused by bacteria or bacterial toxins, whereas dysentery usually results from toxigenic and invasive bacteria such as *Shigella*, *Salmonella*, *Campylobacter*, *Aeromonas*, *Escherichia coli*, or *Entamoeba histolytica* (**Table 161-13**). Traveler's diarrhea is not commonly due to viruses.

Acute abdominal pain among travelers should first be considered to be caused by nontravel causes with an expanded travel-based differential diagnosis. Give empiric therapy to those with pain and severe diarrhea using fluoroquinolones (ciprofloxacin or levofloxacin) before stool testing results are available, although regional resistance can occur and should be verified (see chapter 159, "Food and Waterborne Illnesses").

TABLE 161-12 Common Infectious Diseases Causing Diarrhea in Travelers

Cause	Organism	Comments
Acute (duration <2 wk)		
Viral	Norwalk-like virus Rotaviruses Enteroviruses	Often not diagnosed; may account for 5%–10% of acute traveler's diarrhea
Bacterial	*Escherichia coli* (enterotoxigenic or enteroaggregative) *Campylobacter jejuni* *Salmonella* *Shigella* *Vibrio* *Clostridium difficile*	Most common identified cause of acute traveler's diarrhea; 50%–70%
Parasitic	*Giardia lamblia* *Cryptosporidium parvum* *Entamoeba histolytica* *Cyclospora cayetanensis* *Isospora belli* *Balantidium coli* *Trichinella spiralis*	Accounts for <1%–5% of acute traveler's diarrhea
Chronic or persistent (duration >2–4 wk)		
Bacterial	See above	Rare cause of chronic diarrhea
Parasitic		
Microsporidial	*Enterocytozoon bieneusi* *Encephalitozoon intestinalis*	Almost exclusively in immunocompromised
Protozoal	*G. lamblia* *E. histolytica*	Most commonly identified cause Bloody diarrhea with fever; fecal WBCs are rare
Helminthic	*Trichuris trichiura* *Strongyloides stercoralis* *Fasciolopsis buski* *Schistosoma*	Rarely associated with chronic diarrhea; usually in persons with heavy parasite burdens

AMEBIASIS

Pathogenic species such as *E. histolytica* are found worldwide and disproportionately infect those living in low-income settings. Amebiasis is typically spread by asymptomatic carriers whose excrement contains the encysted organism. Short-term travelers are at low risk, but longer-term travelers, such as Peace Corps volunteers, are at higher risk. The disease is most severe among young children, the elderly, and pregnant women. Incubation times are typically 1 to 3 weeks for colitis and 2 weeks to

TABLE 161-13 Causes of Diarrhea with and without Fever or Blood

	With Fever	Without Fever
With blood	Bacillary dysentery *Campylobacter enterocolitis* *Salmonella enterocolitis* *Escherichia coli*	Amebiasis *Balantidium coli* *Schistosoma* *Trichuris*
Without blood	*Salmonella enteritis* Malaria (especially *Plasmodium falciparum*) Mild shigellosis *Campylobacter* infections Almost any infections in a child	*Staphylococcus aureus* *E. coli* (enterotoxigenic) *Clostridium perfringens* Viral infections of the gut Food toxins

several months for liver abscesses. Once cysts are ingested, amebic trophozoites invade the colon wall, lyse tissues, and cause necrotic abscesses.

Most infected people do not have symptoms. Symptoms range from alternating constipation and diarrhea over 1 to 3 weeks, to abdominal pain, bloody diarrhea, fever, dehydration, and weight loss. Extraintestinal metastases can infect the liver and, rarely, pericardium, lung, and brain. Colitis can lead to intestinal perforation and peritonitis. Complications such as liver abscesses may cause fever, right upper quadrant pain, or chronic, vague abdominal pain accompanied by weight loss. Hepatic abscesses can be fatal if the abscess ruptures.

Stool ova and parasite examination is diagnostic, and organisms are found either as motile trophozoites or cysts. It can be difficult to differentiate pathogenic organisms (*E. histolytica*) from benign organisms (*Entamoeba dispar*) without use of stool antigen detection tests. Serology for elevated antibody titers is almost uniformly sensitive for extraintestinal disease and 80% sensitive for invasive colon disease after 1 week of illness. Ultrasonography or CT scans may be useful to identify hepatic abscesses.

Treatment of asymptomatic cyst passers includes **iodoquinol**, 650 milligrams PO three times a day for 20 days; **paromomycin**, 500 milligrams PO three times a day for 7 days; or **diloxanide furoate**, 500 milligrams PO three times a day for 10 days. For **symptomatic disease**, choices include **metronidazole**, 500 to 750 milligrams PO three times a day for 5 to 10 days, or **tinidazole**, 1 gram PO twice a day for 3 days, followed by either iodoquinol or paromomycin in the doses and duration noted earlier. For **liver abscess**, treat with metronidazole, 750 milligrams PO or IV three times a day for 5 days, followed by iodoquinol or paromomycin as described above.

GIARDIASIS

Giardia lamblia is a flagellated protozoan infecting the small intestine and biliary tree. It is distributed worldwide and is food- or waterborne by fecal contamination with encysted parasites. It is common to rural areas with poor sanitation and impure surface water but has also occurred in day care settings in the United States. In Eastern Europe, it is a common cause of chronic traveler's diarrhea and can be contracted at camping sites and rural swimming areas. Long-term residents of tropical nations are at high risk, but short-term travelers are also at risk. Ingested parasites reside in the duodenum and may lead to malabsorption because of duodenal microvilli obstruction. Symptoms include abdominal cramping, flatulence, and foul-smelling, watery diarrhea without blood or mucus. Chronic infections cause weight loss and anemia, and a common complication is lactose intolerance. Diagnosis is by stool ova and parasites showing either motile trophozoites or cysts. *Giardia* antigen detection in stool has good sensitivity and specificity. Treatment is with **metronidazole** (250 milligrams PO three times daily for 5 to 7 days), **tinidazole** (2 grams PO for one dose), **quinacrine** (100 milligrams PO three times daily for 7 days), or **nitazoxanide** (500 milligrams twice daily for 3 days). In children, treat with tinidazole, 50 milligrams/kg up to 2 grams in a single dose, or metronidazole, 35 to 50 milligrams/kg/d PO up to 750 milligrams/dose, three times per day for 10 days. Treatment is not always successful regardless of drug used.

CHOLERA

Cholera is an acute diarrheal disease caused by the bacterium *Vibrio cholerae*. It is endemic and epidemic to many tropical nations. It is reported in Africa, Asia, Latin America, and most recently Haiti and Mexico. Epidemics occur after flooding or acute population displacement with disruption of the water-sanitation system. Transmission is by fecal contamination of water or food (including raw or poorly cooked seafood and shellfish). Significant bacterial ingestion is required to cause symptoms. The incubation time is 2 to 3 days, and symptoms result from sodium pump inhibition in the GI tract by the cholera toxin. Infection is usually mild but can be life-threatening, particularly among vulnerable populations, such as malnourished children, migrants, and those with chronic illness. Another group at risk are individuals with achlorhydria or those using medications decreasing gastric acidity. There is an asymptomatic carrier state.[16]

Severe disease is characterized by profuse, usually painless, watery diarrhea ("rice water stools"), severe dehydration, vomiting, leg cramps, and, occasionally, fever. Rapid fluid loss (up to 15 L/d) leads to extreme dehydration and shock. Without aggressive rehydration, death can occur within hours. With proper fluid resuscitation, almost no patients should die. Diagnosis is clinical, and when suspected, a rectal swab or stool specimen can be sent to a reference laboratory for culture confirmation. Rapid dipstick testing of stool is possible, but should be followed by confirmatory testing.

The cornerstone of treatment is aggressive fluid resuscitation with PO rehydration solution or IV fluids, coupled with correction of metabolic acidosis and hypokalemia. For those with severe illness, antibiotics can shorten the illness course, diminish vomiting, lessen volume resuscitation needs, and ensure that bacteria are eradicated from stool. **Doxycycline** is the antibiotic of choice, followed by azithromycin or erythromycin for children and pregnant women. Secondary transmission is rare, and close contacts should not be given antibiotics as prophylaxis.

PARASITIC HELMINTH (WORM) INFECTIONS

Major infestations are discussed here, and diagnosis and treatment are presented in **Table 161-14**.

In the patient in whom empirical therapy is chosen due to the appearance of a worm in fecal matter, treatment for nematodes can be considered. **By treating the adult patient empirically with albendazole, 400 milligrams twice daily for 3 days (with a single repeat dose in 2 weeks), a number of pathologies can be treated** (roundworm, pinworm, whipworm, and hookworm). Send stool samples for laboratory analysis to provide more focused treatment.

ASCARIASIS (ROUNDWORM)

The risk of infection with *Ascaris lumbricoides* to short-term travelers is low and suspected following ingestion of street vendor foods or vegetables fertilized by "night soil" (human feces) or animal feces. Eggs survive for years in moist soil, and transmission is typically fecal–oral or through poorly cooked food. Symptoms are usually minimal; a dry cough or pneumonia may occur as young worms are expectorated and migrate from the lungs to the esophagus and gut. A large worm burden can lead to malnutrition and weakness, and a mass of worms may lead to bowel obstruction. Wandering *Ascaris* also traverse internal organs, rarely leading to biliary obstruction, hepatic abscess, acute pancreatitis, acute appendicitis, or hypersensitivity pneumonitis. The diagnosis and treatment are described in Table 161-14.

ENTEROBIASIS (PINWORM, SEATWORM)

Enterobiasis vermicularis is a common tropical disease caused by a small intestinal parasite transmitted by the fecal–oral route and is often acquired from contaminated objects such as toys, utensils, and bedding. It is a common disease among U.S. children and is more likely to be peridomestic rather than after tropical travel. The disease is characterized by intense perianal itching. The diagnosis and treatment are found in Table 161-14.

TRICHURIS (WHIPWORM DISEASE)

Whipworm (*Trichuris trichiura*) is a nematode parasite of the large intestine distributed globally but most heavily in the tropics. Long-term travelers, former tropical residents, and visitors from the tropics are at high risk. It is obtained by ingesting contaminated soil or vegetables and is not transmissible from person to person. Light infestations are asymptomatic, and heavy infestations cause bloody diarrhea and rectal prolapse. Diagnosis and treatment are found in Table 161-14.

HOOKWORM

Hookworm is a common chronic nematodal infection caused by *Ancylostoma duodenale* and *Necator americanus*, which are globally distributed but most heavily in the tropics and subtropics. Because symptoms require large worm burdens, it is a low risk among short-term travelers. Hookworm causes chronic, severe anemia, especially in children. The cutaneous

TABLE 161-14 Common Parasitic Helminth (Worm) Infestations

Name	Source of Contamination	Human Symptoms	Diagnosis	Treatment
Ascaris lumbricoides (roundworm)	Fecal–oral contamination or poorly cooked food	Minimal symptoms; or pneumonia, malnutrition, biliary or bowel obstruction, hepatic abscess, appendicitis, etc.	Stool examination, serology.	Albendazole, 400 milligrams single dose *or* Mebendazole, 100 milligrams twice a day for 3 d or 500 milligrams single dose *or* Ivermectin, 150–200 micrograms/kg single dose
Enterobiasis (pinworm, seatworm)	Fecal–oral and from contaminated objects	Intense perianal itching	Visual inspection, cellophane tape swab of anus upon waking.	Albendazole, 400 milligrams single dose and repeat in 2 wk *or* Mebendazole, 100 milligrams single dose and repeat in 2 wk *or* Pyrantel pamoate, 11 milligrams/kg (up to 1 gram) single dose and repeat in 2 wk
Trichuris trichiura (whipworm)	Fecal–oral contamination	Asymptomatic; or bloody diarrhea, rectal prolapse	Stool examination.	Albendazole, 400 milligrams daily for 3 d *or* Mebendazole, 100 milligrams daily for 3 d or 500 milligrams single dose
Ancylostoma duodenale and *Necator americanus* (hookworm)	Contaminated soil, larvae penetrate the skin	Severe anemia; cutaneous larva migrans	Stool examination, may require serial exams.	Albendazole, 400 milligrams single dose *or* Albendazole, 400 milligrams twice a day for 3 d *or* Pyrantel pamoate, 11 milligrams/kg (maximum, 1 gram) daily for 3 d
Taenia solium (pork tapeworm), *T. saginata* (beef tapeworm), and *Diphyllobothrium latum* (fish tapeworm)	Raw or undercooked pork or beef or fish	Asymptomatic, abdominal pain, bowel obstruction; *Taenia* cysts in skin, eye, brain, heart (see "Cysticercosis" section, above)	Stool examination or serology. Serology may be negative if cysts are calcified.	Praziquantel, 5–10 milligrams/kg single dose
Strongyloides stercoralis (threadworm)	Contaminated soil, larvae penetrate skin	Cough, pneumonia, and wheezing; abdominal pain, bloody diarrhea	Stool examination or stool concentration methods; serology or sputum examination.	Ivermectin, 100 micrograms/kg/d for 2 d or Albendazole, 400 milligrams twice a day for 7 d

form is called *cutaneous larva migrans*. Transmission is by direct skin contact with soil contaminated by human feces, often in children with poor footwear exposed to raw sewage. Filariform larvae penetrate the skin. Microscopic examination of stool for eggs is the usual means of diagnosis. Diagnosis and treatment are found in Table 161-14.

CESTODES (TAPEWORMS)

Among the cestodes, taeniasis and cysticercosis are the most pathologic. Infections occur worldwide, but especially in the tropics, and risk is high among children, the mentally disabled, and immigrants or visitors from endemic nations. Risk to travelers is low but is increased with consumption of undercooked pork, fish, or beef.

Taenia solium and *Taenia saginata* (Pork and Beef Tapeworm)

T. solium **(pork tapeworm)** is encountered in the United States in immigrants or visitors to or from Central America and the Middle East. *T. saginata* (beef tapeworm) is seen more often, especially in those who consume raw beef (e.g., steak tartare), particularly in Latin America, Eastern Europe, Africa, and Russia. Adult worms live in the small intestine. Infected patients can be asymptomatic or present with nausea and vomiting, headache, abdominal pain, pruritus, constipation, diarrhea, and intestinal obstruction. The larval stage of *T. solium* can cause clinical disease (cysticercosis), which can sometimes be fatal. *Taenia* cysts may be found in subcutaneous tissue, the eye, brain, and heart, and cause seizures and hydrocephalus. Radiographs of the soft tissues may reveal curvilinear calcifications indicative of cysts, and cysts can be seen in the meninges and brain parenchyma on CT scanning. Diagnosis and treatment are found in Table 161-14. For discussion of neurocysticercosis see the "Cysticercosis" section, above. *Dipylidium caninum* is discussed in the chapter 160.

Diphyllobothrium latum (Fish Tapeworm)

Diphyllobothrium latum (fish tapeworm) is encountered in those consuming raw fish (e.g., sushi and sashimi) or gefilte fish. Diphyllobothrium can compete with the host for vitamin B_{12}, and patients can develop pernicious anemia. Most patients are asymptomatic, but some develop intestinal or biliary obstruction. Diagnosis and treatment are found in Table 161-14.

STRONGYLOIDES

Strongyloides stercoralis infects the small intestine. Distribution is worldwide, but infection is most common in humid tropics. Infection can develop in overseas military personnel, refugees, or immigrants. The risk is low in short-term travelers. Most infections cause minimal or no symptoms. However, fatalities may occur due to hyperinfection in elderly and immunocompromised patients and those with chronic disease. An upper GI series may reveal a deformed duodenal bulb, and *Strongyloides* may be confused with ulcer disease. Diagnosis and treatment are found in Table 161-14.

DISEASES COMMONLY ASSOCIATED WITH EYE OR SKIN COMPLAINTS

Skin complaints among travelers are common and nonspecific and have many causes. **Travel-related skin disease is generally caused by one of the following: (1) exacerbations of previous conditions (e.g., atopic dermatitis, psoriasis); (2) environmental conditions (e.g., photosensitivity,**

TABLE 161-15 Cutaneous Manifestations of Selected Infections

Appearance of Lesion	Possible Diagnosis
Maculopapular rash	Dengue fever Viral hemorrhagic fevers Leptospirosis Acute human immunodeficiency virus infection
Erythema chronicum migrans	Lyme disease
Rose spots	Typhoid fever
Pustules	Disseminated gonococcal infection
Petechiae, ecchymoses, hemorrhage	Meningococcemia Dengue fever Viral hemorrhagic fevers Yellow fever Rocky Mountain spotted fever Epidemic louse-borne typhus Leptospirosis
Eschar	Tick or scrub typhus Anthrax
Ulcer	Tularemia Cutaneous diphtheria
Urticaria	Helminthic infections

contact allergies); or (3) infective organisms causing infestations or infections.[16] The distribution and timing of the dermatosis may aid diagnosis of rashes associated with systemic illness (**Table 161-15**).[17] Among rashes reported by travelers, most are minor problems such as sunburn, phototoxic/sensitivity reactions, insect bites, and prickly heat, and are often self-limiting and necessitate symptomatic care. **The top 10 tropical travel dermatoses requiring specific therapy are cutaneous larva migrans, pyodermas due to staphylococcal or streptococcal ecthyma, arthropod-reactive dermatoses, myiasis, tungiasis, urticaria, febrile syndromes with rash, cutaneous leishmaniasis, scabies, and fungal infections.**[18] The risk of serious conditions tends to increase with the amount of time spent overseas, and thus short-term travelers rarely contract dermatoses such as filariasis, Buruli ulcer, yaws, and leprosy (Hansen's disease). To further aid diagnosis, travelers with dermatoses can fit into five syndromic and morphologic categories (**Table 161-16**).

Management includes arranging biopsy for patients with chronic ulcerative lesions. Beware of the rare patient presenting with anxiety of parasitosis regardless of travel history. The following are select dermatoses associated with tropical exposures.

ONCHOCERCIASIS (RIVER BLINDNESS)

River blindness is a chronic, nonfatal filarial disease leading to subcutaneous skin changes and blindness. It is caused by *Onchocerca volvulus*, a nematode transmitted by the female black fly, *Simulium* species, found near fast-moving rivers in parts of Central/South America and mostly equatorial Africa. Early treatment can prevent blindness and reduce systemic spread, because the incubation period from fly bite to microfilariae appearing in skin is often more than a year. Symptoms include intractable pruritus, altered skin pigmentation, skin nodules, lymphadenitis, and gradual visual impairment leading to blindness. Adult female worms reside in 2- to 3-cm painless nodules in skin and bones near joints, and release microfilariae that migrate through the skin, causing intense pruritus when they die, leading to chronic dermatitis, edema, and skin atrophy. Skin pigment changes result in "leopard skin," whereas loose pelvic skin is called "hanging groin." Blindness is a result of microfilariae migrating to the eye, invading it, and causing permanent damage when they die. Diagnosis is made by identification of microfilariae from a fresh skin biopsy, nodule biopsies, or in the urine. Slit-lamp examination may reveal microfilariae in the cornea, anterior chamber, or vitreous. Treatment is one dose of ivermectin, 150 micrograms/kg PO, which does not kill the adult worm, but when repeatedly dosed every 6 to 12 months, reduces morbidity by killing microfilariae, suppressing microfilariae release from adults, and preventing spread to eyes and skin. **Diethylcarbamazine citrate (DEC)** and **suramin** (which can kill adult worms and microfilariae) have serious side effects and are avoided. Surgical removal of nodules can reduce symptoms, reduce the worm burden, and, if removed from the frontal scalp, help prevent progression of visual impairment and blindness.

TABLE 161-16 Syndromic Categories of Travel-Related Dermatoses with Select Examples

Fever and rash (petechial or hemorrhagic): dengue fever, arboviruses, rickettsial infections (e.g., scrub typhus), Chikungunya, meningococcemia, leptospirosis, malaria, and erythema multiforme caused by drug reaction or common infection
Papular eruptions: insect bites, persistent lesions (chiggers), scabies, allergic drug reactions, cercarial dermatitis (swimmers), *Pseudomonas* folliculitis (hot-tubbing), onchocerciasis (long-term travel)
Persistent nodules: furunculosis, myiasis (movement within the lesion), chancroid, syphilis, systemic parasites/fungi
Migratory swellings or skin lesions: cutaneous larva migrans, strongyloidiasis (fast-moving and often on the buttocks), urticaria from various causes, and loa loa (rarely)
Ulcerative lesions: pyodermas, spider bites, chancroid and syphilis, cutaneous leishmaniasis

LOA LOA (EYE WORM)

Loiasis is caused by a filarial nematode confined to the rain forests of western and central Africa. It is a low risk to short-term travelers but should be suspected among immigrants, refugees, visiting nationals, and expatriates living several months or more in endemic zones. Among travelers, worm burden is usually low, and symptoms are related to hypersensitivity syndromes and not serious disease. The adult worms inhabit subcutaneous tissues, move about freely, and can live for up to 18 years after the patient's last possible exposure. They are spread from the bite of the *Chrysops* fly and take 1 year to mature. Infections are usually asymptomatic; however, at times, infections cause painful or itchy subcutaneous swellings near the face and extremities known as *Calabar swellings*. The most dramatic presentation is when a worm passes across the eye under the conjunctiva, thus coining the disease "eye worm."

Patients will complain of "something in their eye," intense irritation, pain, and swelling of the periorbital tissues. The worm usually moves out of the conjunctiva in 30 minutes, but it takes usually several days for symptoms to subside.

Diagnosis is made by clinical presentation and by evaluating daytime-drawn blood for distinctively sheathed microfilariae and high-grade eosinophilia. Treatment for microfilariae and adult worms is **diethylcarbamazine citrate,** 2 milligrams/kg PO three times daily for 3 weeks. In patients with very high microfilariae counts, diethylcarbamazine citrate may induce a sudden severe hypersensitivity and encephalitic syndrome, so treatment is begun with a very small dose. Alternatives are albendazole or blood filtration to remove large numbers of larvae. Surgical excision is not recommended because multiple worms may not be visible. Subconjunctival worms, however, can be removed from the eye with analgesia and fine tweezers.

CREEPING ERUPTION (CUTANEOUS LARVA MIGRANS)

This erythematous "creeping eruption" commonly occurs among tropical travelers and beach resort vacationers who walk barefoot or sit in beach sand contaminated by dog feces harboring the parasite *Ancylostoma braziliense*.[19] The lesions are typically slow moving, tracking, and serpiginous, and are a result of an inflammatory reaction from the worm, which is unable to complete its growth cycle in humans (it is only an effective parasite of dogs or cats). Pruritus causes sleeplessness and restlessness, and diagnosis is based on clinical presentation and eosinophilia. Treatment consists of **albendazole**, 400 milligrams daily for 3 to 7 days, or a single dose of ivermectin, 200 micrograms/kg once.

Liquid nitrogen freezing or surgical excision is not recommended because of scarring.

CUTANEOUS LEISHMANIASIS

Cutaneous leishmaniasis is the most important cause of chronic skin ulceration in the world and is spread by sandflies in tropical and subtropical regions of Latin America, Africa, the Middle East, and Asia. This should be suspected among travelers such as military personnel, biologists, ecotourists, and adventure travelers, and should be part of the differential diagnosis of cutaneous ulcers among travelers, foreign visitors, and immigrants from endemic areas. Although there are a variety of subtypes causing varying infections, the common presentation is of a small papule slowly enlarging and forming a painless shallow skin ulcer with a noticeable rolled edge like a volcano, with a raised edge and central crater, often with a scab. Diagnosis is made by tissue biopsy of the indurated ulcer margin or scraping of the base with material placed on a slide followed by Giemsa stain. Many forms are self-limiting; treat based on clinical presentation and in concert with infectious disease consultants or the Centers for Disease Control and Prevention Parasitic Diseases Branch.

BANCROFTIAN FILARIASIS (*WUCHERERIA BANCROFTI*)

Bancroftian filariasis, a filarial disease, is caused by nematodes residing in the subcutaneous tissues and lymphatics for up to 10 years. It is common to South America, Africa, and Asia and the risk to short-term travelers is low, although cases are imported by long-term travelers. It is transmitted by flies or mosquitoes permitting larvae to enter the puncture wound during their blood meal. Adult filariae then reside in lymphatics and produce microfilariae that migrate to the bloodstream at night. Because the incubation period is long, first symptoms usually develop after 6 months or later (up to 5 years). The most common symptom is recurrent bouts of "filarial fevers" lasting 2 to 3 weeks, associated with warmth and tenderness overlying a lymphatic vessel, followed by retrograde lymphangitis. The most frequently affected sites are extremities, breasts, and spermatic cord. As more attacks occur, lymphatics are chronically damaged, and the most important consequence is the disfiguring and ostracizing condition elephantiasis. Diagnosis depends on finding the sheathed microfilariae in a nocturnal peripheral blood smear. Serology is often useful in mild infections. Treatment is **diethylcarbamazine citrate**, 2 milligrams/kg three times daily for 3 weeks. This drug is well tolerated but can cause hypersensitivity reactions because of early antigen liberation, resulting in fever, headache, nausea, and urticaria. Symptoms can be reduced by starting with a small dose. Repeated treatment may be necessary.

DISEASES COMMONLY ASSOCIATED WITH PULMONARY COMPLAINTS

Returning travelers frequently develop respiratory complaints such as persistent cough, sinus congestion, and fever, and such nonspecific symptoms may be due to travel-related causes such as malaria, typhoid fever, typhus, and dengue. Common local respiratory pathogens, such as viral causes like influenza, and bacterial infections are the most common triggers. Risk factors for pulmonary disease include prolonged air travel with recirculation of dry cabin air and exposure to fellow travelers with infectious agents. Long-term travelers are at increased risk for tuberculosis that may manifest many years after travel. **In the ED, isolate the patient** because contagious infections such as tuberculosis, influenza, or coronaviruses, such as severe acute respiratory syndrome or Middle East respiratory syndrome, are possible. Also, have healthcare workers use personal protective devices.

Once public health threats are reasonably excluded, the evaluation is similar as for any nontravel patients. Additionally, ask about travel-related risk factors because a variety of pathogens such as viruses (viral hemorrhagic fevers), helminths (*Strongyloides*, *Schistosoma*, *Paragonimus*, *Ascaris*), and protozoa (*E. histolytica*, *Trypanosoma*, *Leishmania*) produce pulmonary symptoms or radiographic infiltrates.

MIDDLE EAST RESPIRATORY SYNDROME, SEVERE ACUTE RESPIRATORY SYNDROME, AND EMERGING INFECTIONS

Between September 2012 and February 2014, the World Health Organization reported a total of 182 cases of the Middle East respiratory syndrome coronavirus infection with 79 deaths[20]; cases now exist in the United States. Like the 2003 to 2004 outbreak of severe acute respiratory syndrome, Middle East respiratory syndrome is caused by a coronavirus. The Centers for Disease Control and Prevention defines clinical criteria for a suspected case of Middle East respiratory syndrome as follows:

- Fever (≥38°C, 100.4°F) and pneumonia or acute respiratory distress syndrome (based on clinical or radiological evidence);

  AND
- history of travel from countries in or near the Arabian Peninsula within 14 days before symptom onset;

  OR
- close contact with a symptomatic traveler who developed fever and acute respiratory illness (not necessarily pneumonia) within 14 days after traveling from countries in or near the Arabian Peninsula;

  OR
- is a member of a cluster of patients with severe acute respiratory illness (e.g., fever and pneumonia requiring hospitalization) of unknown etiology in which MERS-CoV [Middle East respiratory syndrome coronavirus] is being evaluated, in consultation with state and local health departments.[21]

Although not certain, Middle East respiratory syndrome is likely to be spread by "droplet infection," through exposure to respiratory droplets spread by a cough or sneeze from an infected person. Polymerase chain reaction can be used to detect Middle East respiratory syndrome coronavirus.

Preventative measures are aimed at reducing close contact with infected persons and nosocomial transmission. Hospitalized patients should be placed on airborne precautions, and healthcare providers should use gowns, gloves, eye protection, and respiratory protection with a minimum of an N95 mask.[22] Medical personnel treating patients suspected of infection with Middle East respiratory syndrome coronavirus should promptly notify local and state health departments of the case.

Treatment of Middle East respiratory syndrome is supportive care.

TUBERCULOSIS

Refugees and immigrants or expatriate workers (especially healthcare workers) returning from endemic areas are at higher risk of clinical tuberculosis (e.g., Eastern Europe, Africa, Asia). The risk of tuberculosis in travelers is approximately 3% per year of stay in endemic areas. High-risk sites for multidrug-resistant mycobacteria are Russia, Eastern Europe, Southeast Asia, China, southern Africa and South America. The initial ED management of suspected tuberculosis after respiratory isolation is discussed elsewhere (see chapter 67, "Tuberculosis").

PARAGONIMUS (LUNG FLUKE DISEASE)

Paragonimus westermani is a trematoidal infection primarily affecting the lungs. It is widely distributed, but is mostly found in the Far East and Southeast Asia (China is the major endemic site). It is uncommon in short-term travelers but should be considered among immigrants or long-term residents of Asia who are also at risk for tuberculosis and among travelers indulging in local exotic foods. Humans are infected by swallowing larvae contaminating raw or pickled crustaceans. Incubation lasts 6 to 12 weeks, as larvae migrate from the duodenum to the lungs, where they cause cough (sometimes with rusty sputum), pleuritic chest pain, and hemoptysis. Chest pain is often present, and fever with night sweats may occur during early infections, causing tuberculosis to be incorrectly diagnosed.

Chest radiographs demonstrate diffuse segmental infiltrates, nodules, ring cysts, or pleural effusions. Suspect paragonimiasis when no sputum smear acid-fast bacilli are found. If parasites do not reach the lung, diverse symptoms develop depending on fluke location. Symptoms

include abdominal pain, diarrhea, migrating subcutaneous swelling, blindness, epididymis, testicular inflammation, and a variety of cerebral symptoms. Seizures can occur from intracranial encysted adults. Diagnosis is made by finding the characteristic eggs in sputum, urine, or stool, or by serologic tests. The treatment of choice is **praziquantel** or **bithionol**.

PARASITE-INDUCED BRONCHOSPASM

The most common helminths causing pulmonary symptoms are *Ascaris* and *Strongyloides*. A suggestive clinical history includes recent travel and ingestion of local food of uncertain quality. Suspicion should be raised by any new pulmonary symptoms such as cough or wheezing associated with patchy infiltrates on chest radiograph and hypereosinophilia. For diagnosis and treatment for each helminth, see previous respective sections.

CHAPTER 162

Occupational Exposures, Infection Control, and Standard Precautions

Charissa B. Pacella

INTRODUCTION

The U.S. Occupational Safety and Health Administration defines *occupational exposure* as a "reasonably anticipated skin, eye, mucous membrane, or parenteral contact with blood or other potentially infectious materials that may result from the performance of the employee's duties."[1] Blood is defined as "human blood, blood products, or blood components."[1] *Other potentially infectious materials* are defined as "human body fluids, such as saliva, semen, and vaginal secretions; cerebrospinal, synovial, pleural, pericardial, peritoneal, and amniotic fluids; any body fluids visibly contaminated with blood; unfixed human tissue or organs; HIV [human immunodeficiency virus] or HBV [hepatitis B virus] containing cell or tissue cultures, culture mediums, or other solutions; and all body fluids where it is difficult or impossible to differentiate between body fluids."[1] Healthcare workers should treat all bodily secretions, fluids, and tissues as potentially infectious.

The Hospital Infection Control Practices Advisory Committee of the Centers for Disease Control and Prevention lists select infections and conditions that may be encountered in the ED, along with recommended occupational exposure precautions.[2-4] The concept of *standard precautions* is built on the premise that healthcare workers cannot readily identify patients who are infected or at risk for infection. This is why using infection control practices and personal protective equipment during all patient care activities is key.

U.S. Occupational Safety and Health Administration federal regulations prescribe safeguards to protect workers and reduce risk of exposure to blood and body fluids.[5] Updated and detailed standards (known as the Bloodborne Pathogens Standard) are in Title 29 of the *Code of Federal Regulations* and amended by the Needlestick Safety and Prevention Act.[6,7] The standards require healthcare facilities (1) to develop a written exposure control plan, (2) to use engineering controls to reduce risk by removing the hazard or isolating the worker from exposure, (3) to use work practice controls to standardize and maximize the safety with which work tasks are performed, (4) to identify mechanisms for compliance with Title 29 standards, and (5) to communicate workplace hazards to those with potential for bloodborne disease exposures. The Centers for Disease Control and Prevention and U.S. Occupational Safety and Health Administration Web sites provide the most up to date information regarding current regulations and standards.

PORTALS FOR EXPOSURE

Portals for infectious disease entry are percutaneous, mucous membrane (oral, ocular, nasal, vaginal, or rectal), respiratory, and dermal. The risk of infection in an exposed healthcare provider depends on (1) the route (portal) of exposure, (2) the concentration (number of organisms) of the pathogen in the infectious material, (3) the infectious characteristics (virility) of the pathogen, (4) the volume (dose) of infectious material, and (5) the immunocompetence (susceptibility) of the exposed individual.

Percutaneous exposures pose the highest risk of transmission for bloodborne disease. Needle sticks and lacerations by sharp objects account for the majority of percutaneous injuries. Phlebotomy, initiation of IV access, manipulation of access devices, suturing, and medication injection all put workers at risk.

Mucous membrane exposures result from splatters, splashes, and sprays of blood and body fluids. Tasks associated with risk of mucous membrane exposure include wound management (hemorrhage control, exploration, irrigation, debridement), airway suctioning, nasogastric or orogastric tube placement, intubation, and specimen handling.

Respiratory exposures occur through inhalation of airborne or droplet particulate materials. Exposure risk grows when an individual is confined with an expectorating, coughing, or sneezing patient for prolonged periods or in a poorly ventilated environment.

Dermal exposure involves skin contact with patients (direct contact) or environmental surfaces or objects contaminated with infectious materials (indirect contact). The risk of infection increases if the contact involves a large surface area or nonintact skin (abraded, chapped, or excoriated). Drug-resistant organisms (e.g., methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant enterococci) and parasites of the integument (e.g., scabies, lice) are transmitted by dermal exposure. Workplace activities associated with dermal exposure include patient examination, turning or moving patients, and changing linens or wound dressings. Healthcare workers are also at risk for hypersensitivity reactions to specific inert substances, notably latex, after prolonged or repeated dermal exposure.

INFECTION CONTROL

Infection control practices seek to prevent transmission of microbial agents and to provide a wide margin of safety for healthcare workers. **These practices include hand washing; use of personal protective equipment; cleaning, disinfecting, and sterilizing patient care equipment and environmental surfaces; decontamination and laundering of soiled uniforms, clothing, and patients' linens; disposal of needles, sharps, and infectious waste; and patient location.** Infection control measures that are simple, part of the routine work environment, and uniform across all situations have the greatest likelihood of compliance.

A complete infection control program includes administrative controls, equipment engineering, work practice controls, education of the workforce, and medical management.

Administrative controls organize, define, and direct infection control activities. The written infection control (exposure) plan defines all policies, procedures, and activities related to the education, prevention, and management of infectious diseases in the workforce. Initial and recurrent training in infectious disease hazards and risk activities must be provided to all healthcare workers.

Equipment engineering reduces employee exposure by removing hazards or isolating healthcare workers from exposure. Examples include self-sheathing needles, needleless drug administration devices, sharps containers, disposable airway equipment, syringe splash guards, and personal protective equipment. Medical safety devices reduce occupational exposures experienced by healthcare personnel and should be used whenever possible.

TABLE 162-1 Task-Specific Recommendations for Use of Personal Protective Equipment

Patient Care Activity	Disposable Gloves	Mask and Protective Eyewear	Impervious Gown
Measuring blood pressure	No*	No	No
Measuring pulse	No*	No	No
Measuring temperature	No*	No	No
Examination of bleeding patient	Yes	No†	No†
Wound management, dressing	Yes	No†	No†
Minor hemorrhage control	Yes	No†	No†
Profuse hemorrhage control	Yes	Yes	Yes
Cardiopulmonary resuscitation	Yes	No†	No†
Venipuncture	Yes	No	No
IV line placement	Yes	No	No
IM, SC, IV medication administration	Yes	No	No
Cricothyrotomy, needle decompression	Yes	Yes	No
Intubation, airway adjunct placement, suctioning	Yes	Yes	No†
Childbirth	Yes	Yes	Yes
Nasogastric or orogastric tube placement	Yes	Yes	No†
Specimen handling	Yes	No	No

*Use gloves if task performance includes possible contact with patient's blood, secretions, or body fluids.

†Use mask, protective eyewear, and impervious gown if possibility of splashing or spray exists.

Personal protective equipment is "specialized clothing or equipment which does not permit blood or potentially infectious substances to pass through or reach worker clothing, skin, eyes, mouth, or other mucous membranes under normal conditions of use."[1] Personal protective equipment includes examination gloves, facemasks, eye protection, face shields, and impervious gowns, leggings, and shoe covers. Personal protective equipment mitigates occupational exposures experienced by healthcare personnel; it limits but does not eliminate exposure risks. Recommendations for task-specific use of personal protective equipment are provided in **Table 162-1**.[8]

Work practice controls modify the performance of a task to minimize exposure to blood and blood-containing body fluids and infectious materials. Work practice controls include policies to guide disposal of needles and sharps containers (i.e., avoid shearing, bending, recapping, or breaking); disposal of contaminated linens, clothing, and infectious waste; disinfection of reusable equipment; and restriction of employee activities (eating, drinking, smoking, and application of cosmetics) in work areas where there is a reasonable likelihood of exposure to blood and body fluids.

Workforce education includes information about the agents of infectious disease, epidemiology, disease transmission, signs and symptoms, risky work activities, risk reduction strategies, and postexposure management. Education must occur at the time of initial employment, with recurrent training at specified intervals.

Medical management practices include preexposure preventive vaccinations, postexposure medical evaluation, testing, infectious disease counseling, disease prophylaxis, and referral. The U.S. Occupational Safety and Health Administration mandates preexposure vaccines at initial employee training and within 10 days of employment for all personnel at risk of exposure.[1] The Advisory Committee on Immunization Practices and the Hospital Infection Control Practices Advisory Committee make specific recommendations concerning the use of certain immunizing agents in healthcare personnel.[9]

TABLE 162-2 Outline for Management of Exposures to Blood or Body Fluids

Expedite medical evaluation.
Irrigate exposed areas with water; wash wounds with soap and water.
Obtain history regarding exposure circumstances, source patient, and vaccination history of exposed person (Table 162-3).
Obtain blood samples for laboratory studies (using consents when required) from exposed person; obtain urine pregnancy test for women of childbearing potential.
Order laboratory studies from source patient if known (using consents when required).
Determine need for tetanus immunization.
Determine need for hepatitis B PEP (Table 162-6).
Determine need for human immunodeficiency virus PEP (Table 162-7) and mechanism for dosing as rapidly as possible.
Counsel exposed person regarding risk of specific bloodborne pathogens and discuss risks/benefits of available treatment options.
Review dosing and side effects of recommended treatments (Table 162-8).
Arrange follow-up through employee health clinic within 72 h. Obtain expert consultation in appropriate cases (Table 162-9).

Abbreviation: PEP = postexposure prophylaxis.

EXPOSURE TO HEPATITIS B, HEPATITIS C, AND HUMAN IMMUNODEFICIENCY VIRUS

Once an infectious exposure has occurred, healthcare workers should have access to a plan for postexposure prophylaxis (PEP) medical management 24 hours a day. The plan should include immediate medical assessment, risk analysis, counseling, treatment and prophylaxis, and follow-up appropriate to the type and source of the exposure.[9-14]

An outline for a standardized initial approach is shown in **Table 162-2**.[11]

The medical record of care for the exposed patient (the occupational exposure report) should contain specific information relative to the exposure incident. Key elements include the circumstances of exposure, medical history of the source person, and medical history of the exposed person per Centers for Disease Control and Prevention recommendations (**Table 162-3**).[10]

INITIAL TREATMENT AND ASSESSMENT

Thoroughly wash exposed wounds and skin sites with soap and water, and irrigate mucous membranes with water. **Do not apply** caustics (bleach), antiseptics, or disinfectants directly to the wound.

TABLE 162-3 Recommendations for the Contents of the Occupational Exposure Report

Date and time of exposure.
Details of the procedure being performed, including where and how the exposure occurred; if related to a sharp device, the type and brand of device and how and when in the course of handling the device the exposure occurred.
Details of the exposure, including the type and amount of fluid or material and the severity of the exposure (e.g., for a percutaneous exposure, depth of injury and whether fluid was injected; for a skin or mucous membrane exposure, the estimated volume of material and the condition of the skin [e.g., chapped, abraded, intact]).
Details about the exposure source (e.g., whether the source material contained hepatitis B virus, hepatitis C virus, or HIV; if the source is HIV infected, the stage of disease and prognosis, history of antiretroviral therapy, viral load, and antiretroviral resistance information, if known).
Details about the exposed person (e.g., hepatitis B vaccination and vaccine-response status).
Details about counseling, postexposure management, and follow-up.

Abbreviation: HIV = human immunodeficiency virus.

TABLE 162-4 Factors to Consider in Assessing Healthcare Workers After Occupational Exposures

Type of exposure
Percutaneous injury
Mucous membrane exposure
Nonintact skin exposure
Bites resulting in blood exposure to either person involved
Type and amount of fluid/tissue
Blood
Fluids containing blood
Potentially infectious fluid or tissue (semen; vaginal secretions; and cerebrospinal, synovial, pleural, peritoneal, pericardial, and amniotic fluids)
Direct contact with concentrated virus
Infectious status of source
Presence of hepatitis B surface antigen
Presence of HCV antibody
Presence of HIV antibody
Susceptibility of exposed person
Hepatitis B vaccine and vaccine response status
HBV, HCV, and HIV immune status

Abbreviations: HBV = hepatitis B virus; HCV = hepatitis C virus; HIV = human immunodeficiency virus.

Evaluate the exposure event for the potential to transmit hepatitis B virus, hepatitis C virus, and human immunodeficiency virus (HIV) based on the type of body substance involved and the route and volume of the exposure (**Table 162-4**).[10] Blood, fluid containing visible blood, human tissue, or other potentially infectious material (including semen, vaginal secretions, and cerebrospinal, synovial, pleural, peritoneal, pericardial, and amniotic fluids) may transmit bloodborne viruses. Percutaneous injury or mucous membrane contact with these substances conveys risk for virus transmission. Dermal contact with these substances does not convey risk of virus transmission unless the skin is *not* intact (abraded, chapped, excoriated, open wound).

TESTING FOR EXPOSURE

Perform diagnostic testing to determine the hepatitis B virus, hepatitis C virus, and HIV infection status of an exposure source as soon as possible and with consent (**Table 162-5**).[10] If possible, obtain a rapid HIV-antibody on the exposure source; direct viral assays (HIV p24 antigen enzyme immunoassay, HIV RNA, hepatitis C virus RNA) are not recommended. Testing of needles or sharps instruments for contamination is also not recommended. If the exposure source is HIV positive, obtain additional information as available including CD4+ T-cell count, viral load, current and previous antiretroviral therapy, and history of antiretroviral resistance and prognosis to help identify optimal PEP regimen. If this information is not known at the time of exposure, do not delay the initiation of PEP, as changes in the regimen may be made on follow-up within 72 hours after exposure.[10]

TABLE 162-5 Evaluation of Occupational Exposure Sources

Known sources
Test known sources for hepatitis B surface antigen, anti–hepatitis C virus, and HIV antibody.
Direct virus assays for routine screening of source patients are *not* recommended.
Consider using a rapid HIV-antibody test.
If the source person is *not* infected with a bloodborne pathogen, baseline testing or further follow-up of the exposed person is *not* necessary.
For sources whose infection status remains unknown (e.g., the source person refuses testing), consider medical diagnoses, clinical symptoms, and history of risk behaviors.
Do not test discarded needles for bloodborne pathogens.
Unknown sources
For unknown sources, evaluate the likelihood of exposure to a source at high risk for infection.
Consider likelihood of bloodborne pathogen infection among patients in the exposure setting.

Abbreviation: HIV = human immunodeficiency virus.

HEPATITIS B VIRUS EXPOSURE AND PEP

Factors in the management of hepatitis B virus exposure include the hepatitis B surface antigen status of the source and the hepatitis B vaccination and vaccine response status of the exposed person. Following a percutaneous exposure, the estimated risks of hepatitis in unvaccinated healthcare workers are 22% to 31% (source patient positive for hepatitis B surface antigen and hepatitis B e antigen) and 1% to 6% (source patient positive for hepatitis B surface antigen and negative for hepatitis B e antigen). The estimated risk of transmission is lower following mucous membrane exposure, nonintact skin exposure, or an exposure involving nonbloody fluids or tissues.[10] Every unvaccinated healthcare worker exposed to blood or body fluids should receive the hepatitis B vaccine series. For the rest, recommendations for PEP following hepatitis B virus exposure vary according to the hepatitis B surface antigen status of the exposure source and the vaccination/vaccine-response status of the exposed person (**Table 162-6**).[10] If hepatitis B immunoglobulin is indicated, give it as soon as possible after the exposure (ideally within 24 hours); after 7 days, the effectiveness of hepatitis B immunoglobulin is unknown.

The **Hepatitis Hotline** provides guidance to clinicians with regard to the acute and chronic management of hepatitis (**1-888-443-7232, http://www.cdc.gov/hepatitis**).

HEPATITIS C VIRUS EXPOSURE

For occupational hepatitis C virus exposures, the Centers for Disease Control and Prevention recommends anti–hepatitis C virus testing of the source patient. Test the exposed person for anti–hepatitis C virus and alanine aminotransferase at baseline and follow-up (at 4 to 6 months), and testing for hepatitis C virus RNA may be performed at 4 to 6 weeks after exposure if needed to aid early diagnosis of hepatitis C virus. Confirm all positive anti–hepatitis C virus tests by enzyme immunoassay with supplemental testing (i.e., recombinant immunoblot assay). If the source patient is hepatitis C virus infected, the mean estimated risk of transmission is 1.8% after a percutaneous exposure (range 0% to 7%). Estimated risk of transmission is even lower following mucous membrane exposure, nonintact skin exposure, or an exposure involving nonbloody fluids or tissues.[10] Immunoglobulin and antivirals are not recommended for PEP after exposure to hepatitis C virus–positive blood.

Healthcare workers exposed to hepatitis B virus– or hepatitis C virus–infected blood do not need to take any precautions to prevent secondary transmission during the follow-up period; however, they should not donate blood, plasma, organs, tissue, or semen.

HIV EXPOSURE AND PEP

Healthcare workers potentially exposed to HIV should receive expedited evaluation and baseline testing for HIV. Factors in the management of HIV exposure include the type of exposure (percutaneous, mucous membrane, or dermal), the volume of the exposure (small or large), and the HIV status of the source. Risk of HIV transmission following percutaneous exposure increases with exposure to a larger quantity of blood as indicated by (1) a device visibly contaminated with blood, (2) a needle placed in the source patient's artery or vein, (3) a large-bore hollow needle, or (4) a deep injury.[16] If the source patient is HIV infected, the estimated risk of transmission is 0.3% after a percutaneous exposure and 0.09% after a mucous membrane exposure. Estimated risk of transmission following a nonintact skin exposure or an exposure involving nonbloody fluids or tissues is even lower.[14]

TABLE 162-6 Postexposure Prophylaxis for Percutaneous and Mucous Membrane Exposure to Hepatitis B Virus

Vaccination and Antibody Response Status of Exposed Workers	Treatment		
	Source Is HBsAg Positive	Source Is HBsAg Negative	Source Is Unknown or Not Available for Testing
Unvaccinated/nonimmune	HBIG* × 1 and initiate HB vaccine series	Initiate HB vaccine series	Initiate HB vaccine series
Previously vaccinated			
Previously vaccinated known responder†	No treatment	No treatment	No treatment
Previously vaccinated known nonresponder‡	HBIG × 1 and initiate revaccination or HBIG × 2#	No treatment	If known high-risk source, treat as if source were HBsAg positive
Previously vaccinated antibody response unknown	Test exposed person for anti-HBsf 1. If adequate,† no treatment is necessary 2. If inadequate,‡ administer HBIG × 1 and vaccine booster	No treatment	Test exposed person for anti-HBsf 1. If adequate,† no treatment is necessary 2. If inadequate,‡ administer vaccine booster and recheck titer in 1–2 mo

Note: Ideally, HBIG and first vaccination should be initiated within 24 hours of exposure. Persons who have previously been infected with hepatitis B virus are immune to reinfection and do not require postexposure prophylaxis.

Abbreviations: HB = hepatitis B; HBIG = hepatitis B immunoglobulin; HBsAg = hepatitis B surface antigen.

*Dose is 0.06 mL/kg IM.

†A responder is a person with adequate levels of serum antibody to HBsAg (i.e., anti-HBs ≥10 mIU/mL).

‡A nonresponder is a person with inadequate response to vaccination (i.e., serum anti-HBs <10 mIU/mL).

#The option of giving one dose of HBIG and reinitiating the vaccine series is preferred for nonresponders who have not completed a second three-dose vaccine series. For persons who previously completed a second vaccine series (≥6 doses) but failed to respond, two doses of HBIG are preferred one month apart.[15]

fAntibody to HBsAg.

If the source patient has a negative HIV antibody test, baseline testing and further follow-up of the exposed person are not normally necessary. If the source patient has a positive HIV antibody test, consider the source to be HIV positive *regardless of viral load* for the purpose of PEP and follow-up testing. Exposure to a source patient with an undetectable viral load does not eliminate the possibility of HIV transmission. If the source patient is suspected to have acute retroviral syndrome, consider the source to be HIV positive regardless of HIV test result.

PEP should be initiated as soon as possible; if later testing determines the source to be HIV negative, discontinue PEP. PEP is less effective if started more than 24 to 36 hours after exposure. The interval after which no benefit is gained is unknown, so start PEP even when the postexposure interval exceeds 36 hours.

The U.S. Public Health Service provides guidelines for PEP following occupational exposure to HIV.[14] Guidelines now recommend three (or more) tolerable antiretroviral drugs for all occupational exposures to HIV as shown in **Tables 162-7 and 162-8**. Anticipate side effects and consider preemptive prescribing of ameliorating medications to improve PEP regimen adherence.[14] Also, consult with a local expert or with the **National Clinicians' Post-Exposure Prophylaxis Hotline (PEPline at 1-888-448-7737)** for the more complex situations listed in **Table 162-9**. If a delay in obtaining expert input occurs, start postexposure therapy immediately, allowing later discontinuation based on new information or expert consultation. The optimal duration of PEP is unknown, but the Centers for Disease Control and Prevention recommends 4 weeks of treatment.[10]

Following an exposure to HIV, advise healthcare workers to be reevaluated within 72 hours to assess information about the source patient. Also, emphasize the importance of adherence to the PEP regimen for the duration of treatment. Similarly, recommend that all exposed healthcare personnel try to prevent secondary transmission, especially during the first 6 to 12 weeks after exposure, by doing the following: use condoms or exercise sexual abstinence; refrain from donating blood, plasma, organs, tissue, or semen; avoid pregnancy; and, if possible, avoid breastfeeding. Advise exposed workers to seek medical evaluation for any acute illness that occurs during the follow-up period, as this may signal the onset of acute retroviral syndrome. Follow-up testing includes HIV testing at baseline and at 6 weeks, 12 weeks, and 6 months after exposure, usually concluded 4 months after the exposure if a newer fourth-generation HIV p24 antigen-HIV antibody test is negative.

TABLE 162-7 Human Immunodeficiency Virus (HIV) Postexposure Prophylaxis (PEP) Regimens

Preferred HIV PEP Regimen	
Raltegravir (400 milligrams twice daily) ***plus*** Truvada® (tenofovir DF 300 milligrams + emtricitabine 200 milligrams once daily)	
Alternative Regimens	
May combine 1 drug or drug pair from the left column with 1 drug or drug pair from the right column. Prescribers unfamiliar with these agents/regimens should consult with a physician familiar with these agents and their toxicities.	
Raltegravir	Tenofovir DF + emtricitabine (Truvada®)
Darunavir + ritonavir	Tenofovir DF + lamivudine
Etravirine	Zidovudine + lamivudine (Combivir®)
Rilpivirine	Zidovudine + emtricitabine
Atazanavir + ritonavir	
Lopinavir/ritonavir (Kaletra®)	
The following alternative is a complete fixed-dose combination regimen	
Elvitegravir, cobicistat, tenofovir DF + emtricitabine (Stribild®)	
Other alternative antiretroviral regimens should be used for PEP only with expert consultation.	

TABLE 162-8 Drugs Commonly Used for Human Immunodeficiency Virus Postexposure Prophylaxis (PEP)

Drug (Trade Name; Abbreviation)	Dosage	Advantages/Disadvantages
Atazanavir (Reyataz®; ATV)	ATV 300 milligrams + RTV 100 milligrams once daily (preferred dosing for PEP) ATV 400 milligrams once daily without RTV	Well tolerated Jaundice (indirect hyperbilirubinemia), rash, nephrolithiasis, drug interactions, PR prolongation, absorption depends on low pH, must be given with food
Darunavir (Prezista®; DRV)	DRV 800 milligrams + RTV 100 milligrams once daily (preferred dosing for PEP) DRV 600 milligrams + RTV 100 milligrams twice daily	Well tolerated Rash (sulfonamide moiety), diarrhea, nausea, headache, hepatotoxicity, drug interactions, must be given with food and with RTV
Emtricitabine (Emtriva®; FTC)	200 milligrams daily Also component of fixed-dose combinations: Complera®, Stribild®, Truvada®	Well tolerated, minimal toxicity Skin discoloration, withdrawal may cause acute hepatitis exacerbation in the setting of chronic hepatitis B
Lamivudine (Epivir®; 3TC)	3TC: 300 milligrams twice daily (preferred dosing for PEP) Also component of fixed-dose combinations: generic combination lamivudine/zidovudine, Combivir®, Epzicom®, Trizivir®	Well tolerated, minimal toxicity Withdrawal may cause acute hepatitis exacerbation in the setting of chronic hepatitis B
Lopinavir/ritonavir (Kaletra®; LPV/RTV)	LPV/RTV: 400/100 milligrams = 2 tablets twice daily (preferred dosing for PEP) LPV/RTV: 800/200 milligrams = 4 tablets once daily (alternative dosing)	GI intolerance, nausea, vomiting, and diarrhea are common PR and QT prolongation reported Potential for serious or life-threatening drug interactions
Raltegravir (Isentress®; RAL)	400 milligrams twice	Well tolerated, minimal toxicity Insomnia, nausea, fatigue, headache, severe skin and hypersensitivity reactions
Rilpivirine (Endurant®; RPV)	25 milligrams once daily Also component of fixed-dose combination: Complera®	Well tolerated Depression, insomnia, rash, hypersensitivity, headache Potential for serious or life-threatening drug interactions Caution with H_2 blockers, antacids Coadministration with proton pump inhibitors is contraindicated May increase risk for torsade de pointes Must be given with food
Tenofovir DF (Viread®, TDF)	300 milligrams once daily Also component of fixed-dose combinations: Atripla®, Complera®, Stribild®, Truvada®	Well tolerated Asthenia, headache, diarrhea, nausea, vomiting Nephrotoxicity; should not be administered to individuals with acute or chronic kidney injury, or estimated glomerular filtration rate <60 Withdrawal may cause acute hepatitis exacerbation in the setting of chronic hepatitis B
Zidovudine (Retrovir®; ZDV, AZT)	300 milligrams twice daily Also component of fixed-dose combinations: generic lamivudine/zidovudine, Combivir®, Trizivir®	Side effects common and may impact adherence: nausea, vomiting, headache, insomnia, fatigue Anemia, neutropenia

TABLE 162-9 Situations for Which Expert Consultation for Human Immunodeficiency Virus (HIV) Postexposure Prophylaxis (PEP) Is Recommended

Delayed exposure report (>72 h after exposure)

Unknown source (e.g., needle in a sharps disposal container or laundry)

- Decide PEP case by case based on epidemiologic likelihood of HIV exposure.
- Do not test needles or instruments.

Known or suspected pregnancy or breastfeeding in the exposed person

- Provision of PEP should not be delayed awaiting expert consultation.

Toxicity of the initial PEP regimen

- Symptoms are often manageable without changing regimen by prescribing antimotility or antiemetic agents. Counseling and support are encouraged because anxiety may worsen side effects.

Serious medical illness in the exposed person

- Significant underlying illness (e.g., renal disease) or an exposed provider already taking multiple medications may increase the risk of toxicity and drug interactions.

Expert consultation can be made with local experts or by calling the National Clinicians' Post-Exposure Prophylaxis hotline at 1-888-448-7737.

OTHER COMMON OCCUPATIONAL EXPOSURES

Other infectious diseases require special precautions, preventative measures, and postexposure care in order to minimize the risk of occupational exposure. Common sources of other occupational exposures are listed in **Table 162-10**. Maintain high suspicion for disease in populations at risk, and institute isolation precautions promptly when disease is considered.

INFECTION PRECAUTIONS

The Centers for Disease Control and Prevention's Hospital Infection Control Practices Advisory Committee promulgates two tiers of precautions: standard and transmission based. Standard precautions assume a broad approach to healthcare personnel and patient protection by including agents transmitted by routes other than blood. Transmission-based precautions are designed for patients with documented or suspected transmissible pathogens for which additional protection beyond standard precautions is required. Transmission-based precautions are of three types: airborne, droplet, and contact. Transmission-based precautions are to be used in addition to, not in place of, standard precautions.[2-4]

TABLE 162-10 Other Common Occupational Exposures

Disease	Infective Material	Infection Control and PPE*	Vaccine Availability and Efficacy	Employee Vaccination and Testing	Post Exposure Management
Tuberculosis	Aerosolized bacilli and respiratory secretions	Airborne precautions	Yes (BCG) Limited efficacy Widely used outside U.S. Not recommended in U.S.	Vaccine not recommended in U.S. Routine testing (PPD) for those in high-risk areas every 6–12 months	Approximately 20% of exposed people become infected. CDC recommended prophylactic treatment after exposure, but research does not support that practice.[17]
Measles (rubeola)	Respiratory secretions and droplet nuclei	Airborne precautions	Yes Highly effective Monovalent or combination	Primary immunization recommended 2 doses >4 weeks apart	Previously unvaccinated individuals: Vaccine may prevent disease if given within 72 hours of exposure. IG conveys temporary immunity and may prevent or modify disease if given within 6 days of exposure.[18,19]
Mumps	Respiratory secretions	Droplet precautions	Yes Highly effective Monovalent or combination	Primary immunization recommended 2 doses >4 weeks apart	Previously unvaccinated individuals: Vaccine is unlikely to prevent disease but is not harmful and may protect in case of future exposure. IG is not effective and not recommended.[18]
Rubella	Respiratory secretions and contact	Droplet and contact precautions	Yes Highly effective Monovalent or combination	Primary immunization recommended 2 doses >4 weeks apart	Previously unvaccinated individuals: Vaccine is unlikely to prevent disease but is not harmful and may protect in case of future exposure. IG is not effective and not recommended.[18]
Varicella zoster (herpes zoster, chickenpox, shingles)	Respiratory secretions and aerosols from vesicular fluid	Airborne and contact precautions†	Yes Highly effective	Immunization (or evidence of immunity) recommended[20,21]	Previously unvaccinated individuals: Vaccine may prevent infection. VZIG conveys temporary immunity and may prevent or modify disease if given within 4 days. Employee should be on furlough from day 10–21 following exposure.[20]
Influenza	Respiratory secretions	Droplet precautions Recommend exclusion or reassignment of employees who are ill with fever and respiratory symptoms	Yes Efficacy varies annually	Annual immunization recommended[22,23]	Individuals not vaccinated within the past year: Vaccine will not prevent disease but is not harmful and may protect in case of future exposure. Consider oseltamivir or zanamivir for chemoprophylaxis in higher risk employees who experience a significant influenza exposure.[24]
Meningococcus	Respiratory secretions	Droplet precautions	Yes Not recommended without specific indication[25]	None recommended	Chemoprophylaxis should be reserved for individuals who performed mouth-to-mouth, intubated, or suctioned the patient without a mask in the setting of confirmed meningococcus.[26,27] Rifampin 10 milligrams/kg (max 600 milligrams/dose) every 12 hours for 2 days Ceftriaxone 250 milligrams in single dose Ciprofloxacin 500 milligrams in single dose
Severe acute respiratory syndrome[28]	Respiratory secretions and droplet nuclei	Airborne and contact precautions Eye shield	None available	None recommended	No disease-specific recommendations
Scabies (mites)	Direct and indirect contact	Contact precautions	None	None available	No disease-specific recommendations
Pediculosis (lice)	Direct and indirect contact	Contact precautions	None	None available	No disease-specific recommendations

Abbreviations: BCG = bacillus Calmette-Guérin; CDC = Centers for Disease Control and Prevention; IG = immunoglobulin; PPD = purified protein derivative; PPE = personal protective equipment; VZIG = varicella zoster immunoglobulin.

*Standard precaution should always be applied in addition to other recommended precautions.

†If all skin lesions can be covered completely, then contact precautions alone are acceptable.

STANDARD PRECAUTIONS

Standard precautions are exercised when caring for *all* patients and include hand washing/sanitization, gloves, mask and eye protection or face shield, gowns, handling of patient care equipment and linens, environmental controls, workplace controls, and patient location or placement depending on the indication.

Hand Washing Hand washing is required after touching blood, body fluids, secretions, excretions, and contaminated items *even if gloves are worn*. Wash hands immediately after gloves are removed, between patient contacts, and when otherwise indicated to avoid the transfer of organisms to other patients or environments. It may be necessary to wash hands between procedures on the same patient to prevent cross-contamination of different body sites. *Plain soap and water are recommended for routine use*. Washing with an antimicrobial agent or waterless antiseptic may be done for control of outbreaks or hyperendemic infections, but some pathogens, such as *Clostridium difficile*,[29] are not eradicated by alcohol-based antiseptics.

Gloves Use clean, nonsterile gloves when touching blood, body fluids, secretions, excretions, and contaminated items. Change gloves between tasks and procedures involving blood or other potentially infectious materials. Remove gloves and wash hands before touching noncontaminated items or environmental surfaces (e.g., phones, light switches, writing implements) or other patients.

Masks and Shields Facemasks, eye protection, and face shields that are fluid resistant are worn to protect mucous membranes of the eyes, nose, and mouth during patient care activities and procedures likely to generate splashes or sprays of blood, body fluids, secretions, excretions, and infectious materials. Replace masks that are soiled, moistened by the user's exhaled vapor, or contaminated by fluids as soon as possible. Protective function may be lost when the barrier device is completely saturated.

Gowns Clean, nonsterile gowns that are fluid resistant protect the worker's skin and clothing during patient care activities and procedures likely to generate splashes or sprays of blood, body fluids, secretions, and excretions. Replace soiled gowns as soon as possible because barrier protection is lost if the garment is saturated with contamination. Use sleeve protectors, booties, and leggings if exposure to a large volume of contamination or infectious material is anticipated.

Disposal Handle patient care equipment and linens soiled with blood, body fluids, secretions, and excretions specifically to avoid skin and mucous membrane exposure, contamination of clothing, and transfer of microorganisms to other patients and environments. Reusable items should be cleaned and reprocessed to eliminate infectivity. Promptly discard single-use items.

ENVIRONMENTAL AND WORK PRACTICE CONTROLS

Environmental controls include hospital procedures for the decontamination of objects in patient care areas. Clean and disinfect environmental surfaces, beds, bed rails, bedside equipment, and frequently touched surfaces between patient uses.

Workplace controls (work practice controls) include proper disposal of needles, scalpels, and other sharp instruments. Avoid recapping, excessive handling, and manipulation of sharp devices. Use self-sheathing devices and puncture-resistant containers, and replace sharps containers before they overflow. Patients who contaminate the environment or those who cannot assist in their own hygiene should be located in a private room if available.

AIRBORNE PRECAUTIONS

In addition to standard precautions, use airborne precautions for patients known or suspected of being infected with microorganisms transmitted by airborne droplet nuclei. Airborne precautions also apply to small-particle (<5 μm) residue of evaporated droplets containing microorganisms that remain suspended in the air and can be widely dispersed by air currents. Examples of infectious agents spread by this method are found in **Table 162-11**.[2]

TABLE 162-11 Airborne-Spread Infectious Diseases

Rubeola (measles)
Varicella (including disseminated zoster)
Tuberculosis

ISOLATION

Isolate ED patients requiring airborne precautions in an **airborne infection isolation room** with (1) monitored negative air pressure in relation to surrounding areas, (2) 6 to 12 air changes per hour, and (3) discharge of the room air to the outdoors or high-efficiency filtration of the air before it is circulated to other areas in the hospital. The patient must remain in the isolation room with the door closed. Limit the movement in and out of the room and transportation of the patient. When movement is unavoidable, the patient should wear respiratory protection to avoid contamination of other areas within the hospital. Healthcare workers entering the room must wear respiratory protection, such as a personalized, fitted mask with efficient filters (approved particulate respirator).

DROPLET PRECAUTIONS

In addition to standard precautions, use droplet precautions for patients known to have or suspected of having serious illnesses transmitted by large particle droplets (>5 μm). Droplets are generated during talking, sneezing, or coughing and during the performance of procedures. Examples of infectious agents spread by this method are listed in **Table 162-12**.[2,4]

ISOLATION AND FACE MASKS

Place the patient in a private room when possible. Prioritize patients with excessive cough and sputum production to available single-patient rooms. Special air handling and ventilation are not required, and the door may remain open. If a private room is not available, the patient may be placed in a room with other patients who have active infections with the same microorganism (i.e., cohorting). If cohorting is also not possible, place a mask on the patient and maintain a spatial separation of at least 3 ft (1 m) between the infected patient and other patients and visitors. Avoid placing patients with droplet precautions in the same room with patients at increased risk for adverse outcomes from infection. Limit the movement and transportation of patients with droplet precautions. When movement is required, place a face mask on the patient. Healthcare workers should wear face masks when working within 3 ft (1 m) of the patient. Healthcare workers should wear respiratory protection equivalent to a fitted N95 filtering respirator or higher level of protection during aerosol-generating procedures such as suctioning. Change protective attire and perform hand hygiene between contacts with all patients.

TABLE 162-12 Droplet-Spread Infectious Diseases

Invasive *Haemophilus influenzae* type B (including meningitis, pneumonia, epiglottitis, sepsis)
Invasive *Neisseria meningitidis* (including meningitis, pneumonia, sepsis)
Serious bacterial respiratory infections
Diphtheria (pharyngeal)
Mycoplasma pneumonia
Pertussis
Pneumonic plague
Streptococcal pharyngitis, pneumonia, scarlet fever
Serious viral infections
Adenovirus
Influenza (including H1N1)
Mumps
Parvovirus B19
Rubella

TABLE 162-13 Contact-Spread Infectious Diseases

Multidrug-resistant infections or colonization (GI, respiratory, skin, wound sites)
Enteric infections with low infective dose or prolonged environmental survival
Clostridium difficile
Enterohemorrhagic *Escherichia coli* O157:H7
Shigella
Hepatitis A
Rotavirus
Respiratory syncytial virus
Parainfluenza virus
Enteroviral infections
Skin infections that are highly contagious or that may occur on dry skin:
Diphtheria (cutaneous)
Herpes simplex virus (neonatal or mucocutaneous)
Impetigo
Major, noncontained abscesses, cellulitis, decubiti
Pediculosis
Scabies
Staphylococcal furunculosis
Herpes zoster (disseminated or in an immunocompromised host)
Viral hemorrhagic conjunctivitis
Viral hemorrhagic infections (Ebola, Lassa, Marburg, Crimean-Congo hemorrhagic fever)

CONTACT PRECAUTIONS

In addition to standard precautions, use contact precautions when patients are known to have or suspected of having serious illnesses transmitted by direct patient contact or contact with items in the patient's environment. Examples of such infectious diseases are shown in **Table 162-13**.[2,4]

Change gloves whenever the examination and care of a patient result in contact with infectious materials and a high concentration of microorganisms (wound drainage or fecal material). When expecting contact with infectious materials (incontinence, dressing changes, attention to colostomy), wear a clean, nonsterile gown and gloves. Remove the gown and gloves before leaving the care area. Wash hands with an antimicrobial agent or waterless antiseptic after removal of gloves, and avoid contact with potentially contaminated environmental surfaces or items in the room after hand washing.

Limit transportation and movement of the patient. When movement is required, cover contaminated areas with large, bulky dressings. Bulky, adsorbent, leakproof dressings contain contaminated secretions and limit spread of disease.

Durable, multiuse medical equipment (e.g., blood pressure cuffs, stethoscopes, bedside commodes) should be dedicated to a single patient (or cohort of similarly infected patients). Personnel who use personal medical equipment (e.g., stethoscopes) should thoroughly clean these items between patient contacts to avoid contamination.

LATEX ALLERGY

Rubber latex is a manufactured polymer that exhibits excellent tensile strength, elasticity, and barrier capacity.[30] Rubber latex is in many medical products, including gloves (for surgery, examination, and housekeeping and cleaning), intravascular devices (balloon catheters, IV tubing, and ports), airway devices (nasopharyngeal airways, endotracheal tubes, and oxygen masks), tourniquets, blood pressure cuffs, ECG leads, tape, and dressings.

REACTIONS TO LATEX

Immune reactions to latex products may take three forms: irritant, contact dermatitis (type IV), and immunoglobulin E (type I).

Irritant reactions are nonimmune in nature and result in dry dermal erythema limited to the site of contact.

Contact dermatitis occurs as a result of dermal exposure to chemicals used in the manufacturing of latex products. Thirams and thiazoles are the most common chemicals to induce this type IV response. This reaction, which may extend beyond the site of contact, results in a dry dermal erythema, pruritus, weeping, and vesiculation. Such loss of skin integrity permits the access of latex proteins to the immune system and may result in an immunoglobulin E–mediated response.

An immunoglobulin E (type I) response is an immunologic reaction to protein allergens contained in latex. Clinical manifestations of such reactions include urticaria, asthma, rhinitis, angioedema, laryngeal edema, and anaphylaxis. Immunoglobulin E reactions may occur as a result of mucosal, dermal, contact, or inhalational exposure. Cornstarch powder, which serves as a lubricant to ease the donning of latex gloves, binds and aerosolizes protein allergens, leading to inhalation exposure.

At highest risk of developing immunoglobulin E–mediated latex allergy are those with high exposure to latex and who are atopic. Workers in industries that make rubber products (e.g., tire manufacturers and doll makers) and those who use rubber products (e.g., housekeepers, hairdressers, and healthcare workers) are at high risk of developing this allergy. Although anyone can develop latex allergy, those at higher risk have a history of multiple allergies, asthma, eczema, multiple food allergies, frequent surgical or dental procedures, spina bifida and related conditions of spinal dysraphism, urogenital anomalies, or sensitivity to ethylene oxide (a sterilizing agent).

LATEX-FREE PRODUCTS AND MINIMIZING LATEX ALLERGY

Many latex-free medical products exist on the market and may be substituted for currently used products. Prevention of disease in healthcare workers is critical and requires the use of synthetic or low-allergen powder-free gloves.[30,31] To protect themselves from latex exposure and allergy in the workplace, healthcare personnel may also use nonlatex gloves for workplace activities that do not involve contact with infectious materials, use synthetic or low-allergen powder-free gloves when handling infectious materials, avoid oil-based hand lotions or creams when wearing latex gloves (to prevent glove deterioration), wash hands with mild soap and dry thoroughly upon removal of latex gloves, frequently clean work areas and equipment contaminated with latex-containing dust, obtain education and training regarding latex allergy, and recognize the symptoms of latex allergy. Hypoallergenic latex gloves do not reduce the risk of latex allergy but do reduce reactions to chemical additives in latex.

RESOURCES FOR POSTEXPOSURE PROPHYLAXIS

The National Clinicians' Post-Exposure Prophylaxis Hotline offers 24-hour telephone consultation for physicians managing occupational exposures to bloodborne pathogens (888-448-7737, http://www.nccc.ucsf.edu). The Hepatitis Hotline provides guidance to clinicians with regard to the acute and chronic management of hepatitis (1-888-443-7232, http://www.cdc.gov/hepatitis).

Acknowledgments: The author thanks David M. Cline and Kathy J. Rinnert, the authors of this chapter in the previous edition of this book.

CHAPTER 163

Pharmacology of Antimicrobials

Ralph H. Raasch

ANTIBACTERIAL DRUGS

Effective antibacterial drugs can either inhibit the growth of (bacteriostatic) or kill (bactericidal) bacteria. Antibacterial effects result from the inhibition of cell wall synthesis, inhibition of intrabacterial protein synthesis, alteration in nucleic acid metabolism, or intrabacterial enzyme inhibition (**Table 163-1**). The drug mechanism of action does not necessarily correlate with bacteriostatic or bactericidal effects, because the latter are affected also by the concentration of antibiotic to which bacteria are exposed. Drugs of choice for most infections are not based on a bacteriostatic or bactericidal effect of an agent, but rather are chosen based on whether the drug reaches the site of infection in adequate quantities, the spectrum of the agent, its safety, and cost.

MECHANISMS OF ACTION

CELL WALL ACTIVE AGENTS

β-Lactam (penicillins, cephalosporins) and glycopeptide antibiotics (vancomycin, telavancin, teicoplanin) bind to receptors in the bacterial cell wall. The target receptors for penicillins and cephalosporins are called *penicillin-binding proteins*. Autolytic enzymes within the cell wall bind to penicillin-binding proteins; once activated, the enzymes damage the peptidoglycan component of the cell wall, creating weakening and eventual cell lysis. Glycopeptide antibiotics bind to a terminal dipeptide (alanine-alanine) in the cell wall peptidoglycan and prevent the necessary cross-linking for a competent cell wall structure. At usual doses, β-lactam and glycopeptide antibiotics are bactericidal. Resistance arises due to mutations in the penicillin-binding proteins, leading to reduced β-lactam binding (e.g., by oxacillin-resistant *Staphylococcus aureus* or penicillin-resistant *Streptococcus pneumoniae*) or changes to the terminal dipeptide (e.g., by vancomycin-resistant *Enterococcus faecium*) that reduce the level of binding. Daptomycin inserts a lipophilic part of the molecule into the cell wall of gram-positive bacteria, depolarizing the cell wall, which causes the leakage of intracellular content and a bactericidal effect.

The emergence of multidrug-resistant organisms (most commonly in species of *Pseudomonas, Acinetobacter,* and *Klebsiella*) has led to the renewed use of older, but more toxic drugs such as colistin and polymyxin B. These agents interact with the lipids within the cell wall, increasing cell wall permeability, which leads to a bactericidal effect because of the leakage of intracellular contents.

TABLE 163-1 Mechanisms of Action of Antibacterial Drugs

Cell wall active agents	*Nucleic acid inhibitors*
Penicillins	Fluoroquinolones
Vancomycin	Rifampin
Cephalosporins	Nitrofurantoin
Teicoplanin	***Enzyme inhibitors***
Telavancin	Fosfomycin
Daptomycin	Sulfonamides
Colistin	Trimethoprim
Polymyxin B	
Protein synthesis inhibitors	
Aminoglycosides	
Macrolides	
Linezolid	
Tetracyclines (including tigecycline)	
Clindamycin	
Quinupristin/dalfopristin	

PROTEIN SYNTHESIS INHIBITORS

Several classes of antibacterial drugs bind to ribosomes within bacteria, blocking necessary protein synthesis. Aminoglycosides and tetracyclines (including tigecycline) bind to the 30S ribosomal subunit, whereas macrolide antibiotics and clindamycin bind to the 50S subunit. Ribosomal binding inhibits transfer RNA function, decreasing the amount of protein synthesis. Ribosomal-binding drugs enter through the cell wall and bind in adequate concentrations to reversibly inhibit protein synthesis. Resistance mechanisms arise with reduced cell wall permeability, an active efflux pump that removes the antibiotic from the cell, or ribosomal-binding site mutations that decrease antibiotic affinity.

NUCLEIC ACID INHIBITORS

Fluoroquinolone antibiotics inhibit DNA gyrase, the enzyme responsible for DNA unwinding for transcription and recoiling during bacterial replication. Fluoroquinolones must reach the nucleus of the bacterial cell to provoke these effects; resistance can arise when cell wall permeability is reduced, active efflux occurs, or a DNA gyrase mutation has arisen that reduces fluoroquinolone binding. Rifampin is a broad-spectrum antimicrobial agent active against many gram-positive and gram-negative bacteria and mycobacteria. Rifampin (or rifampicin) inhibits RNA synthesis by binding to DNA-dependent RNA polymerase, thereby blocking the initiation of RNA chain formation. Nitrofurantoin is modified by bacterial metabolism to a compound that damages DNA. Susceptible bacteria rarely become resistant to nitrofurantoin.

ENZYME INHIBITORS

Sulfonamides and trimethoprim block sequential steps in the formation of folic acid. Sulfonamides inhibit dihydropteroate synthase, the enzyme that converts *p*-aminobenzoic acid to dihydrofolic acid; trimethoprim inhibits dihydrofolate reductase, the enzyme that converts dihydrofolic to tetrahydrofolic acid. Together, this paired action is an effective bactericidal process and not far removed from the intracellular actions of methotrexate. Fosfomycin inactivates enolpyruvate transferase, inhibiting cell wall synthesis; it is gaining resurgent popularity for single-dose treatment (3 grams orally) of uncomplicated urinary tract infections given the activity against the common pathogens involved. Resistance to these drugs arises by enzyme mutations that reduce the affinity of sulfonamide, trimethoprim, or fosfomycin to their respective enzyme targets.[1] These antibacterial drug mechanisms of action are summarized in **Figure 163-1**. **Table 163-2** summarizes the classification, names, and routes of the most common antibiotics within each antibiotic class.[1]

INDICATIONS IN THE ED AND DRUGS OF CHOICE

Drugs of choice for specific infections are based on clinical effectiveness and adverse events. Successful effectiveness is based on the knowledge of the likely bacterial pathogen responsible for a specific infection type and the usual antimicrobial spectrum of antibiotics. Alternate drugs of choice are selected in cases of resistance to an initial drug, a history of intolerance or allergy to the drug of choice, or because of a higher risk of adverse events. Taking into account those infections most likely to be present in ED patients and the most likely pathogens involved in these infections, **Table 163-3** summarizes drugs of choice for common infections.[2]

ANTIBIOTIC DOSAGE AND DOSAGE ADJUSTMENTS

Adequate drug dosage takes into account achievable serum and tissue levels plus the concentrations necessary (determined in the laboratory) to inhibit the growth of susceptible bacteria. Standard dosing guidelines usually result in successful treatment when a susceptible organism is present and barriers to drug penetration (i.e., abscess) are absent. If antibiotic penetration issues exist, such as in suspected meningitis,

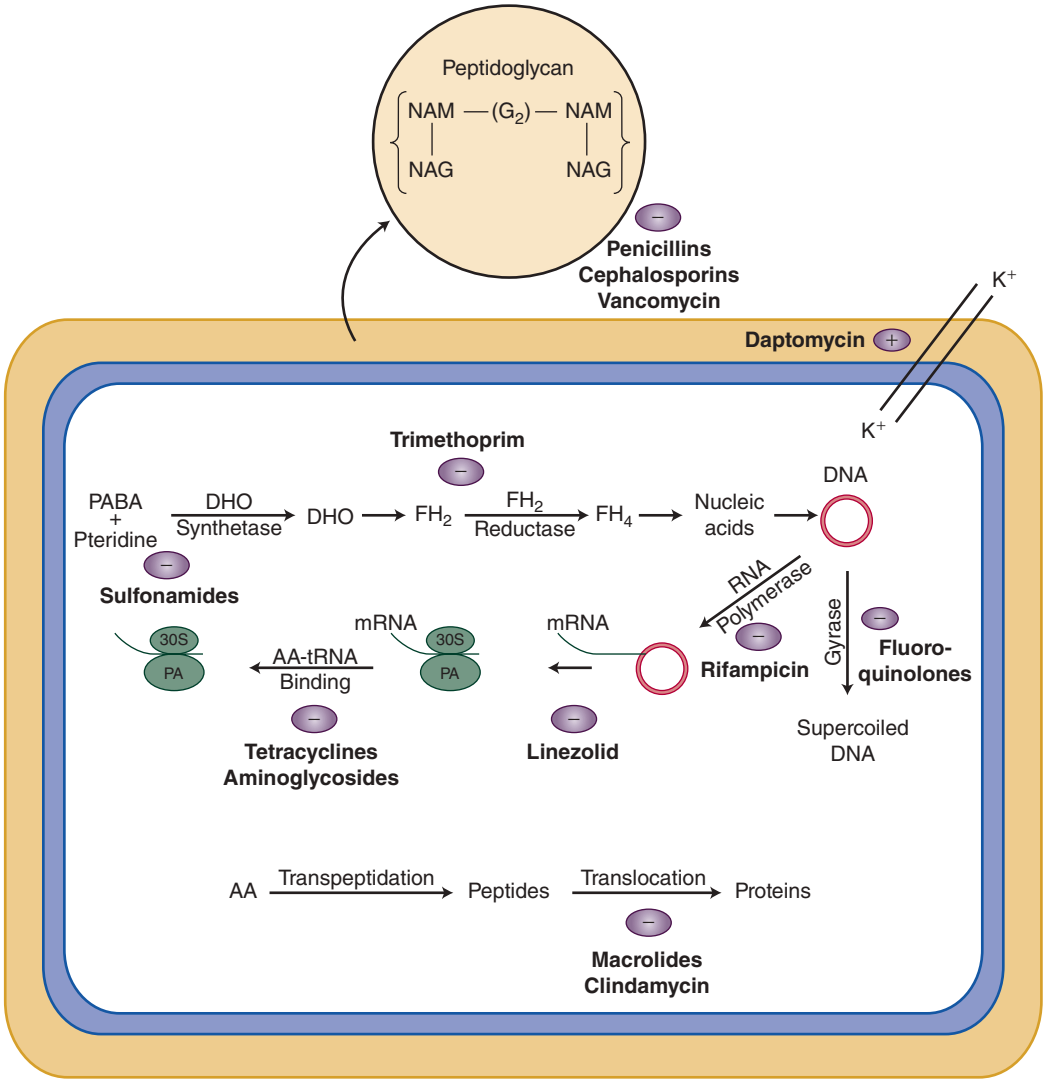

FIGURE 163-1. Mechanisms of action of antibacterial drugs. The peptidoglycan layer in the bacterial cell wall is a crystal lattice structure formed from linear chains of two alternating amino sugars, namely *N*-acetylglucosamine (GlcNAc or NAG) and *N*-acetylmuramic acid (MurNAc or NAM). Penicillins, cephalosporins, and vancomycin are cell wall active agents, preventing the necessary cross-linking within the peptidoglycan layer, rendering it incompetent. Other listed antibiotics exert their actions on cellular mechanisms within the bacteria as shown. AA = amino acids; DHO = dihydropteroate; FH_2 = dihydrofolate, FH_4 = tetrahydrofolate; (G_2) = glucose; K^+ = potassium; PA = peptide donor-acceptor site; PABA = *p*-aminobenzoic acid; + = enhance; – = inhibit.

endocarditis, or osteomyelitis, give the highest doses recommended to improve effect.

Dosage adjustments of many antibiotics are necessary for patients with renal disease to prevent adverse events from drug accumulation, most notably when using IV administration. Oral doses are typically lower, so toxic drug accumulation is less likely in those with renal dysfunction. Dosage modifications in liver disease are less clear because of limited ways to accurately assess decreases in drug elimination characteristics or rate. Fosfomycin in single-dose use for urinary tract infection requires no adjustment. Guidelines for dosing adjustment, primarily with IV therapy, are summarized in **Table 163-4**.[3]

ADVERSE EFFECTS AND CONTRAINDICATIONS OF ANTIBACTERIAL DRUGS

Allergic reactions and direct pharmacologic-based toxicity are the two general categories of adverse drug reactions to antibiotics.

Allergic reactions are not dose related, are unpredictable, and cannot be studied effectively in animal models. Allergic reactions vary from mild skin rashes to life-threatening events, such as toxic epidermal necrolysis or anaphylactic reactions. Drug fever, hepatitis, and interstitial nephritis are also examples of allergic drug reactions.

Direct dose-related toxicity is the result of the pharmacologic properties of the drug. These reactions are possible in any recipient if the dose or accumulated drug in the body is high. Dose-related adverse events typically are reversible once the antibiotic is discontinued. There is some predictability to these reactions, such as renal dysfunction caused by an aminoglycoside; these drugs are ideal candidates for appropriate dose adjustments of antibiotics (Table 163-4).

Certain adverse effects of antibiotics, such as pseudomembranous colitis, do not fall into either category; all antibiotics can cause this side effect. The common allergic and dose-related adverse effects of antibacterial drugs are summarized in **Table 163-5**.[3]

CONTRAINDICATIONS AND DRUG INTERACTIONS

DRUG ALLERGY

In general, previous allergy is a contraindication for use. This circumstance is most pertinent for patients with a penicillin or cephalosporin allergy; between 1% and 10% of patients report a penicillin allergy. Some agents exhibit cross-reactivity; those with penicillin or amoxicillin allergy have a higher risk of the same with oral first-generation cephalosporins, likely due to similarities in antibiotic side chain

TABLE 163-2 Classification of Antibacterial Drugs with Common Trade Names

Penicillins

Natural Penicillins	Aminopenicillins	Penicillinase-Resistant Penicillins	Antipseudomonal Penicillins	β-Lactam / β-Lactamase Inhibitor Combination	Monobactams and Carbapenems	Aminoglycosides	Fluoroquinolones
Penicillin G IV, PO	Ampicillin IV, PO	Oxacillin (Bactocill®) IV, PO	Piperacillin IV	Amoxicillin-clavulanic acid (Augmentin®) PO	Aztreonam (Azactam®) IV	Amikacin IV	Moxifloxacin (Avelox®) IV, PO
Penicillin V PO	Amoxicillin (Amoxcil®) PO	Dicloxacillin PO		Ticarcillin-clavulanic acid (Timentin®) IV	Ertapenem (Invanz®) IV	Gentamicin IV	Ciprofloxacin (Cipro®) IV, PO
		Nafcillin (Nallpen®) IV, PO		Ampicillin-sulbactam (Unasyn®) IV	Meropenem (Merrem®) IV	Neomycin (Neo-Fradin®) PO	Levofloxacin (Levaquin®) IV, PO
				Piperacillin-tazobactam (Zosyn®) IV	Imipenem (Primaxin®) IV	Streptomycin IM, IV	Gemifloxacin (Factive®) PO
					Doripenem (Doribax®) IV	Tobramycin IV	

Cephalosporins

First Generation	Second Generation	Third Generation	Fourth/Fifth Generation	Macrolides/Tetracyclines	Enzyme Inhibitors	Miscellaneous
Cefazolin (Ancef®) IV	Cefaclor PO Cefotetan IV	Ceftibuten (Cedax®) PO	Cefepime (Maxipime®) IV	Erythromycin (Erythrocin®) IV, PO	Trimethoprim-sulfamethoxazole (Bactrim®, Septra®) IV, PO	Clindamycin (Cleocin®) IV, PO
Cefadroxil PO	Cefuroxime axetil (Ceftin®) PO	Cefotaxime (Claforan®) IV	Ceftaroline (Teflaro®) IV	Azithromycin (Zithromax®) IV, PO	Trimethoprim PO	Metronidazole (Flagyl®) IV, PO
Cephalexin (Keflex®) PO	Cefprozil PO Cefoxitin (Mefoxin®) IV	Ceftazidime (Fortaz®, Ceptaz®, Tazicef®) IV		Clarithromycin (Biaxin®) PO	Fosfomycin (Monurol®) PO	Nitrofurantoin (Macrodantin®, Macrobid®) PO
	Cefuroxime (Zinacef®) IV	Ceftriaxone (Rocephin®) IV		Tetracycline PO		Quinupristin/dalfopristin (Synercid®) IV
		Cefpodoxime PO		Minocycline (Minocin®) PO		Vancomycin (Vancocin®) IV, PO

		Cefixime (Suprax®) PO		Tigecycline (Tygacil®) IV		Daptomycin (Cubicin®) IV

structure, with about a 10% cross-reactivity occurrence. However, true allergies, as documented by antibiotic skin tests, are less common than often stated, so obtaining a clear description is important before choosing alternate therapy. For example, a patient with a history of respiratory distress, wheezing, angioedema, or hives (an immediate-type hypersensitivity) during a previous course of β-lactam treatment may be at higher risk for a life-threatening reaction upon re-exposure to another β-lactam, particularly if the patient reacts to skin tests with the other β-lactam. Unfortunately, with the exception of penicillin, these antibiotic skin tests are not commercially available and not used in clinical practice. So in this case, it would be wise to avoid a penicillin or first-generation cephalosporin, although a carbapenem or third-generation cephalosporin would have little cross-reactivity. On the other hand, if the patient history is a mild maculopapular rash while taking amoxicillin or other penicillin (a delayed-type hypersensitivity reaction), treatment later with a cephalosporin would not likely provoke an allergic event. Similarly, a fainting spell with injection may not represent a drug allergy at all, although it clearly was an adverse event for that treatment interval. Note that sulfa moieties are contained in many other drugs, such as furosemide, thiazides, sulfonylureas (glyburide), and celecoxib. Despite package labeling that suggests cross-sensitivity in a patient who is allergic to sulfonamides is a risk, the frequency of any allergic reaction upon exposure to one of the nonantibiotic sulfas is not common. A patient allergic to sulfonamides is at a higher risk to develop another allergic reaction to another drug, including penicillins.[4] Several of the human immunodeficiency virus protease inhibitor agents also contain a sulfa moiety (amprenavir, fosamprenavir, tipranavir, darunavir), but the risk of cross-reactivity in a sulfonamide-allergic patient is not well known.[4]

DRUG INTERACTIONS

Drug interactions with antibacterial drugs derive from two mechanisms. The first mechanism is an inhibition of absorption of oral antibiotics. The best example of this interaction occurs when any of the tetracycline or fluoroquinolone antibiotics are given at the same time as divalent cations (Ca^{2+}, Mg^{2+}, Fe^{2+}). This reduces absorption, so these agents must not be given orally with calcium or iron preparations or with antacids.

Second, certain antibiotics can slow the metabolism of other drugs by inhibiting several of the hepatic cytochrome P450 enzymes in the liver. In particular, ciprofloxacin, clarithromycin, and trimethoprim-sulfamethoxazole are drugs that are able to provoke this enzyme inhibition. Summaries of these antibiotic contraindications and drug interactions are included in **Tables 163-6 and 163-7**.[3]

ANTIFUNGAL DRUGS

The mechanism of action of antifungal agents is primarily based on actions that decrease cell wall integrity. Amphotericin B and its lipid-based derivatives bind to cell wall ergosterol, increasing cell wall permeability that eventually results in cell lysis. Triazole antifungals (e.g., fluconazole, itraconazole) block ergosterol synthesis by inhibition of a fungal cytochrome P450–dependent enzyme. Echinocandin antifungals (caspofungin, micafungin, and anidulafungin) are other enzyme inhibitors; in this case, the inhibition is of β-glucan synthetase. β-Glucan, like ergosterol, is another necessary component of the cell wall of several fungal species. Flucytosine is an antimetabolite that disrupts DNA function after conversion intracellularly to 5-fluorouracil. These mechanisms of action of antifungal agents are illustrated in **Figure 163-2**.

TABLE 163-3 Antibiotics of Choice for Treatment of Common Adult Infections in the ED

Site/Type of Infection	Suspected Organisms	Drug of Choice	Alternative
Respiratory			
Pharyngitis	Group A streptococci	Penicillin V	Macrolide
Bronchitis,* otitis,* acute sinusitis*	*Streptococcus pneumoniae* *Haemophilus influenzae*	Amoxicillin, amox/clav, or cefuroxime	Macrolide or doxycycline
Epiglottitis	*H. influenzae,* Group A streptococci	Ceftriaxone	Cefuroxime
Community-acquired pneumonia			
Normal host	*S. pneumoniae*, viral, *Mycoplasma*	Azithromycin or doxycycline	Levofloxacin
Aspiration	Aerobes and anaerobes	Clindamycin	Pip/TZ, ceftriaxone plus metronidazole
Alcoholic	*S. pneumoniae, Klebsiella*	Ceftriaxone	Levofloxacin
Urinary tract infection	*Escherichia coli* and other enteric gram-negative rods	TMP/SMX†	Ciprofloxacin, cephalexin, nitrofurantoin, or fosfomycin (latter single dose 3 grams PO)
Sexually transmitted infections			
Urethritis	*Neisseria gonorrhea, Chlamydia*	Ceftriaxone, azithromycin	Cefixime, doxycycline
Genital ulcers	*Treponema pallidum*, herpes simplex virus	Penicillin G Acyclovir	Doxycycline Valacyclovir
Skin/soft tissue			
Cellulitis	Group A streptococci, *Staphylococcus aureus*	Cephalexin†	Dicloxacillin, clindamycin, TMP/SMX, or vancomycin
Necrotizing fasciitis	Polymicrobial	Imipenem or meropenem Plus vancomycin	—
Fresh/brackish water infections	Mixed flora, *Aeromonas*	TMP/SMX	Fluoroquinolone
Cat bite	*Pasteurella*, mixed flora	Amox/clav	Clindamycin and ciprofloxacin
Meningitis			
Normal host	*S. pneumoniae, Neisseria meningitidis, S. aureus*	Ceftriaxone and vancomycin	—
Immunocompromised or >50 y old	*Listeria, H. influenzae*	Add ampicillin	—
Acute abdomen (perforation)	Gram-negative rods, anaerobes, enterococci	Ampicillin/sulbactam or Pip/TZ	Cefoxitin or cefotetan or imipenem

Abbreviations: amox/clav = amoxicillin/clavulanate; Pip/TZ = piperacillin/tazobactam; TMP-SMX = trimethoprim-sulfamethoxazole.

**Note:* Many authorities question the need for antibiotics for uncomplicated presentations of these diseases; see appropriate chapters in this text to determine indications for treatment.

†Resistance to the listed antibiotic is a significant clinical issue; see chapter 152, "Soft Tissue Infections" for a discussion of alternatives for treatment in the event of known resistance in your community.

These agents for systemic fungal infections are summarized in **Table 163-8**. Multiple topical antifungal preparations are available, as summarized in **Table 163-9**, and are indicated for *Candida* or tinea infections.[1,3]

Of the various lipid-based amphotericin B preparations, liposomal amphotericin B (AmBisome®) is preferred because of a lower rate of infusion-related reactions and a lower frequency of renal dysfunction compared with the other lipid products. Because amphotericin B has the broadest antifungal spectrum of all these systemic agents, it is the preferred drug for empiric therapy until further diagnostics determine the pathogen involved. All amphotericin B infusions, whether conventional (infused over 4 hours) or lipid-based (infused over 2 hours), can be preceded by acetaminophen (650 milligrams PO) and diphenhydramine (Benadryl®, 25 to 50 milligrams PO or IV) given 30 minutes prior to attenuate development of fever and rash.

In addition to infusion-related reactions, amphotericin B also causes renal dysfunction. The lipid-based products reduce but do not eliminate the risk of renal toxicity. The kidney dysfunction created includes renal tubular acidosis and renal wasting of bicarbonate, potassium, and magnesium. When using this antifungal, monitor electrolyte levels and supplement as needed. Amphotericin B may elevate blood urea nitrogen and serum creatinine, although slightly less when using lipid-based products. If this occurs, reduce the daily dose or extend the infusion intervals to every other day if the creatinine level rises to >2.5 to 3.0 milligrams/dL.

Fluconazole, itraconazole, voriconazole, posaconazole, caspofungin, and micafungin do not provoke the renal dysfunction associated with amphotericin B. Occasionally, liver function test elevations and hepatitis result from triazole therapy, so patients on prolonged courses of these drugs should have liver function tests assessed monthly.

Triazoles (particularly itraconazole) can interact with other drugs metabolized by the cytochrome P450 system. In particular, warfarin, phenytoin, cyclosporine, and tacrolimus levels routinely increase in patients on itraconazole. Fluconazole is a less potent inhibitor of cytochrome P450, so interactions are less frequent. Flucytosine can cause reversible bone marrow suppression, with leukopenia and thrombocytopenia. Dose-modification issues are relevant for fluconazole and flucytosine. For creatinine clearance <50 mL/min, reduce fluconazole to 200 milligrams daily and flucytosine to 25 to 37.5 milligrams/kg every 12 hours; for creatinine clearance <10 mL/min, reduce flucytosine to 25 to 37.5 milligrams/kg every 24 hours.[3]

The pregnancy category for the amphotericin products is category B; for the triazoles, caspofungin, and flucytosine, the category is C.

ANTIVIRAL AGENTS

Advances in antiviral agents can treat infections caused by herpes simplex virus I and II, varicella-zoster virus, cytomegalovirus, influenza A and B, human immunodeficiency virus, and hepatitis B and C. **Table 163-10** summarizes the mechanism of action of the agents and spectrum of use for these drugs outside of human immunodeficiency virus and hepatitis.[1] Human immunodeficiency virus care is discussed elsewhere in the text, including postexposure prophylaxis. Uses for the non–human immunodeficiency virus antiviral agents for patients in the ED are summarized in **Table 163-11**. **Table 163-12** summarizes the drugs available and common side effects of drugs for hepatitis B and hepatitis C; dosing is usually outside ED care and not reviewed.[1,3,5,6]

TABLE 163-4 IV Dosage Guidelines for Selected Antibacterial Drugs in Adults

Drug	Major Route of Elimination	Maximum Daily IV Dose (grams)	Dose Adjustment for Creatinine Clearance (mL/min)		
			>50	10–50	<10
Ampicillin	Renal	12	1–2 grams every 4–8 h	1 gram every 6 h	1 gram every 12 h
Ampicillin/sulbactam	Renal	12	1.5–3 grams every 6 h	1.5–3 grams every 12 h	1.5–3 grams every 24 h
Aztreonam	Renal	8	1–2 grams every 6–8 h	1–2 grams every 12 h	1 gram every 12 h
Cefazolin	Renal	8	1–2 grams every 8 h	1 gram every 12 h	1 gram every 24 h
Cefotaxime	Renal	12	1–2 grams every 4–8 h	1–2 grams every 12 h	1 gram every 12 h
Ceftazidime	Renal	6	1–2 grams every 8 h	1–2 grams every 24 h	0.5 gram every 24 h
Ceftriaxone	Biliary	4	1–2 grams every 12–24 h	No adjustments	No adjustments
Cefepime	Renal	4	1–2 grams every 12 h	1–2 grams every 24 h	0.5–1 gram every 24 h
Ciprofloxacin	Renal	1.2	0.4 gram every 8–12 h	0.4 gram every 12 h	0.4 gram every 24 h
Levofloxacin	Renal	0.75	0.25–0.75 gram every 24 h	0.25–0.75 gram every 48 h	0.25–0.5 gram every 48 h
Clindamycin	Biliary	4.8	0.6–0.9 gram every 6–8 h In hepatic failure, limit dose to 0.6 gram every 8 h	No adjustments	No adjustments
Imipenem	Renal	2	0.5 gram every 6–8 h	0.5 gram every 12 h	0.5 gram every 24 h
Meropenem	Renal	3	0.5–1 gram every 8 h	0.5 gram every 12 h	0.5 gram every 24 h
Metronidazole	Biliary	2	0.5 gram every 6–8 h In hepatic failure, limit dose to 0.5 gram every 12 h	No adjustments	No adjustments
Nafcillin, oxacillin	Biliary	12	1–2 grams every 4–6 h	No adjustments	No adjustments
Penicillin G	Renal	24 MU	3–4 MU every 4 h	2 MU every 6 h	1 MU every 6 h
Piperacillin/tazobactam	Renal	18	3.375 grams every 6 h	2.25 grams every 6 h	2.25 grams every 8 h
Tobramycin, gentamicin	Renal	7 milligrams/kg per dose	Every 24 h	Every 36–48 h	Do not use
Vancomycin	Renal	15 milligrams/kg per dose	Every 12–24 h	Every 24–48 h	Use levels

Abbreviation: MU = million units.

TABLE 163-5 Antibacterial Adverse Effects

Antibiotic Class	Pregnancy Category*,†	Allergic Reactions	Dose-Related Effects
β-Lactams (penicillins, cephalosporins, monobactams, carbapenems)	B	Anaphylaxis, urticaria, rash, fever, serum sickness; hepatitis, nephritis, anemia, thrombocytopenia Cross-reactivity between penicillins and cephalosporins is <5%; little cross-reactivity between cephalosporin and aztreonam or imipenem	Diarrhea (amoxicillin/clavulanate), biliary sludging (ceftriaxone); phlebitis; seizures (imipenem, penicillin G); antiplatelet effects and hemolytic anemia; decreased vitamin K synthesis and disulfiram reaction (cefotetan); nausea, hypotension (rapid infusion of imipenem)
Aminoglycosides	C	Rare	Nephrotoxicity: incidence 10%–15%, usually reversible Ototoxicity: incidence 1%–5%, causes deafness and/or dizziness; toxicity is both dose- and duration-related
Macrolides	B/C	Cholestatic jaundice: associated with IV erythromycin	GI toxicity: nausea, vomiting, diarrhea, cramping—mostly with erythromycin
Clindamycin	B	Rash	Diarrhea—most common adverse effect; pseudomembranous colitis
Tetracyclines, including tigecycline	D	Rash (including photosensitivity), anaphylaxis, urticaria, fever, hepatitis	Nausea, vomiting, diarrhea; increase in blood urea nitrogen; deposits in and discolors teeth and bone (avoid in pediatrics); dizziness and vertigo (minocycline)
Vancomycin	C	Rash (rare)	Infusion-related reactions: phlebitis, "red-person syndrome" from rapid infusions—give 1 gram over 60 min; oto- and nephrotoxicity with high doses, or in combination with other oto or nephrotoxins
Fluoroquinolones	C	Rare	Nausea, vomiting, diarrhea; confusion, headache, seizures; tendonitis and tendon rupture; prolonged QT interval
Sulfonamides	X	Rash, Stevens-Johnson syndrome, exfoliative dermatitis (more common in acquired immunodeficiency syndrome); cholestatic hepatitis; bone marrow suppression	Nausea, vomiting, diarrhea; crystalluria (doses taken with insufficient fluids); hyperkalemia (with trimethoprim); kernicterus (in neonates)

*U.S. Food and Drug Administration Safety-in-Pregnancy Code: A: controlled human studies show no risk. B: no evidence of risk in humans; the chance of fetal harm is remote but remains a possibility. C: risk cannot be ruled out; well-controlled human studies are lacking, and animal studies have shown risk or are lacking; there is a chance of fetal harm if administered during pregnancy. D: positive evidence of risk; studies in humans have demonstrated fetal risk. X: contraindicated in pregnancy; the risk of fetal abnormalities outweighs the potential benefit of the drug.

†LactMed is an NLM database providing information on drugs and lactation http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?LACT

TABLE 163-6 Antibiotic Contraindications

Antibiotic Class	Contraindications
Aminoglycosides	Prior allergic or toxic reactions to aminoglycosides
Cephalosporins	Sensitivity to cephalosporins, imipenem (carbapenems), penicillins
Clindamycin	Sensitivity to clindamycin; meningitis (inadequate CNS penetration)
Fluoroquinolones	Sensitivity to fluoroquinolones; tendonitis or tendon rupture; use of QT interval–prolonging drugs (amiodarone, procainamide); myasthenia gravis
Macrolides	Sensitivity to macrolides; meningitis (inadequate CNS penetration)
Metronidazole	Sensitivity to metronidazole; first trimester of pregnancy
Penicillins	Sensitivity to penicillins, cephalosporins, imipenem (carbapenems)
Sulfonamides	Sensitivity to sulfonamides, pregnancy at term, lactation
Tetracyclines	Sensitivity to tetracyclines
Vancomycin	Sensitivity to vancomycin

Abbreviation: CNS = central nervous system.

TABLE 163-7 Antibacterial Drug Interactions

Antibiotic Class	Drug Interactions
Aminoglycosides	Neuromuscular blockers—may prolong respiratory depression; loop diuretics—may increase auditory toxicity
Cephalosporins	Antacids—may reduce the oral absorption of cefaclor, cefdinir, and cefpodoxime Warfarin—cefotetan enhances the anticoagulant effect of warfarin
Fluoroquinolones	Antacids, iron salts, sucralfate—absorption of the fluoroquinolone is reduced by chelation Theophylline—metabolism is slowed by ciprofloxacin, may cause theophylline toxicity; warfarin elimination is slowed by fluoroquinolones—follow clotting times carefully
Macrolides	Clarithromycin can increase levels of warfarin, cyclosporine, lovastatin, theophylline—monitor additive effects carefully
Penicillins	Allopurinol—increased rash with ampicillin Aminoglycosides—when administered IV simultaneously, inactivation occurs Probenecid—reduced renal elimination of penicillin
Tetracyclines	Antacids, iron salts—bind to tetracycline and reduce oral absorption (occurs least with doxycycline) Oral contraceptives—failure
Trimethoprim-sulfamethoxazole	Warfarin—can prolong clotting times; phenytoin—increase in serum levels and possible toxicity
Vancomycin	Aminoglycosides—may increase risk of nephrotoxicity

Acyclovir, valacyclovir, famciclovir, and valganciclovir are oral drugs for the treatment of herpes simplex virus and cytomegalovirus infections. Of all, the absorption of acyclovir is less than others, requiring higher doses to achieve adequate blood and tissue levels to inhibit viral replication.

The development of new agents for hepatitis B and C infections has been similar to that of several of the antiretroviral drug classes. Effective drugs are analogues of nucleotides or nucleosides that result in nucleic

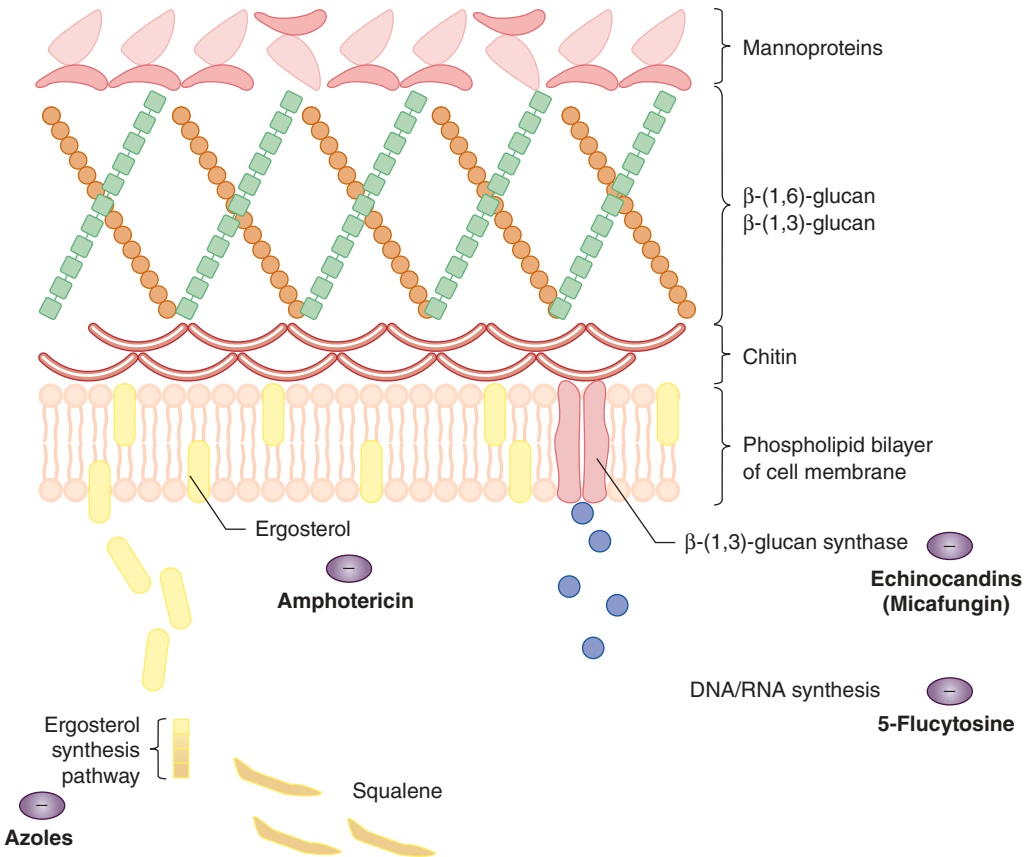

FIGURE 163-2. Mechanisms of action of antifungal agents.

TABLE 163-8 Antifungal Agents for Systemic Infections

Drug	Spectrum	Usual Doses
Amphotericin B, IV	*Aspergillus, Candida, Cryptococcus,* histoplasmosis, mucormycosis	0.5–1.0 milligram/kg/d
Conventional (Fungizone®)		5.0 milligrams/kg/d
Lipid complex (Abelcet®)		5.0 milligrams/kg/d
Liposomal (AmBisome®)		5.0 milligrams/kg/d
Colloidal dispersion (Amphotec®)		
Triazoles		
Fluconazole (Diflucan®) IV, PO	*Candida, Cryptococcus, Aspergillus* (not fluconazole), histoplasmosis, mucormycosis (posaconazole)	400–800 milligrams per day
Itraconazole (Sporanox®) IV, PO		200 milligrams twice daily
Posaconazole (Noxafil®) PO		200 milligrams three times daily with food
Voriconazole (Vfend®) IV, PO		6 milligrams/kg IV every 12 h for 2 doses, then 4 milligrams/kg IV every 12 h; 200 milligrams PO every 12 h
Echinocandins		
Anidulafungin (Eraxis®) IV	*Aspergillus, Candida* (not *Cryptococcus*)	200 milligrams × 1, then 100 milligrams every day
Caspofungin (Cancidas®) IV		70 milligrams × 1, then 50 milligrams every day
Micafungin (Mycamine®) IV		100 milligrams every day
Antimetabolite		
Flucytosine (Ancobon®), PO	*Candida, Cryptococcus* (should not be used as monotherapy)	25.0–37.5 milligrams/kg every 6 h

TABLE 163-9 Selected Topical Antifungal Agents

Class and Products	Dosage Forms	Comments
Allylamines/benzylamines		
Butenafine (Mentax®, Lotrimin® ultraTM)	1% cream, gel, solution, spray	Treatment for 1–4 wk for tinea
Naftifine (Naftin®)		
Terbinafine (Lamisil AT®)		
Imidazoles		
Clotrimazole (Lotrimin AF®, Mycelex 7®)	1% cream, lotion, 100- and 200-milligram vaginal suppositories	Topical (Candida, tinea) apply twice daily Vaginal suppository, 100 milligrams × 7 d or 500 milligrams at bedtime × 1
Miconazole (Micatin®, Monistat®)	2% cream, ointment, vaginal suppository	As above, except 200-milligram vaginal suppository × 3 d, or 500 milligrams once
Tioconazole (Vagistat-1®)	6.5% vaginal ointment	Application at bedtime × 1
Miscellaneous (for tinea only)		
Tolnaftate (Tinactin®, Ting®)	1% cream, solution, gel, powder, spray	Apply twice daily for 2–6 wk Less effective than imidazoles

TABLE 163-10 Antiviral Agents for Cytomegalovirus, Systemic Herpes, Varicella, and Influenza

HSV I and II, VZV	HSV I and II, VZV, Cytomegalovirus	Influenza A	Influenza A and B
Acyclovir (Zovirax®), valacyclovir (Valtrex®), famciclovir (Famvir®)	Valganciclovir (Valcyte®) Mechanism: nucleoside analogue (guanine); when phosphorylated, inhibits viral DNA polymerase	Amantadine (Symmetrel®), rimantadine (Flumadine®)	Oseltamivir (Tamiflu®), zanamivir (Relenza®)
Mechanism: purine nucleoside analogues; triphosphate form inhibits HSV DNA polymerase and viral DNA replication	Foscarnet (Foscavir®) Mechanism: inorganic pyrophosphate analogue that inhibits DNA polymerase Cidofovir (Vistide®) Mechanism: nucleotide analogue that inhibits viral DNA polymerase	Mechanism: inhibits uncoating of virus and uptake of nucleic acid by host cells	Mechanism: inhibitor of influenza virus neuraminidase with possible alteration in viral aggregation and release

Abbreviations: HSV = herpes simplex virus; VZV = varicella-zoster virus.

TABLE 163-11 Antiviral Therapy (Non–Human Immunodeficiency Virus) in the ED

Diagnosis	Drug	Dosage	Route
Herpes encephalitis	Acyclovir	10 milligrams/kg every 8 h × 10 d (adult) 500 milligrams/m^2 every 8 h (6 mo–12 y old)	IV
Mucocutaneous herpes (immunocompromised)	Acyclovir	5 milligrams/kg every 8 h × 7 d (adult) 250 milligrams/m^2 every 8 h (<12 y old)	IV
Varicella-zoster (immunocompromised)		Same as above for herpes encephalitis	IV
Herpes zoster (normal host)	Acyclovir, or famciclovir, or valacyclovir	800 milligrams five times/day × 7–10 d 500 milligrams three times daily × 7 d 1 gram three times daily × 7 d	PO PO PO
Varicella (chickenpox)	Acyclovir	20 milligrams/kg (≤800 milligrams) four times a day (adults and children >2 y old) × 5 d	PO
Influenza A	Amantadine	100 milligrams twice daily × 10 d (adults and children >9 y old) 4.4–8.8 milligrams/kg/d, but <150 milligrams/d (children 1–9 y old)	PO
	Rimantadine	100 milligrams twice daily × 7 d (adults and children >10 y old) 5 milligrams/kg/d, but <150 milligrams/d (children 1–10 y old)	PO
	Oseltamivir	75 milligrams twice daily (adults and children >12 y old) × 5 d Pediatrics (age 2 wk thru 12 y): based on weight Also active against influenza B	PO
	Zanamivir	10 milligrams (two inhalations) twice daily × 5 d (adults and children >6 y old) Also active against influenza B	Inhalation

TABLE 163-12 Antiviral Agents for Hepatitis B and Hepatitis C

Hepatitis B		Hepatitis C		
Interferons: interferon alfa-2b (Intron A®); peginterferon alfa-2a (Pegasys®)	Nucleotide or nucleoside analogues: Preferred agents: Entecavir (Baraclude®) 0.5–1 milligram PO daily Tenofovir (Viread®) 300 milligrams PO daily Alternate agents: Adefovir (Hepsera®) 10 milligrams PO daily Lamivudine (Epivir-HBV®) 100 milligrams PO daily Telbivudine (Tyzeka®) 600 milligrams PO daily	Interferons: Products for hepatitis B: Interferon alfa-2a (Roferon®) Peginterferon alfa-2b (Pegintron®) Interferon alfacon-1 (Infergen®)	Ribavirin (CoPegus®, Rebetol®) 800–1400 milligrams PO every day depending upon hepatitis C virus genotype and body weight	Enzyme inhibitors: Boceprevir (Victrelis®) 800 milligrams PO three times daily with food Simeprevir (Olysio®) 150 milligrams PO once daily with food Sofosbuvir (Sovaldi®) 400 milligrams PO once daily with or without food Sofosbuvir 400mg + ledipasvir 90mg (Harvoni®) one tablet PO once daily with or without food
Mechanism: immunostimulant; activates cytolytic T cells against infected hepatocytes Adverse effects: flu-like syndrome, nausea, diarrhea, fatigue, depression, myelosuppression	Mechanism: inhibitor of viral DNA polymerase Adverse effects: headache, fatigue, nausea, asthenia, abdominal pain and distention, insomnia, lactic acidosis, hepatomegaly, increased creatinine	Mechanism and adverse effects: See Hepatitis B	Mechanism: nucleoside analogue, inhibits hepatitis C virus polymerase Adverse effects: hemolytic anemia and pancytopenia, allergic reactions, dyspnea, pneumonitis, bacterial infections	Mechanism: boceprevir and simeprevir inhibit NS3/4A protease; sofosbuvir inhibits RNA polymerase Adverse effects: anemia, nausea, fatigue, headache, rash, pruritus ledipasvir inhibits NS5A protein

acid polymerase inhibition (for example, entecavir for hepatitis B or simeprevir for hepatitis C) or directly inhibit RNA polymerase (sofosbuvir for hepatitis C). These agents are used in combination (for example, sofosbuvir with ribavirin and peginterferon).

HYPERSENSITIVITY SYNDROME

Used in human immunodeficiency virus care, abacavir (Ziagen®, also contained in Trizivir® and Epzicom®) causes a hypersensitivity syndrome. This is more common in individuals who are positive for the major histocompatibility complex class I allele HLA-B*5701, and this allele is now screened before a patient is placed on abacavir.[5] The syndrome is characterized by rash and other systemic complaints. The reaction is reversible with discontinuation of abacavir. However, if the patient then takes abacavir again, life-threatening cardiovascular and respiratory insufficiency can develop.

Many other infrequent adverse reactions are possible but beyond the scope of one chapter. Multiple online sources can aid if needed.[3,5]

CHAPTER 164

Neurologic Examination

J. Stephen Huff
Andrew D. Perron

INTRODUCTION

In most patients, the physical examination confirms thoughts formulated during history taking that are often the key to patient evaluation. Time of onset, symptom progression, associated complaints, and exacerbating factors are important historical points to guide appropriate examination and other testing. The neurologic examination does not exist in isolation from the general physical examination or imaging procedures, and it is unusual for the neurologic examination to delineate a problem not already suggested by the patient's history or general physical examination. Few findings of the neurologic examination are pathognomonic of clinical conditions or are sufficiently specific that examination alone secures the diagnosis. Further complicating the value of the neurologic examination is that the sensitivity and specificity of different examination techniques have not been rigorously investigated, and the degree of interobserver variability is not known. The uncooperative patient or patient with altered mental status presents additional challenges in performing a detailed examination.

The idea of performing a "complete" examination in the ED is impractical, because most frequently, a "complete" examination is neither required nor appropriate. An adequate examination is one that is sufficient for the task at hand. Examination of children follows the same framework as that for adults, but even more information is gathered indirectly by observation. For example, interacting with a child playing with a toy or other object allows the examiner to assess vision, extraocular motion, coordination, and strength as the child reaches for and grasps the toy.[1] Traditional neurologic formulation follows a three-tiered approach: (1) Is there a lesion of the nervous system? (2) Where is the lesion? (3) What is the lesion? The examination detailed in this chapter is arbitrarily divided into eight sections with basic and advanced levels described for each section.

ORGANIZATIONAL FRAMEWORK

Organization of the neurologic examination into a framework of subsections is a convenient technique. At the bedside, mentally review the framework as during the examination, and select more detailed tests as needed. Some of the tests grouped in a section assess several aspects of nervous system function, and listing of tests in a particular section is for organizational convenience. For example, visual field testing, although technically a test of higher cortical function, is listed with cranial nerve testing because the examining physician may find it easier to evaluate visual fields during that portion of the examination assessing cranial nerve function. One organizational scheme divides the examination into eight elements:

1. Mental status testing
2. Higher cerebral functions
3. Cranial nerves
4. Sensory examination
5. Motor system
6. Reflexes
7. Cerebellar testing
8. Gait and station

MENTAL STATUS TESTING

A mental status examination is part of every patient encounter. The observation may be brief and descriptive, such as, "The patient is awake, alert, and conversant," or it may be quite detailed. Mental status assesses the emotional and intellectual functioning of the patient. It is important to make some assessment of mental status, because the patient with an abnormal mental status cannot be relied on for an accurate medical history.

Major elements of mental status testing are assessment of appearance, mood, and insight; assessment for thought disorders or abnormal thought content such as hallucinations; and testing of the sensorium. *Sensorium* is a term for the appropriate awareness and perception of consciousness. Mental status testing is covered more fully in chapter 168, Altered Mental Status and Coma.

One key element in mental status testing is attention and memory assessment. Attention testing is performed with digit repetition. The average adult of normal intelligence should be able to repeat six or seven digits forward and four or five digits backward. Failure to do so may suggest confusion, delirium, or a problem with language perception. Often this represents a problem with attention rather than with memory. Memory is a complex process but is often simply broken into long-term and short-term activities. *Long-term memory* is recall of events of some months or years ago. *Short-term memory* is assessed by asking about events of the day or by three-object recall at 5 minutes. State three items in a neutral tone and ask the patient to repeat; reassess at 5 minutes to obtain a gross assessment of short-term memory function. Failure to repeat the items immediately after presentation is likely an indication of an attention problem rather than of a memory problem.

Evaluation by screening tools is described in chapter 168. Other screening tests for depression, substance abuse, and other problems are outside the scope of this chapter.

In general, patients with abnormal mental status, especially attention problems or disorientation, are more likely to have medical problems rather than functional or psychiatric causes. If a patient suffers from significant inattention, it is unlikely that the examiner will truly be able to determine whether the primary problem is one of cognition or attention.

HIGHER CEREBRAL FUNCTIONS

Higher cerebral functions test neurologic tasks that are thought to reside in the cerebral cortex. Language function defines the dominant hemisphere. The majority of the population is right-handed; for 90% of these patients, the left hemisphere is where language functions reside; hence, they are referred to as *left-hemisphere dominant*. Even in left-handed patients, most will be left-hemisphere dominant for language. Thus, a large cortical stroke affecting the cortex of the dominant hemisphere (the left hemisphere in most patients, whether they are left- or right-hand dominant) likely will affect language functions.

The nondominant hemisphere is concerned with spatial relationships. Often a nondominant hemispheric problem is suspected in the ED when the patient has consistent visual inattention to a care provider approaching from one side (usually the left since most patients are left-hemisphere dominant).

Higher cerebral function pragmatically involves the assessment of language. For a patient with speech that is difficult to understand, a fundamental distinction must be made between *dysarthria* and a *dysphasia* (aphasia and dysphasia are often used interchangeably in clinical practice). Dysarthria is a mechanical disorder of speech resulting from difficulty in the production of sound from weakness or incoordination of facial or oral muscles; this may result from a motor system problem (cortical, subcortical, brainstem, cranial nerve, or cerebellar), but it does not represent a disorder of higher cerebral function. Dysphasia is a problem of language resulting from cortical or subcortical damage; the portion of the brain concerned with comprehension, processing, or producing language is impaired.

There are many different types of aphasias, but a simplified scheme is sufficient for assessment. A description of aphasia into fluent, nonfluent, or mixed patterns is adequate for testing in the ED and for communicating with other physicians.

BASIC

Normal conversation monitoring for correct responses is the common screening examination for a language disorder. If suspicion of a language disorder exists, a series of assessments allows confirmation and categorization of the aphasia.

Test comprehension initially by the ability to follow simple commands. Asking the patient to identify common objects may also be part of the assessment. Use commonly available objects, such as a watch, a pen, or a glass, as a stimulus. Query the patient regarding the names of different parts of the objects. Ask the patient to demonstrate how an object is used. The inability to show how an object is used, assuming hearing and motor functions are intact, may represent an apraxia, defined as the inability to perform a willed act.

In a nonfluent aphasia (a rough synonym is motor or expressive aphasia), the speed of language and the ability to find the correct words may be impaired. A common type of nonfluent motor aphasia is known as *Broca's aphasia*. Speech may be halting and slow, with stops between words or word fragments.

In a fluent aphasia (a rough synonym is auditory or receptive aphasia), the quantity of word production is normal or even increased. Sentences may have normal grammatical structure with normal rhythm, and intonation may be clearly articulated. However, language is impaired, and the listener may be struck by peculiarities of conversation that lack appropriate content. Incorrect words may be substituted within sentences that may be sound-alike words or words with similar yet incorrect meanings. A global or mixed aphasia involves elements of fluent and nonfluent aphasias and is the most common type encountered in clinical practice.

Nondominant hemisphere problems may show problems of auditory or visual inattention or sensory inattention.

ADVANCED

Testing of mental status and cognitive function requires an appreciation of cultural context and language barriers. Further assessment of comprehension may involve showing the patient a picture (there are some standard stimuli, but almost any magazine photo may be used) and asking for the patient's interpretation of the picture while noting if the content is correctly described and if the sentence structure and word selection of the descriptions are correct.

Assessing the ability of the patient to repeat a phrase may be a key point in delineating some types of fluent aphasias. Typically, the ability to repeat short words is more impaired than the ability to repeat longer words. A classic test involves the patient repeating the phrase, "No ifs, ands, or buts." In one type of fluent aphasia, *Wernicke's aphasia*, comprehension is impaired, as is repetition.

Paraphasic errors may be further characterized in patients with fluent aphasia. A literal paraphasic error is one in which part of a word is replaced by an incorrect sound. The use of *spool* when *spoon* is meant is an example of a literal paraphasic error. At times, the errors may reach the point at which the substitutions are not understandable, and a neologism (a meaningless collection of syllables that takes the place of a word in conversation) is produced. Verbal paraphasic errors involve substitution of one correct word for another; for example, a patient may wish to use *spoon* in a sentence and substitute *fork* or even *bike*; the word is a correct word, but the meaning of the sentence is transformed erroneously.[2]

A patient aphasic in speaking will also be aphasic in written communication. Writing and drawing simple constructions may be revealing in some patients. A sequence of simple commands such as requesting the patient to draw a circle and then placing numbers like numbers on a clock may reveal constructional errors. A response consistent with dysfunction of the nondominant hemisphere might be numbering half the clock face and stopping or placing all the numbers around one half of the circle.

Impairment of sensory perception on the cortical level may involve the inability to distinguish objects by touch alone. Implied in this testing is that the primary sensory modalities (sharp, light touch, etc.) are intact. In cases of nondominant hemisphere lesions, the ability to identify objects placed in a hand, such as a coin, may be impaired.

SPECIAL CIRCUMSTANCES

Fluent aphasias may so severely impair communication that the patient is thought to be intoxicated or psychotic. Pay attention to the pattern of speaking—this may give the first indication of a language problem, and further constructional or language testing may demonstrate the presence of an aphasia.

CRANIAL NERVES

BASIC

A survey of the cranial nerves is an integral part of neurologic assessment. Much information may be gathered informally. Look for facial asymmetry (cranial nerve VII) at rest or with movement. Lingual movement (XII) and other facial movements may be inferred during conversation if articulation is good. However, a more formal approach often is used in examination. Most examiners start sequentially with cranial nerve II in testing; cranial nerve I (olfactory) testing has infrequent application in emergency medicine.

Cranial nerve II is the optic nerve active in the afferent function of light and visual perception. The optic nerve head is visible with direct ophthalmoscopy and may be inspected for abnormalities. Common tests for optic nerve function include visual acuity and stimulation for pupillary reactivity. The response to bright light stimulation involves direct and indirect (consensual) pupillary responses. This is a reflex arc, with the afferent limb being cranial nerve II and the efferent limb of the arc being cranial nerve III, which carries the pupilloconstrictors. A bright light directed into one eye should cause a brisk constriction of equal magnitude in both pupils. In the swinging flashlight test, observe the pupils as the light is slowly moved from one pupil to the other. A seemingly paradoxical dilation of one pupil as the light is moved onto that pupil may indicate optic nerve dysfunction of that eye; this is referred to as an *afferent pupillary defect* (see chapter 241, Eye Emergencies).

Cranial nerves III, IV, and VI are concerned with extraocular eye movements (see chapter 241). Tracing an object through a full-H pattern allows assessment of the different cranial nerves. Cranial nerve VI innervates the lateral rectus muscle, which abducts the globe, moving it laterally away from the midline; this lateral movement will be impaired or lost in the case of cranial nerve VI palsy. In fact, the unopposed adduction movement of medial rectus muscle innervated by cranial nerve III may result in the globe being medially deviated. Cranial nerve III innervates the extraocular muscles that adduct each eye and those that elevate and depress the globe. Impairment of cranial nerve III will reveal several abnormalities of extraocular movement, reflecting weakness in the innervated muscles. A complete paresis of cranial nerve III will show a dilated pupil in a globe deviated downward and outward. An isolated cranial nerve IV weakness may be hard to detect; cranial nerve IV supplies the superior oblique muscle that elevates and intorts the globe.

Cranial nerve III also carries the parasympathetic pupilloconstrictors to the eye; a lesion of cranial nerve III may impair those fibers, resulting in unopposed dilatation (by functioning sympathetic fibers reaching the eye by a circuitous path) and a pupil larger than in the unaffected eye.

Ptosis from levator muscle paralysis is another finding of cranial nerve III paresis.

Cranial nerve V has motor and sensory functions. It supplies the muscles of mastication and is assessed by appreciating the masseter bulk. The sensory component of cranial nerve V supplies the cornea; the corneal reflex is a reflex arc of cranial nerves V to VII. Cranial nerve VII supplies the muscles for facial movement as well as facial proprioception.

Cranial nerve VIII has auditory and vestibular afferent components. Cranial nerves IX and X are tested by observing pharyngeal musculature and gag reflexes. Cranial nerve XI is assessed by a shoulder shrug. Cranial nerve XII controls lingual movement and can be assessed by asking the patient to stick out the tongue and observing for any asymmetry of motion.

ADVANCED

In approximately 20% of the population, some degree of physiologic anisocoria is present on the order of 1 to 2 mm. Small differences in pupillary size in otherwise asymptomatic patients likely represent this normal variant. A peripheral lesion of cranial nerve VII will cause complete facial paralysis on the same side as the lesion. A cortical lesion (often stroke) results in weakness of the lower and midface on the opposite side of the injury, with preservation of motor function in the upper face ("central VIIth pattern"). This is due to the bilateral cortical upper motor neuron innervation of the forehead musculature present in most patients.

SPECIAL CIRCUMSTANCES

In the comatose patient, a **unilaterally dilated pupil** that is unreactive or reacts sluggishly to light may represent third nerve dysfunction or paresis from impingement of the oculomotor (III) nerve at the tentorium; this finding is consistent with the uncal herniation syndrome.

Vertigo often is a symptom from a vestibular system dysfunction but may result from a central nervous system disorder such as posterior circulation stroke. The horizontal head impulse test is a bedside maneuver to detect peripheral vestibular disease (see later discussion).[3] A normal (negative) finding of the horizontal head impulse test reliably identifies patients with a central cause of acute vertigo, but an abnormal test (positive) may occur with both peripheral and central causes of vertigo.[4] Two additional maneuvers are advocated in conjunction with the horizontal head impulse test to reliably exclude central causes of vertigo, examination for nystagmus and assessment for skew gaze.[5] Nystagmus that changes direction with gaze to either side is predictive of a central lesion, as is spontaneous vertical or multidirectional nystagmus.[6] Skew deviation refers to misalignment of the eyes. Though subtle at times, it may be unmasked by alternately covering each eye while the patient fixes gaze on the examiner.[7]

Assess the **horizontal head impulse test** by rapidly rotating the head to one side then the other; inability to maintain visual fixation during head rotation requires a rapid corrective jerking (saccade) back to the target; this is a positive horizontal head impulse test and suggests a peripheral vestibular lesion. Additional maneuvers help confirm the assessment. Observe the patient for nystagmus while looking ahead; if present while simply looking ahead, especially if vertical or direction-changing, a central cause of vertigo is likely. If **vertical skew gaze** is present or provoked by alternately covering each eye with the patient looking directly ahead, a central cause may be present. Again, a negative horizontal head impulse test (no corrective saccade observed) in the presence of acute vertigo suggests the possibility of a CNS lesion. The horizontal head impulse test has not been tested in the ED.

SENSORY EXAMINATION

BASIC

The sensory evaluation can be key in some patients with sensory complaints. The primary sensory modalities are light touch, pinprick, position, vibration, and temperature sense. Because of variability in neuroanatomy, at times, dissociation of these modalities occurs and allows localization of problems to anatomic areas within the CNS.

Practically establishing that touch or pinprick is perceived in all extremities is often the only sensory assessment needed in a screening examination. However, if touch or pinprick is not intact or if peripheral nerve or spinal cord injury is suspected, additional detailed examination is usually necessary.

Position testing is best used for the detection of peripheral neuropathy or posterior column spinal cord disease. Position and vibration sensations are conveyed in the posterior columns of the spinal cord, so that there is no need to test both position and vibration—just test one.

ADVANCED

Spinal cord dermatome levels are illustrated in **Figure 164-1**. If sensory alteration conforms to a level or selectively involves specific dermatomes, further localization to the peripheral nerve or nerve root may be possible.

If primary sensory modalities are intact, then testing of higher sensory functions may be pursued; these are covered in the section on Higher Cerebral Functions.

SPECIAL CIRCUMSTANCES

A few patterns of sensory loss are worthy of special mention. In cervical spinal cord injury or compression, an area of apparent sensory demarcation often appears to be just above the nipples. This transverse sensory level suggests a spinal cord lesion in the low cervical to high thoracic area. Most cervical dermatomes are represented in the upper extremity and not in the trunk (see Figure 164-1), and further testing is necessary to delineate the sensory level.

With suspected spinal cord injury, test the area of the perineum for sensation. The sacral dermatomes are distributed in an onion skin pattern around the perineum and are represented only in that region. The demonstration of a preserved island of sensation around the perineum may be the only sign of an incomplete spinal cord injury, which has a different prognosis than a complete spinal cord injury.

Some general comments may be made about patterns of sensory alterations. In general, a half-body sensory loss or alteration suggests cortical or subcortical lesions. A localized problem in one limb suggests a peripheral nerve or nerve root problem, although there are other possible locations of abnormalities in the CNS.[8]

MOTOR SYSTEM

There is more to evaluation of the motor system than simple assessment of strength. Muscle bulk and muscle tone are basic areas of assessment.

BASIC

Muscle tone may be characterized as normal, decreased, or increased. Assess tone by movement of muscle groups and appreciating any resistance to movement. Ask the patient to relax and not resist. Increased tone is greater than normal resistance to passive motion. **Cogwheeling** is transient increase or catching in resistance followed by release to the movement. Assess axial or truncal tone by standing behind the patient, grasping the shoulders, and gently moving the shoulders back and forth in a gentle rotation. A patient with normal tone will offer little resistance to repeated motions, and some spontaneous swing of the arms will be noted. A patient with increased axial tone (e.g., Parkinson's disease) may turn without the arm swing.

Simply having the patient hold the arms outstretched with palms upward and observing for any inward rotation or downward drift is a very sensitive sign for upper extremity weakness (**pronator drift**); this also may be assessed in unresponsive patients (**Figure 164-2**). If both arms are held outright at the same time, comparison is easy, with observation of the upper extremity of one side as opposed to the other. A similar maneuver may be performed in the lower extremities. Another sensitive test for a subtle hemiparesis is the forearm-rolling technique. With the forearms outstretched, ask the patient to make tight circles with each arm. The movements should be small and rapid. Asymmetry or slowness with one arm suggests a weak

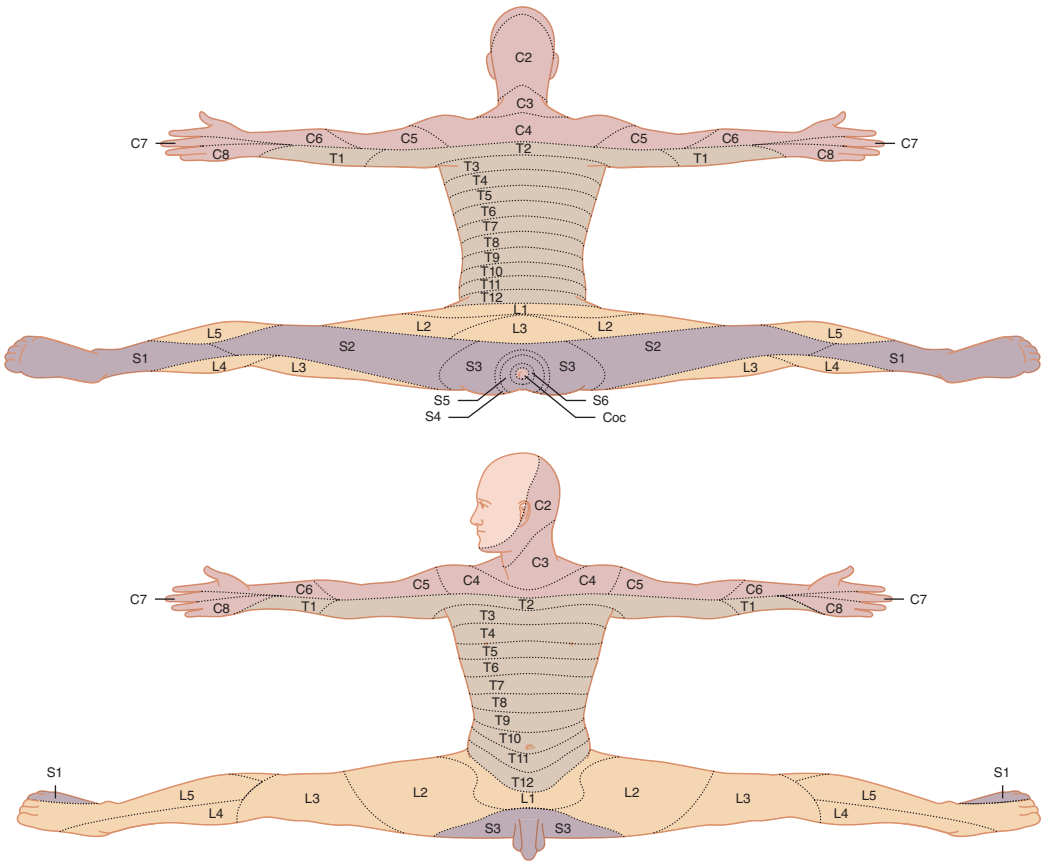

FIGURE 164-1. Sensory dermatomes.

limb.[9] Decreased speed of foot tapping also may suggest weakness and an upper motor neuron probem.[10]

Tremor can be difficult to characterize, and there are many types of tremor. Action tremors, those that are absent at rest but evident with action or sustained limb position, include those from caffeine, hyperthyroidism, and alcohol or sedative withdrawal. Essential familiar tremor is also an action tremor. Rest tremors characterize **Parkinson's disease**, with tremor present during rest, diminishing with willed movement, and then resuming with the new position.

Assessment and recording of other motor strength are best done by description of the stimulus and response. For example, the fact that the patient is able to strongly resist elbow extension or elbow flexion against the examiner is an appropriate notation.

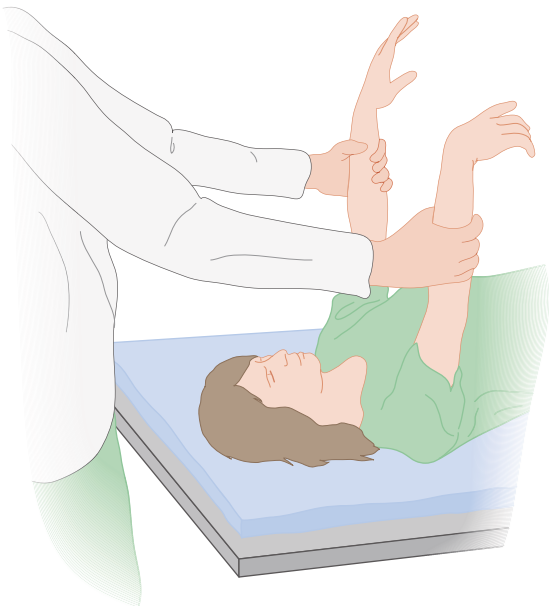

FIGURE 164-2. Testing for weakness in the comatose patient; diagram illustrates assessment of muscular tone in a patient with a right hemiplegia. A similar maneuver may be used in the conscious patient.

ADVANCED

Compare muscle mass or bulk of the affected area with muscle groups of the unaffected areas. If weakness or paralysis has been present for some time, muscle wasting or atrophy may be present. Brief, rapid twitches of small parts of a muscle may represent fasciculations, which may indicate a process involving the lower motor neurons.

A formal rating scale for muscle strength exists but is not straightforward to apply. A rating of 5 is assigned for normal strength, and a rating of 4 indicates weakness and the ability to contract the muscle against some resistance. Thus, a tremendous range of strength is covered within the range of the 4 rating; rating is often further roughly quantified by adding 4+ and 4– to that rating range. A rating of 0 represents complete paresis, and a rating of 1 indicates a minimal flicker of contraction. A rating of 2 is assigned for active movement of a muscle with gravity eliminated by limb repositioning (e.g., so that elbow flexion and contraction are demonstrated by a horizontal rather than by a vertical movement). A value of 3 is assigned to a muscle able to voluntarily demonstrate full motion against gravity only. It is better for the examiner to describe the strength of a muscle by noting the amount of resistance than by invoking what may be a little-used scale and erroneously applying a rating.

Listings of some muscle innervations, actions to test, and dermatomal representations are found in **Tables 164-1 and 164-2.**

TABLE 164-1 Muscle Innervation: Shoulder and Upper Extremity

Nerve	Action to Test	Muscle*
Long thoracic	Forward shoulder thrust	Serratus anterior
Dorsal scapular	Elevate scapula	Levator scapulae
Suprascapular	Arm external rotation	Infraspinatus; C5, C6
Axillary	Abduct arm (>90 degrees)	Deltoid; C5
Musculocutaneous	Flex and supinate arm	Biceps brachii
Ulnar	Ulnar flexion of hand	Flexor carpi ulnaris; C7, C8,† T1
	Flex DIP of fingers 4 and 5	Flexor digitorum profundus
	Thumb adduction	Adductor pollicis; C7, C8†
	Abduction of finger 5	Abductor digitorum minimi
	Opposition of finger 5	Opponens digitorum minimi
	Flexion of finger 5	Flexor digitorum minimi brevis
	Finger abduction and adduction	Interossei; C8, T1†
	Flex PIP and extend DIP of fingers 4 and 5	Lumbricals 3 and 4
Median	Forearm pronation	Pronator teres
	Radial hand flexion	Flexor carpi radialis; C7, C8, T1
	Hand flexion	Palmaris longus
	PIP flexion of fingers 2–5	Flexor digitorum superficialis
	Abduct thumb at the metacarpophalangeal	Abductor pollicis brevis
	Flex proximal phalanx thumb	Flexor pollicis brevis; C7, C8†
Anterior interosseous	Flex DIP fingers 2–5	Flexor digitorum profundus (radial)
	Flex thumb interphalangeal	Flexor pollicis longus
	Oppose thumb	Opponens pollicis; C8, T1†
	Flex PIP and extend DIP of fingers 2 and 3	Lumbricals 1 and 2
Posterior interosseous	Extension of digits 2–5	Extensor digitorum
	Ulnar hand extension	Extensor carpi ulnaris
	Thumb abduction	Abductor pollicis longus
	Thumb extension	Extensor pollicis longus and brevis
	Index finger extension	Extensor indicis proprius
Radial	Forearm extension	Triceps brachii; C6, C7,† C8
	Forearm flexion	Brachioradialis; C5, C6
	Radial hand extension	Extensor carpi radialis
	Forearm supination	Supinator

Abbreviations: DIP = distal interphalangeal joint; PIP = proximal interphalangeal joint.

*Dermatomal representations are listed after some muscles.

†Predominant dermatome.

TABLE 164-2 Muscle Innervation: Hip and Lower Extremity

Nerve	Action to Test	Muscle*
Femoral	Hip flexion	Iliopsoas; T12, L1,† L2, L3
	Leg extension	Quadriceps femoris; L2, L3,† L4
Obturator	Thigh adduction	Pectineus
		Adductor longus, brevis, magnus; L2, L3, L4
		Gracilis
Superior gluteal	Thigh abduction	Gluteus medius and minimus
	Thigh flexion	Tensor fascia lata
	Lateral thigh rotation	Piriformis
Inferior gluteal	Thigh abduction	Gluteus maximus
Sciatic (trunk)	Leg flexion	Biceps femoris; L5,† S1, S2
		Semitendinosus
		Semimembranosus
Deep peroneal	Foot dorsiflexion and supination	Tibialis anterior; L4, L5
	Toes 2–5 and foot extension	Extensor digitorum longus/brevis
	Great toe and foot dorsiflexion	Extensor hallucis longus
Superficial peroneal	Plantar flexion foot and eversion	Peroneus longus/brevis; L5, S1
Tibial	Plantar flexion and inversion	Posterior tibialis
	Flex distal phalanx toes 2–5	Flexor digitorum longus
	Flex distal phalanx great toe	Flexor hallucis longus
	Flex middle phalanx toes 2–5	Flexor digitorum brevis
	Flex proximal phalanx great toe	Gastrocnemius; L5, S1,† S2
	Knee flexion and ankle plantar flexion	Flexor hallucis brevis
	Ankle plantar flexion	Plantaris, soleus
Pudendal	Voluntary pelvic floor contraction	Perineal and sphincters; S3, S4

*Dermatomal representations are listed after some muscles.

†Predominant dermatome.

SPECIAL CIRCUMSTANCES

Although not classically described as part of the motor system examination, information regarding bladder tone and function is at times vital to the examiner. In patients with complaints of incontinence and low back pain, for example, discovery of a probable neurogenic bladder by demonstrating large US-assessed or postcatheterization **residual urine volume** might be a key to diagnosis of spinal cord compression. What is an abnormal postvoid residual bladder volume is difficult to say with certainty, and the literature is not clear on this point, but **in general, a volume of >100 mL, and certainly 200 mL, is cause for concern**.

REFLEXES

Muscle stretch reflexes are the least important part of the neurologic examination and offer little value when used in isolation. Correctly termed *muscle stretch reflexes*, the jerk or involuntary motor movement follows the stretching of intrafusal muscle spindle fibers by the strike of the reflex hammer and the involuntary muscle contraction that follows. Muscle stretch reflexes serve mainly to confirm evidence collected in other parts of the history or physical examination.

Depending on the force of the reflex hammer strike and local impact factors, an elicited reflex may seemingly change from moment to moment. Make sure the patient and the muscle tested are relaxed. Often several reflex strikes are performed. Record the best response.

BASIC

Muscle stretch reflexes are graded on a scale from 1 to 4 that is not rigorously defined, with 0 representing the absence of reflex, 2 or 3 being normal, and 4 representing hyperactive reflexes. Patterns of reflex abnormalities (e.g., upper vs. lower extremity, left vs. right) may suggest a location of a problem within the CNS or peripheral nervous system.

The **Babinski response** is the toe that moves upward in response to a mildly noxious stimulation applied to the lateral plantar or lateral aspect of the foot. The application of stimuli should not be hard or forceful. In

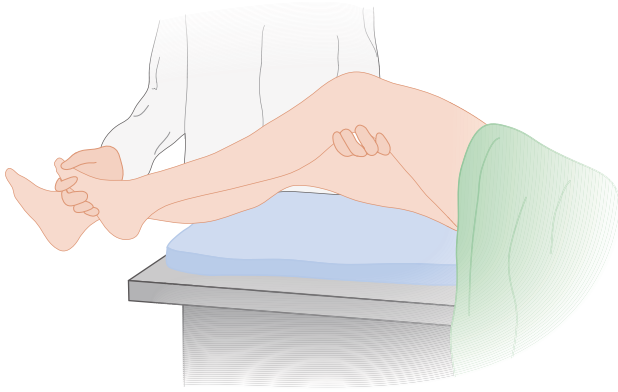

FIGURE 164-3. Method for eliciting ankle clonus.

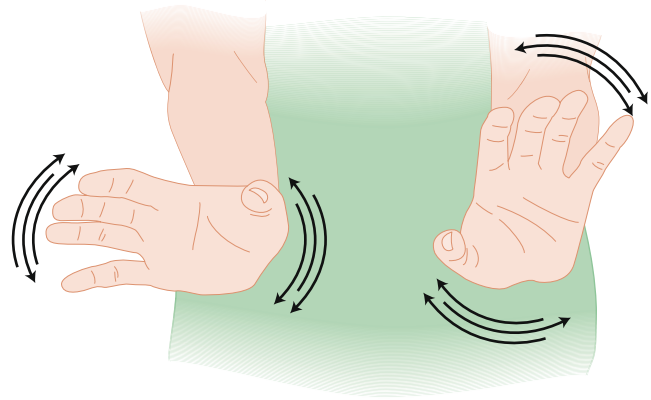

FIGURE 164-4. Pronation and supination test: cerebellar testing.

adults, the normal response of the toe is to move downward to plantar stimulation. The presence of a **Babinski's sign**—that is, the abnormal reflex with movement of the great toe upward and perhaps fanning of the other toes—is the classic indicator of an upper motor neuron lesion. The reliability and accuracy of a Babinski's sign have been called into question.[10] Asymmetry of rapid foot tapping, a little-used test, was found to be more accurate in one small study, with a slowing of foot tapping being the abnormal response.[10]

ADVANCED

Clonus is the rhythmic oscillation of a body part, typically the ankle, elicited by a brisk stretch (**Figure 164-3**). It is one sign of spasticity, in addition to a Babinski response (or slowing of foot tapping), increased muscle tone, and hyperactive muscle stretch reflexes. It may be seen in conditions of metabolic disturbance and primary neurologic dysfunction.

SPECIAL CIRCUMSTANCES

Disease processes involving upper motor neurons or their processes (cortical or spinal cord injuries) result in hyperactive reflexes, a Babinski response, and clonus. Processes injuring lower motor neurons, their axons, peripheral nerve roots, peripheral nerves, or the muscles themselves may result in hypoactive reflexes. However, in spinal cord injury or stroke, reflexes may take several hours or even days to become hyperactive, so the absence of these signs is not valuable in excluding acute spinal cord injury.

Spinal cord emergencies are high-risk clinical scenarios. Although the presence of a Babinski's sign and hyperreflexia are cardinal signs of upper motor neuron syndrome, the absence of these signs does not reliably exclude a diagnosis of spinal cord compression; pursue the diagnosis if historical or other physical examination findings suggest the possibility of this critical diagnosis.[11,12]

CEREBELLAR TESTING

The cerebellum is concerned with involuntary activities of the CNS and is a structure that helps with smoothing muscle movements and aiding with movement coordination. Very simply, the central cerebellar structures may be thought of as controlling coordination of posture and truncal movements (**axial coordination**). The lateral cerebellar structures are more coordinated with movements of the extremities (**appendicular coordination**).

BASIC

Rapidly alternating movements may be assessed by a variety of maneuvers. Hand-slapping tests, asking the patient to rapidly pronate and then supinate the forearm, and slapping the thigh with each movement is a commonly used test. The movements are normally small, and the hand slapping should be symmetric. Rapid pronation and supination of the hands is another test for dystaxia and dysmetria; the movements should be equal with both hands (**Figure 164-4**).

ADVANCED

Although usually included in cranial nerve testing, eye movements are useful in assessing cerebellar function, and abnormalities in their movements may suggest cerebellar dysfunction. Tracking an object slowly should show smooth, slow eye movements; breakup of the smooth movement may be evident and is analogous to the decompensation of movements that may occur in isolated cerebellar impairment. Similarly, if a patient is asked to look back and forth between two objects (finger-to-nose testing involves the patient looking back and forth quickly between the examiner's outstretched finger and nose), the eyes should quickly and conjugately look at the target without overshoot. These faster movements are, at least in part, reflective of intact cerebellar function. **Nystagmus** is rapid involuntary movements of the eyes that may be present with primary (straight-ahead) gaze or provoked by looking at extremes of gaze. Coarse nystagmus or other abnormalities of eye movements are at times present with cerebellar problems (see chapter 170, Vertigo, for a discussion of nystagmus).

GAIT AND STATION

It has been said that, if only one neurologic test could be performed, observation of the patient walking would be the most informative. The posture that the patient assumes when stationary defines the station of the patient. A variety of abnormal gaits and postures are discussed further in chapter 169, Ataxia and Gait Disturbances, as are different techniques of physical examination.

One feature common in many patients with cerebellar hemorrhage is the sudden inability to walk. Keep the possibility of cerebellar injury in mind when evaluating a patient with sudden onset of symptoms that include the inability to walk. Patients with cerebellar hemorrhage may also have severe nausea and vomiting and be massively diaphoretic. Their clinical condition is such that fine neurologic examination is simply not possible.

Acknowledgments: The authors would like to acknowledge the work of Dr. Greg Henry and Dr. Hugh S. Mickel, authors of chapters on this topic in previous editions of the study guide. Their chapters served as a check for completeness and provided some tabular information. J. Stephen Huff would like to acknowledge the influence of the late Dr. William DeMyer of Indiana University, whose instruction in the neurologic examination years ago stimulated an interest in this area.

CHAPTER 165

Headache

Michael Harrigan
Ana C. G. Felix

INTRODUCTION AND EPIDEMIOLOGY

Headache is the fifth most common symptom presenting to the ED in the United States, with a total of 2.1 million visits per year.[1] Overall, headaches affect people across all ethnic, geographic, and economic levels, with an estimated global prevalence of 47% in adults.[2]

In the ED, the approach to headache focuses on identifying patients at risk for rapid deterioration, morbidity, and mortality; rapidly identifying high-risk headache syndromes; and providing appropriate headache therapy.

PATHOPHYSIOLOGY

The brain parenchyma has no pain sensors.[3] Early theories postulating vasoconstriction and rebound vasodilatation as the cause of migraine have been refuted.[4] Numerous physiologic mechanisms play a role in the development of the various clinical headache syndromes. For example, occipital nerve irritation may lead to the development of occipital neuralgia.[5] Similarly, headaches associated with disturbances in intracranial pressure (both high and low) are related to compression of, or traction on, pressure-sensitive structures in the meninges.[6] The pathophysiologic mechanisms of other headache syndromes, such as migraine headaches, cluster headaches, and toxic and metabolic headaches, are less clear. Discussion of these mechanisms is beyond the scope of this chapter.

CLINICAL FEATURES

Most patients with headache have conditions that are painful but benign in etiology. Identifying those at high risk is the first step in management (**Table 165-1**). A high-risk cause for headache accounts for only 4% of all headaches but 10% to 14% of acute-onset ("thunderclap") headaches.[7,8] Although headaches are typically classified as **primary headaches** when there is no underlying cause (such as migraine or cluster headaches) and **secondary headaches** if associated with an underlying cause (such as tumor, meningitis, or subarachnoid hemorrhage), this distinction is not clinically useful in the ED setting.

TABLE 165-1 High-Risk Features for Headache: Clinical "Red Flags"

Onset	Sudden Trauma Exertion
Symptoms	Altered mental status Seizure Fever Neurologic symptoms Visual changes
Medications	Anticoagulants/antiplatelets Recent antibiotic use Immunosuppressants
Past history	No prior headache Change in headache quality, or progressive headache worsening over weeks/months
Associated conditions	Pregnancy or postpregnancy status Systemic lupus erythematosus Behçet's disease Vasculitis Sarcoidosis Cancer
Physical examination	Altered mental status Fever Neck stiffness Papilledema Focal neurologic signs

HISTORY

Features associated with high-risk headaches are as follows:

Patient Age Patients >50 years of age, with a new or worsening headache, represent a high-risk group. The incidence of migraine, cluster, and tension headaches decreases with age, raising the likelihood of ominous pathology for older patients.[9]

Onset of Symptoms The abrupt onset of severe headache, or **"thunderclap" headache**, requires immediate and thorough evaluation.[10] Thunderclap headache associated with intracerebral aneurysmal leak ("sentinel hemorrhage" or "herald bleed") may precede catastrophic aneurysmal rupture. Associated symptoms may include neck stiffness, nausea, vomiting, loss of consciousness, neurologic deficit, or altered mentation.[11] Onset of thunderclap headache during periods of exertion raises suspicion for subarachnoid hemorrhage or **arterial dissection** of the carotid or vertebrobasilar circulation. Headaches associated with the Valsalva maneuver may herald an intracranial abnormality.[12] Rarely, spontaneous intracranial hypotension and acute hydrocephalus associated with third ventricular colloid cyst may present with thunderclap headache.[13] Other causes for thunderclap headache are listed in **Table 165-2**.

Headache Quality A change in pattern, frequency, quality, or intensity of a preexisting headache syndrome needs the same evaluation as a new-onset headache syndrome.

Fever Fever raises concern for CNS infection, such as meningitis, encephalitis, or brain abscess. However, the absence of fever does not exclude a CNS infection, especially in patients at the extremes of age and with immunocompromised states.

Medication History Ask about over-the-counter medications, anticoagulants, antiplatelet agents, chronic steroids, immunomodulatory agents, or antibiotics (prescribed or not) to identify patients at high risk for infection (e.g., eculizumab and its elevated risk for meningococcal infection). Chronic use of analgesic and anti-inflammatory agents may result in **rebound or withdrawal headaches**. Medication overuse is defined as use >10 times a month and is notable for ergots, triptans, and opioids.[12] Anticoagulants and antiplatelet agents increase the risk for hemorrhage, both spontaneous and traumatic.[14] The recent use of antibiotics may present with a falsely reassuring clinical appearance due to partial treatment of a potentially dangerous CNS infection.

Prior Headache History A prior history suggestive of migraine, tension, or cluster-type headaches, and response to specific therapy, may obviate the need for extensive ED evaluation (**Tables 165-3 and 165-4**).

TABLE 165-2 Causes of Thunderclap Headache

Hemorrhage	Intracranial hemorrhage "Sentinel" aneurysmal hemorrhage Spontaneous intracerebral hemorrhage
Vascular	Carotid or vertebrobasilar dissection Reversible cerebral vasoconstriction syndrome (RCVS) Cerebral venous thrombosis Posterior reversible encephalopathy syndrome (PRES)
Other causes	Coital headache Valsalva-associated headache Spontaneous intracranial hypotension Acute hydrocephalus (e.g., colloid cyst obstructing third ventricle)[13] Pituitary apoplexy

TABLE 165-3 Clinical Features Suggestive of Migraine

Prior history of migraine	Moderate/severe intensity
Younger age	Unilateral
Multiple prior episodes	Throbbing
Aura and prodrome	Nausea/vomiting
Familiar triggers	Photophobia/phonophobia
Family history	Lasts hours
History of motion sickness	

Substance Use History Use of adrenergic agents such as cocaine, amphetamine, or derivative compounds such as methamphetamine increases risk of intracranial hemorrhage or the less common entity of reversible cerebral vasoconstriction syndrome.[15] Patients with a history of alcohol abuse are at increased risk of intracranial bleeding due to falls, interpersonal violence, and the potential for liver dysfunction associated with prolonged coagulation times and thrombocytopenia.

Family History Known aneurysm or sudden death in first-degree relatives raises the suspicion for intracranial aneurysm.[16] The incidence of aneurysm in patients with a family history is three to five times higher than in those without a family history. A personal or family history of autosomal dominant polycystic kidney disease also increases the risk for intracranial aneurysm. In patients with autosomal dominant polycystic kidney disease, aneurysmal rupture is more likely to occur at a younger age. The presence of migraine in a first-degree relative is associated with a two- to four-fold increased risk of developing migraine.[17]

PHYSICAL EXAMINATION

Vital Signs Headache is a common symptom associated with fever. For example, headache is seen in up to 60% of patients with upper respiratory tract infection symptoms.[7,18] However, the persistence of headache in the presence of a normalized temperature suggests consideration for further evaluation of a possible CNS infection. The presence of fever in association with neck stiffness and altered mental status represents the classic triad of meningitis. Ninety-five percent of patients with bacterial meningitis present with at least two of the four findings (classic triad plus headache).[19]

Severe hypertension can be associated with headache and the development of acute changes in mental status and neurologic function. Posterior reversible encephalopathy syndrome[20] and hypertensive urgency should be considered in such patients (see "Posterior Reversible Encephalopathy Syndrome" section).

Examination of the Head and Neck

Meningismus is an important clinical clue to the presence of infection or hemorrhage.[19] Examine the ears, nose, and throat to identify otitis media and sinusitis, both of which may cause headache and contribute to the extension of infection to the CNS. Palpate for scalp tenderness and tenderness over the temporal arteries to assess for possible temporal arteritis.

Examination of the Eye

Headache can occur with acute angle-closure glaucoma, scleritis, and endophthalmitis. Consider **acute angle-closure glaucoma** even when there is no focal ocular complaint, because the pain can be so severe the patient may fail to localize pain to the eye. Measure intraocular pressure to exclude glaucoma. Check visual acuity and visual fields and examine the pupils and eyelids, checking for signs of Horner's syndrome.

TABLE 165-4 Clinical Features Suggestive of Cluster Headache

At least 5 attacks that meet the following criteria:	Associated **ipsilateral symptoms** (at least one):
• Severe	• Lacrimation
• Unilateral	• Conjunctival injection
• Lasts 15–180 min (untreated)	• Nasal congestion or rhinorrhea
• Circadian/circannual pattern	• Ptosis and/or miosis
	• Edema of the eyelid and/or face
	• Sweating of the forehead and/or face

Funduscopic Examination

Papilledema can be seen in the presence of raised intracranial pressure. However, there is typically a delay in the onset of papilledema once intracranial pressure begins to elevate, and papilledema can persist once intracranial pressure returns to normal.[21] The ability to recognize papilledema by routine direct ophthalmoscopy alone (particularly with nondilated pupils) is limited, but using a panoptic ophthalmoscope provides a more reliable view of the retina.[22] Bedside US of the optic nerve sheath can also assess for papilledema.[23,24] The presence of papilledema requires CT imaging before lumbar puncture.[25]

Neurologic Examination A baseline neurologic assessment includes the following: mental status assessment; cranial nerve examination, including pupillary examination (for asymmetry or ptosis, which may suggest third nerve compression by posterior communicating artery aneurysms); assessment for other cranial neuropathies (which may raise suspicion for carcinomatous meningitis); motor examination to detect extremity weakness (particularly subtle weakness with pronator drift); reflex examination for subtle asymmetry or a Babinski reflex; and gait and coordination testing (which may be impaired in cerebellar lesions).

DIAGNOSIS

There are many causes of headache, each of which is diagnosed and managed differently. See discussions of specific causes of headache below.

LABORATORY TESTING

Routine blood testing is of limited utility in the diagnosis of acute headache and should be guided by the patient's age, history, relevant comorbidities, and medication history.

The laboratory evaluation of patients with high-risk headaches may include basic metabolic profile, CBC, coagulation panel, erythrocyte sedimentation rate, and blood cultures for possible infection.

IMAGING

Selecting an appropriate imaging study depends on the history, physical examination findings, and differential diagnosis of headache,[26-28] as well as the resources available to the emergency provider. **Table 165-5** summarizes some of the American College of Radiology recommendations for

TABLE 165-5 Choice of Imaging Modality

Noncontrast Head CT	MRI of Brain With and Without Contrast
• Trauma	• New-onset headache *plus* focal neurologic deficit/papilledema
• Thunderclap headache	• Possible encephalitis
• New headache *plus* focal neurologic deficit or papilledema	• Possible vertebral/carotid dissection
• Chronic headache *plus* change in clinical features*	• Horner's syndrome
	• Valsalva or coital headache
	• Immunocompromised individual
	• Patient with cancer history/current cancer
	• Suspected temporal arteritis
	• Intracranial hypotension (low-pressure headache)
	• Headache with suspected intracranial complication of sinusitis/mastoiditis/oromaxillofacial origin
	• New-onset headache in pregnant woman (without contrast)
	• Headache of trigeminal autonomic origin
	• Chronic headache with *new* feature or focal deficit (CT can be first step)

appropriate imaging. When MRI is immediately unavailable and diagnostic uncertainty regarding the possibility of an underlying lesion prevails, further imaging may be necessary, the timing of which will depend on the clinical circumstances and likelihood of the patient being able to follow-up in a reliable fashion.[26]

If the patient presents with a typical history of headache that responds to typical measures and a normal neurologic examination, avoiding imaging may be prudent to reduce the risk for radiation exposure. For most patients in the ED with headache, a noncontrast head CT is the fastest and most appropriate initial imaging study, as well as the most sensitive for detecting acute intracranial hemorrhage.[28,29]

Contrast (iodinated contrast and gadolinium-based magnetic resonance contrast agents) is contraindicated for patients with renal insufficiency due to risk for renal toxicity and nephrogenic systemic fibrosis.[30] Gadolinium is also relatively contraindicated in pregnancy and breastfeeding women. **MRI** can be limited by claustrophobia. A discussion with the radiologist and/or radiology technical staff can clarify the safety of MRI in patients with devices or foreign bodies.

Magnetic resonance angiography is useful in detecting arterial disease (stenosis, congenital anomalies, dissection, CNS vasculitis) and should be considered in any case where there may be arterial pathology underlying the patient's symptoms. Discuss concerns for dissection with the radiologist to determine the most appropriate MRI method.

If MRI is unavailable or not clinically feasible, consultation with radiology regarding other appropriate imaging modalities is prudent.

LUMBAR PUNCTURE

After the clinical assessment, blood work, and imaging, the next step is to determine whether or not to perform a lumbar puncture (LP) and, if so, the timing of LP. LP can serve as both a diagnostic tool (as in meningitis, subarachnoid hemorrhage, intracranial hypotension, carcinomatous meningitis) and therapeutic tool (as in pseudotumor cerebri).

Ideally, perform the LP with the patient in the lateral decubitus position in order to allow for the accurate measurement of opening pressure. Seated LP does not allow for accurate assessment of opening pressure. Opening pressure provides critical information about the patient's intracranial pressure, should be performed routinely, and should be considered a routine procedure when performing LP.

The possibility of herniation in association with LP is a frequent concern of emergency providers. There is no randomized controlled trial assessing the question of when it is safe to perform an LP. The cumulative evidence suggests that in patients without a history of immunosuppression, who have a normal sensorium, and who have no focal neurologic deficits, it is safe to proceed with LP without imaging prior to LP.[31,32]

In the evaluation of patients with suspected acute bacterial meningitis, clinical signs of "impending" herniation are the best predictors of when to delay an LP because of the risk of precipitating herniation. Risk of an abnormal CT scan is elevated in patients with any of the following clinical features: a deteriorating or altered level of consciousness (particularly a Glasgow coma scale score of ≤11), brainstem signs (including pupillary changes, posturing, or irregular respirations), focal neurologic deficit, history of recent seizure, history of a preexisting neurologic disorder, or history of immunocompromised state. In patients with these clinical features, imaging prior to LP is appropriate, but antibiotic administration should not be delayed while imaging is obtained. In patients without such findings, it is usually safe to perform LP without performing a CT scan in cases of suspected bacterial meningitis.[33]

DISPOSITION AND FOLLOW-UP

Most patients with headache can be treated and released from the ED with an appropriate follow-up plan. Identification of potential barriers to follow-up is an important step in ensuring that proper follow-up will be available to all patients, particularly for patients with limited resources or other barriers to accessing medical care. For some patients, inpatient care or observation may be warranted until symptoms improve or until testing is completed. A follow-up plan is especially important for patients with high-risk conditions, such as temporal arteritis or idiopathic intracranial hypertension. Follow-up is similarly important for patients with chronic headaches, given the potential for substance abuse, overutilization of resources, and repeated unnecessary imaging with potentially harmful radiation.[27]

SPECIFIC CAUSES OF HEADACHE

MENINGITIS

Consider meningitis in patients with headache and the classic triad of fever, altered mentation, and neck stiffness.[19] The source of infection can be viral, bacterial, and less commonly, fungal or parasitic. Have a high index of suspicion for meningitis in those with immunosuppression (particularly acquired immunodeficiency syndrome, human immunodeficiency virus, cancer history, chemotherapy, chronic steroids), which may be associated with more insidious types of meningitis such as *Cryptococcus*. An LP is indicated for suspected meningitis. **If the LP is delayed (e.g., CT, coagulopathy, thrombocytopenia, agitation) and meningitis is strongly suspected, administer antibiotics without delay.**[25,34] For many patients who are awake, are alert with no evidence of papilledema or focal neurologic deficit, and have no history to suggest immunocompromised state or new-onset seizure, the head CT can be delayed until after the LP.[25]

SUBARACHNOID HEMORRHAGE

Subarachnoid hemorrhage resulting from rupture of an intracranial aneurysm carries only a 50% 30-day survival rate.[35,36] Approximately half of survivors have some degree of neurologic impairment. Early detection and appropriate management lead to improved clinical outcome. Only 1% of patients presenting to the ED with headache have subarachnoid hemorrhage. However, 10% to 14% of those complaining of the "worst headache of their life" have subarachnoid hemorrhage.[7,8] **Acute onset of a severe headache is subarachnoid hemorrhage until proven otherwise.**[10,11] Inquire about a family history as outlined above.[16] Obtain a noncontrast head CT as the first step in evaluation.[37] With third-generation CT equipment, CT scan done within 6 hours of headache onset is reported to have a sensitivity of 93% and specificity of 100%, with a negative predictive value of 99.4% and positive predictive value of 100%.[38] If head CT is negative for blood but suspicion for subarachnoid hemorrhage is strong, the next step is LP to detect blood or xanthochromia in the cerebrospinal fluid.[39] For further discussion, see chapter 166, "Spontaneous Subarachnoid and Intracerebral Hemorrhage." Consultation with a neurologist or neurosurgeon may be appropriate if the history is highly suggestive of subarachnoid hemorrhage, because both the CT and LP can be normal.[40-42] CT angiogram, magnetic resonance angiogram, MRI with fluid-attenuated inversion recovery/susceptibility-weighted images,[43,44] or four-vessel cerebral angiogram may be reasonable.[26]

SUBDURAL HEMATOMA AND INTRACEREBRAL HEMORRHAGE

Intracranial hemorrhage may occur with or without a history of trauma, in the context of new or progressive headache, with or without associated neurologic deficit. This is particularly important in the elderly, those with chronic alcohol and substance abuse, and patients using antiplatelet and anticoagulant agents. The antiplatelet agent clopidogrel increases the risk of acute intracranial bleeding immediately after trauma, so patients receiving antiplatelet agents and anticoagulants should be screened using head CT, regardless of symptoms. In a prospective trial of patients with blunt head trauma, 12% of those taking clopidogrel and 5.1% of those taking warfarin had acute intracranial hemorrhage noted on their initial CT scan. The risk of delayed intracranial hemorrhage was small in both groups (0 of 296 patients taking clopidogrel and 4 of 687 patients taking warfarin).[14]

Acute headache with associated vestibular symptoms (vertigo or ataxia) should be considered a cerebellar hemorrhage until proven otherwise. Cerebellar hemorrhages make up approximately 10% of all intracerebral hemorrhages and may require prompt surgical evacuation of the hematoma in order to prevent the rapid progression to severe disability or death.[45]

BRAIN TUMOR

Headache in the setting of brain tumor is caused, at least in part, by cerebrospinal fluid flow obstruction and intracranial hypertension.[46]

Clinical signs and symptoms suggesting brain tumor include abnormal neurologic examination, headache worsened by Valsalva maneuver, headache causing awakening from sleep, seizures, recent cancer diagnosis, or mental status change. Of course, the absence of these features does not exclude the possibility of a brain tumor. MRI with and without gadolinium is the study of choice for detecting brain tumors, but cost and limited access make it unfeasible in many settings. A noncontrast CT will identify large masses and edema associated with large masses, but may fail to identify smaller masses. Evaluate for potential barriers to access of medical care in clinical decision making, because additional imaging may be needed at follow-up.

CEREBRAL VENOUS THROMBOSIS

Cerebral venous thrombosis is a rare, but dangerous, cause of headache. Consider the diagnosis in patients presenting with new headache symptoms, especially in the presence of certain known risk factors. Cerebral venous thrombosis is more common in women, especially in the peripartum period, and in patients with a recent surgical history. It is associated with hypercoagulable states such as use of oral contraceptives, hematologic disorders, factor V Leiden homozygous mutation, protein S or protein C deficiency, and anti–thrombin III deficiency.[47] The presentation can vary widely, from a progressive headache developing over days to weeks to, in some instances, a "thunderclap" headache. Similarly, the patient's clinical appearance can be quite benign, especially early on in the course of the illness, or in more severe cases, patients may present with seizures, stroke symptoms, and even coma.[48,49]

In the presence of abnormal imaging (CT, MRI), focal neurologic deficit, or altered mental status, the diagnosis is made definitively with magnetic resonance venography. Given the rare nature of this diagnosis, it is likely that patients suffering from cerebral venous thrombosis may be undergoing evaluation for other causes of severe headache. An elevated LP opening pressure should raise suspicion of central venous thrombosis in the appropriate clinical setting and prompt further imaging with magnetic resonance venography or consultation with a neurologist.[50,51] LP can safely be performed in patients with central venous thrombosis.

POSTERIOR REVERSIBLE ENCEPHALOPATHY SYNDROME (PRES)

Patients with posterior reversible encephalopathy syndrome can present with severe headache, visual changes, seizures, and encephalopathy in the setting of marked blood pressure elevation (usually rapidly developing). It is most common in patients undergoing active treatment with immune-suppressing or -modulating medications or chemotherapeutic agents, as well as in patients with end-stage renal disease. Imaging with MRI typically shows evidence of symmetrical vasogenic edema in the occipital area of the brain, although other areas of the brain can be involved. Treatment involves blood pressure control and supportive care.[52]

REVERSIBLE CEREBRAL VASOCONSTRICTION SYNDROME

This condition is one of a short list of conditions that can mimic subarachnoid hemorrhage (Table 165-2). Characterized by the occurrence of one or more "thunderclap" headaches, the diagnosis should only be considered when the evaluation for subarachnoid hemorrhage has proven negative. The underlying pathophysiology of the syndrome is poorly understood, but it appears to coexist with a number of other cerebral angiopathies (including posterior reversible encephalopathy syndrome) that are characterized by diffuse cerebral vasospasm. The incidence is greater in women, and the peak age of onset is in the early 40s. Most patients will have more than one thunderclap headache over the course of a few weeks. Severe headache may be the only presenting feature, although some patients can present with seizure or focal neurologic deficit. The key diagnostic feature (multiple areas of cerebral vasoconstriction on cerebral angiography) is most commonly found on follow-up angiography between 2 and 3 weeks after symptom onset.[15]

TABLE 165-6 American College of Rheumatology Criteria for Diagnosis of Temporal Arteritis

Clinical Features	Comments
Age at disease onset ≥50 years	
New headache	Onset or type
Temporal artery abnormality	Tenderness to palpation of temporal arteries Decreased pulsation of temporal arteries
Erythrocyte sedimentation rate ≥50 mm/h	Westergren method
Abnormal artery biopsy (can be done after initiating steroids)	Vasculitis Predominance of mononuclear cell infiltration or granulomatous inflammation Multinucleated giant cells

In three published series, the rate of permanent neurologic disability was between 6% and 20%. Reversible cerebral vasoconstriction syndrome, although not widely known among nonneurologists, does not appear to be that rare. One prospective case series included 67 patients diagnosed at a single hospital over a 3-year period of data collection.[53,54]

Initial neuroimaging in these patients may show evidence of nonaneurysmal subarachnoid hemorrhage, ischemic stroke, or intracranial hemorrhage. However, head CT is most commonly normal in these patients. Ultimately, there will be magnetic resonance angiography evidence of cerebral vasoconstriction in all patients, but this may be delayed in appearance. As such, the clinical presentation of thunderclap headache without evidence of subarachnoid hemorrhage should be the main prompt to making this diagnosis or consulting with a neurologist.

TEMPORAL ARTERITIS

Temporal arteritis, also known as giant cell arteritis, is an inflammatory condition affecting the small and medium-sized intracranial and extracranial vessels. Primarily a disease of those >50 years old, its incidence increases with age. In addition to headache, associated symptoms may include fatigue, fever, proximal muscle weakness, jaw claudication, or transient ischemic attack symptoms, especially transient visual loss. Sedimentation rate may be elevated. Check intraocular pressure to exclude glaucoma. Diagnosis is made by the presence of three of the five criteria listed in **Table 165-6**, with a sensitivity of 93.5% and a specificity of 91.2%.[55] Begin treatment with prednisone, 60 milligrams PO daily, to minimize morbidity from visual impairment and stroke. Consult with an ophthalmologist to determine optic nerve function and a rheumatologist. It is important to ensure that there is rapid and appropriate follow-up for patients discharged from the ED, ideally with their primary care provider.

MIGRAINE

The most common non–life-threatening headache in the ED is **migraine** (Table 165-3). Migraine is defined as a headache of moderate to severe intensity that lasts hours (4 to 72 hours on average) and is usually unilateral, pulsatile in quality, typically associated with both photophobia and phonophobia, and generally made worse with physical activity. Migraine can be episodic or chronic and can occur with or without aura. The characteristics of migraine aura vary widely. Among the most common aura symptoms are lightheadedness and visual changes (scotoma and scintillations). Migraines usually start in childhood and peak around age 40 years, with gradual decline thereafter. Prevalence is about 5% for males and 15% to 17% for females.[9]

Chronic migraine is defined as 5 or more migraine headache days per month over the past 3 months. Migraine sufferers who present to the ED are more likely to be chronic headache sufferers.[56,57]

There are many effective treatment options for management of migraine headache, based on randomized controlled trials. Triptans are considered first-line abortive therapy for migraine. However, in the ED setting, most patients have failed abortive therapy and require rescue therapy.

TABLE 165-7 Treatment Options for Migraine Headache

Drug	Dosing	Contraindications	Precautions and Pregnancy Category	Notes
Ketorolac	30 milligrams IV or IM	History of peptic ulcer disease (especially in elderly)	Pregnancy Category B Avoid in third trimester	
Prochlorperazine	5–10 milligrams IV or PR		Pregnancy Category C Drowsiness Dystonic reactions	**Antiemetic** Concurrent: diphenhydramine
Metoclopramide	10 milligrams IV		Pregnancy Category B Drowsiness Dystonic reactions	**Antiemetic** Concurrent: diphenhydramine
Droperidol	2.5 milligrams IV slow, or 2.5 milligrams IM		Pregnancy Category C QT interval prolongation and/or torsade de pointes	Concurrent: diphenhydramine
Chlorpromazine	7.5 milligrams IV		Pregnancy not classified Hypotension Drowsiness Dystonic reactions	**Antiemetic** Pretreat with: normal saline bolus to minimize hypotension Concurrent: diphenhydramine
Magnesium sulfate	2 grams IV over 30 min		Pregnancy Category D but effective in pre-eclampsia and eclampsia	Nonvalidated
Methylprednisolone	125 milligrams IV or IM		Rescue therapy	Nonvalidated
Dexamethasone	6–10 milligrams IV		Rescue therapy	Adjunctive therapy to reduce recurrence
Sumatriptan	6 milligrams SC	Ischemic Heart Disease Uncontrolled hypertension Basilar or hemiplegic migraine	Pregnancy Category C	
Dihydroergotamine (DHE)	1 milligram IV over 3 min	Pregnancy Uncontrolled hypertension Ischemic Heart Disease Recent sumatriptan use (within 24 h)[61] Basilar or hemiplegic migraine	Pregnancy Category X Nausea Vomiting Diarrhea Abdominal pain	Pretreat with antiemetic
Valproate	500 milligrams IV	Pregnancy	Pregnancy Category X	Nonvalidated

ED Treatment of Migraine Initial treatment consists of IV hydration and repetitive IV treatment with nonsteroidal anti-inflammatory drugs and an antiemetic (**Table 165-7**). Many combinations are effective. **Combination with antihistamine (usually diphenhydramine 25 to 50 milligrams IV) is helpful,** because increased histamine levels correlate with migraine attacks, and diphenhydramine can also treat akathisias from antiemetics. Antihistamines alone are not helpful.[58]

Steroids can be useful to reduce the risk for headache recurrence after ED discharge.[59,60]

Opiates and barbiturate-containing compounds should not be used routinely for abortive migraine therapy unless other standard treatments fail. Not recommended for routine use are ergotamine and codeine- and tramadol-containing medications, as well as butorphanol and butalbital-containing medications.[62,63]

In **pregnancy**, there is scant data on treatment of migraine. In general, triptans are contraindicated; acetaminophen, opioids, or corticosteroids can be used. Metoclopramide (U.S. Food and Drug Administration Category B) may be used. Nonsteroidal anti-inflammatory drugs may be also used until the third trimester. Ergotamines and combination agents with caffeine and isometheptene are absolutely contraindicated in pregnant women.

Upon discharge from the ED, more than half of patients will have some residual headache, and there is an increased rate of recurrence of headache within the first 3 days after discharge.[59,60,64] Therefore, a prescription for abortive medications should form part of the discharge plan for patients being discharged from the ED with a diagnosis of migraine. Providers should be familiar with one or two fast-acting triptans (such as sumatriptan, sold as Imitrex™ in the United States, and rizatriptan, sold as Maxalt™ in the United States), as well as combinations of triptans, such as sumatriptan/naproxen (sold as Treximet™ in the United States), or combination drugs, such as Midrin™ (acetaminophen, 325 milligrams/dichloralphenazone, 100 milligrams/isometheptene, 65 milligrams).

OCCIPITAL NEURALGIA

Occipital neuralgia is characterized by paroxysms of lancinating pain at the back of the head, in the distribution of the greater and/or lesser occipital nerve. Patients describe the pain as stabbing or electric shock–like in quality, with hypersensitivity in the distribution of the affected nerve. Most cases are attributed to chronic neck tension or unknown causes. However, the condition can be associated with osteoarthritis or degenerative disease of the upper cervical spine. Occipital nerve block typically results in marked improvement of symptoms, and the results can persist for weeks after the injection. The procedure is both diagnostic and therapeutic. The procedure can be performed with ease in any setting and requires minimal expertise.

IDIOPATHIC INTRACRANIAL HYPERTENSION (PSEUDOTUMOR CEREBRI SYNDROME)

Idiopathic intracranial hypertension, also known as pseudotumor cerebri, is most common in obese women. The incidence is 19.3 per 100,000 obese women between the ages of 20 and 44 years and has increased along with the obesity epidemic. The most prominent symptoms include headache (84%), transient visual obscurations (68%), back pain (53%), and pulsatile tinnitus (52%). Only 32% of patients report visual loss. Untreated, idiopathic intracranial hypertension can lead to permanent visual impairment if not recognized and treated appropriately.[65]

The diagnostic criteria include papilledema with an otherwise normal neurologic examination and elevated opening pressure on LP (>25 cm H_2O in adults and >28 cm H_2O in children), in the setting of normal cerebrospinal fluid composition and normal imaging (having excluded other causes of raised intracranial pressure). Treatment is focused on preservation of vision. A variant of pseudotumor has been identified that does not present with papilledema but may present with the other clinical features of pseudotumor cerebri, along with abducens nerve palsy (unilateral or bilateral). In the absence of either papilledema or abducens nerve palsy, the diagnosis of pseudotumor without papilledema can be made if at least three of the following neuroimaging findings are present: empty sella, flattening of the posterior aspect of the globe, distention of the perioptic subarachnoid space with or without a tortuous optic nerve, and transverse venous sinus stenosis.[66]

LP is necessary to make the diagnosis of idiopathic intracranial hypertension, and concomitant removal of a volume of cerebrospinal fluid can provide temporary relief of symptoms. However, subjective improvement of symptoms after LP is not reliable in establishing the diagnosis.[66] Perform the LP with the patient in the lateral decubitus position, without sedation (which may cause mild hypercapnia and, subsequently, an elevated cerebrospinal fluid pressure measurement). The knees should be extended for measurement of cerebrospinal fluid pressure, and the base of the manometer should be level with the right atrium. Elevated cerebrospinal fluid pressures can occur in the setting of the Valsalva maneuver, such as breath holding and crying, and if the pressure is measured in the sitting position. Cerebrospinal fluid can be removed in multiple aliquots, measuring cerebrospinal fluid pressure after each removal, until a target pressure of 15 to 20 cm H_2O is achieved. Determine the opening pressure. **In general, removal of 1 mL of cerebrospinal fluid will lower the cerebrospinal fluid pressure by about 1 cm H_2O.**[67] To avoid lowering the pressure excessively, first remove 1 mL for every 1 cm H_2O reduction desired, and then remeasure cerebrospinal fluid pressure. Excess cerebrospinal fluid removal can result in intracranial hypotension and a "low-pressure headache," which may require epidural blood patch for relief.

Oral acetazolamide can be effective in lowering intracranial pressure and decreasing the symptoms of idiopathic intracranial hypertension. Treatment is typically started at 250 to 500 milligrams twice a day.[68] The dose can be increased to as much as 4 grams/d, but dose escalation is associated with significant side effects (paresthesias, fatigue, decreased libido, metallic taste) and should be done under the supervision of a neurologist or ophthalmologist for ongoing monitoring of papilledema and visual field testing to minimize the risk of visual loss.[69] Long-term interventional management may include cerebrospinal fluid shunting and optic nerve sheath fenestration for failing vision. For obese patients, weight loss is recommended.[69]

INTRACRANIAL HYPOTENSION

The headache of intracranial hypotension (low-pressure headache) is most commonly associated with recent dural penetration, either during LP, epidural anesthesia, or any operative procedure that involves opening the dura. Using a noncutting needle reduces the risk of post-LP headache.[70] Rarely, intracranial hypotension can occur spontaneously or in association with head or spine trauma.[71-73] Clinical features include headache that increases in severity with upright posture but improves or resolves in the supine position. Associated symptoms, such as alterations in hearing or vision, nausea, vomiting, diplopia, and visual changes, may occur. MRI, with and without contrast, confirms the diagnosis by showing diffuse enhancement of the meninges. The LP, if performed, should have an opening pressure <6 cm H_2O. Most patients experience spontaneous resolution of their symptoms. Evidence to support treatments, including IV fluid resuscitation and IV caffeine, is limited. The most effective therapy for low-pressure headache is an epidural blood patch, typically performed by anesthesiologists.[71,74]

CARCINOMATOUS MENINGITIS

About 5% to 10% of patients with cancer develop leptomeningeal metastases. In addition to headache, cranial nerve abnormalities (typically more than one) and other neurologic findings may be present. Risk factors for carcinomatous meningitis include aggressive lymphoma subtypes and uncontrolled systemic disease. In suspected patients, the appropriate testing would include MRI with and without contrast (to evaluate for meningeal enhancement). Obtain MRI before LP because MRI evidence of meningeal enhancement is common after LP and may confound the diagnosis. LP may reveal an elevated opening pressure (>20 cm H_2O). Cerebrospinal fluid analysis should include cytology (solid tumors) or flow cytometry (hematologic tumors). Malignant cells degrade quickly, so timely review of cerebrospinal fluid is important.[75]

CLUSTER HEADACHE

Cluster headaches (Table 165-4) occur in about 0.4% of the general population and can mimic dental pain. More common in men, cluster headaches typically start in adulthood and tend to occur in "clusters," with a circadian and circannual pattern, recurring daily for more than a week and remitting for at least 4 weeks. Episodes are typically unilateral and excruciating, but brief and self-limited. Up to 10% of patients will experience a more chronic form, with fewer episodes of remission. Associated **ipsilateral symptoms are common** (Table 165-4), and a distinguishing feature of this headache is the need for the patient to "pace," in contrast to the patient with migraine, who prefers to lie still in a quiet and dark room. Treatment consists of 100% oxygen administered at 12 L/min for 15 minutes through a nonrebreathing facemask.[76,77] Sumatriptan, 6 milligrams SC, can also be used.

HYPERTENSIVE HEADACHE

There is no compelling evidence linking mild to moderate **hypertension** with headache. Several studies using ambulatory blood pressure monitoring have found no association between mild to moderate high blood pressure (systolic blood pressure <180 mm Hg and/or diastolic blood pressure <120 mm Hg) and patient self-reported headache.[78] Uncontrolled hypertension can be associated with headache, especially in conditions where there is a rapid and marked rise in blood pressure, such as pheochromocytoma, posterior reversible encephalopathy syndrome,[20] hypertensive crisis, pre-eclampsia, and eclampsia.[78]

METABOLIC CAUSES OF HEADACHE

Metabolic headaches are hallmarked by deterioration in the setting of a disorder of homeostasis and typically improve after resolution of the disorder of homeostasis (**Table 165-8**).[78]

COITAL HEADACHE

Coital headache, also known as orgasmic headache, is a thunderclap headache that occurs at orgasm. Coital headache is considered benign with no specific treatment needed. Recovery is complete. However, the diagnosis is one of exclusion, to ensure that other causes of thunderclap headache are not missed, including subarachnoid hemorrhage and reversible cerebral vasoconstriction syndrome.[79] The clinical diagnosis of coital headache is one of exclusion and cannot be made without imaging. If MRI is unavailable or not clinically feasible, consultation with radiology regarding other appropriate imaging modalities is prudent.[26]

VALSALVA-ASSOCIATED HEADACHE

Valsalva maneuver may trigger thunderclap headache, a diagnosis made when the headache is only associated with cough, straining, or a Valsalva maneuver, with normal neuroimaging. Symptomatic cough headache is the diagnosis made when an underlying pathology (usually a type I Chiari malformation) is likely to be the cause of the headache.[80]

PITUITARY APOPLEXY

Pituitary tumor apoplexy is a rare clinical diagnosis, that is usually due to spontaneous hemorrhage or infarction of a preexisting pituitary adenoma.[81] The earliest symptom is sudden, severe headache.

TABLE 165-8 Metabolic Causes of Headache

History	Examples	Treatment
Hypoxia/hypercapnia	High altitude	Acetaminophen/ibuprofen Acetazolamide 125–250 milligrams twice a day Steroids (dexamethasone) Prophylaxis: acetylsalicylic acid, 320 milligrams at 4-h intervals, starting 1 h prior to ascent; repeat 3 times
	Air travel	Nonsteroidal anti-inflammatory drugs (NSAIDs), pseudoephedrine, and nasal decongestants
	Pulmonary disease Congestive heart failure Sleep apnea	
Dialysis		NSAIDs/analgesics during dialysis
Autonomic dysreflexia (typical in quadriplegia)		Seated position Remove/loosen clothing Scrutinize for bladder distension/bowel impaction
Other	Hypothyroidism Fasting Cardiac cephalgia (associated with myocardial ischemia)	

The headache location tends to be retro-orbital, bifrontal, or suboccipital. Between 63% and 100% of patients will experience headache.[81] Associated symptoms may include ophthalmoplegia, reduced visual acuity, visual field defects, altered consciousness, meningismus, and nausea and vomiting. CT (noncontrast) and MRI may show a sellar mass and hemorrhage. In the first 1 to 2 hours, the hyperacute hemorrhage may be easier to see on CT than MRI. Pituitary adenomas and cerebral aneurysms have a co-occurrence rate of 7.4%.[81] Pituitary tumor apoplexy requires immediate treatment with corticosteroids and urgent neurosurgical consultation. The treatment usually requires consultations from endocrinology, ophthalmology, and neurology with intensive care monitoring.

THIRD VENTRICLE COLLOID CYSTS

Colloid cysts of the third ventricle are a rare cause of acute neurologic deterioration and sudden death. The colloid cyst is usually congenital, slow growing, and benign, accounting for about 0.2% to 2% of all intracranial tumors, but it is the most common tumor of the third ventricle.[82] The usual clinical presentation is a history of severe paroxysmal and episodic attacks of (typically frontal) headache associated with nausea and vomiting. The presumptive cause is the intermittent obstruction of cerebrospinal fluid flow through the foramina of Monro with associated rapid increase in intracranial pressure.[83]

SINUSITIS

Classic features of purulent nasal discharge, nasal or facial congestion, hyposomia, or anosmia with or without fever, along with headache, ear pain or fullness, halitosis, and dental pain, allow for clinical diagnosis of **sinusitis**,[84] and treatment with antibiotics is warranted.

CHAPTER 166

Spontaneous Subarachnoid and Intracerebral Hemorrhage

Jeffrey L. Hackman
Anna M. Nelson
O. John Ma

INTRODUCTION

Although nontraumatic subarachnoid and intracerebral hemorrhages account for a relatively small portion of ED visits, a missed diagnosis can produce devastating results. Early recognition and aggressive management may improve outcomes.

Subarachnoid hemorrhage is the leakage of blood into the subarachnoid space, most often due to a ruptured intracranial aneurysm. The classic presentation is a sudden, severe headache.

Intracerebral hemorrhage, or hemorrhagic stroke, typically presents as an acute neurologic deficit, often accompanied by headache. The features and treatment of subarachnoid and intracerebral hemorrhage are discussed in this chapter. Management of intracerebral hemorrhage is very different from the management of ischemic stroke. Ischemic stroke is discussed in chapter 167, Stroke Syndromes.

SUBARACHNOID HEMORRHAGE

EPIDEMIOLOGY

About 75% of subarachnoid hemorrhages are caused by a ruptured aneurysm. In about 20%, a cause is not identified.[1] The remaining causes are related to a variety of miscellaneous conditions, including arteriovenous malformations, sympathomimetic drugs, and other less common causes. About 20% of patients with one aneurysm will have an additional aneurysm, which makes identification of the initial aneurysm important.

Two percent of family members of patients with subarachnoid hemorrhage will develop the same disease. This risk rises with increasing number of family members involved or with a family history of adult polycystic kidney disease.[1] Hypertension and smoking increase the risk. Additional risk factors are listed in **Table 166-1**.

PATHOPHYSIOLOGY

Cerebral aneurysms are focal arterial pouches typically located in areas of bifurcation of the circle of Willis. While the precise pathophysiology is not known, many factors have been associated with aneurysmal development and rupture. Such factors include familial/genetic predisposition, cellular aberrations in vascular wall repair or remodeling, and aberrations in local blood flow.[2] While it is not possible to predict rupture risk of a particular aneurysm, larger aneurysms (>5–10 mm) are more likely to rupture than smaller aneurysms.[2,3]

TABLE 166-1 Risk Factors for Subarachnoid Hemorrhage

Hypertension
Smoking
Excessive alcohol consumption
Polycystic kidney disease
Family history of subarachnoid hemorrhage
Coarctation of the aorta
Marfan's syndrome
Ehlers-Danlos syndrome type IV
α_1-Antitrypsin deficiency

CLINICAL FEATURES

Patients with subarachnoid hemorrhage classically present to the ED with a severe headache of acute onset (termed a "thunderclap" headache) that reaches maximal intensity within minutes. Typically, the headache persists for several days, but may resolve in a shorter period.[1] Subarachnoid hemorrhage is diagnosed in 11% to 25% of patients who present to the ED with a thunderclap headache.[4,5] **Even if a patient is not experiencing the "worst ever" headache, a headache that is different in intensity or quality from past headaches raises concern for subarachnoid hemorrhage.** Headaches associated with loss of consciousness, seizure, diplopia or other neurologic signs, or nuchal rigidity also require clinical investigation.[6] Less frequently, patients may present with nausea and vomiting, altered mental status, photophobia, or symptoms suggestive of ischemic stroke. Approximately 20% of patients develop their symptoms while engaged in activities that cause increased blood pressure, such as exercise, sexual intercourse, or defecation. Isolated, uncomplicated true syncope without head trauma, headache, seizure, neurologic deficits, nuchal rigidity, or other symptoms of subarachnoid hemorrhage does not require evaluation for subarachnoid hemorrhage. In the absence of blunt trauma, subhyaloid retinal hemorrhage is pathognomonic of subarachnoid hemorrhage but is not commonly seen.

DIAGNOSIS

Patients with subarachnoid hemorrhage who are misdiagnosed at their initial ED visit have worse outcomes than those who are diagnosed early.[7,8] Misdiagnosis is associated with normal mental status (present in about half of patients with subarachnoid hemorrhage) and smaller size of hemorrhage.[8] Complications of missed diagnosis include repeat hemorrhage and obstructive hydrocephalus. Symptomatic improvement following analgesics does not exclude life-threatening causes of headache.[9] **Table 166-2** lists the differential diagnosis of subarachnoid hemorrhage.

Imaging The initial diagnostic modality of choice when subarachnoid hemorrhage is suspected is a noncontrast CT of the head (**Figures 166-1** and **166-2**). **The sensitivity of CT in diagnosing subarachnoid hemorrhage is highest shortly after symptoms begin and is estimated to be 98% within 6 to 12 hours of the onset of symptoms.** Sensitivity decreases to about 91% to 93% at 24 hours and continues to decline rapidly thereafter, reaching 50% at 1 week.[6,9] Newer-generation CT scanners provide increased sensitivity for detecting subarachnoid hemorrhage, especially in the setting of (1) patients presenting within 6 hours of symptom onset, and (2) greater availability of a timely interpretation by a neuroradiologist.[10-12] For suspected subarachnoid hemorrhage, a negative head CT is typically followed by LP (see later discussion).

CT/CT angiography (CTA) and MRI/MRA are options after a negative head CT, when these studies are clinically appropriate and available.[13] In a small study, two of 116 patients had an aneurysm discovered by CTA after normal findings on both CT and LP.[14] The probability of excluding a subarachnoid hemorrhage following CT/CTA is about 99.4%.[15]

TABLE 166-2 Differential Diagnosis of Subarachnoid Hemorrhage

Vascular (other intracranial hemorrhage, ischemic stroke or transient ischemic attack, arterial dissection, venous thrombosis)
Drug toxicity
Infection (meningitis, encephalitis)
Intracranial tumor
Intracranial hypotension
Metabolic derangements
Primary headache syndromes (benign thunderclap headache, migraine, cluster headache)
Hypertensive disorders

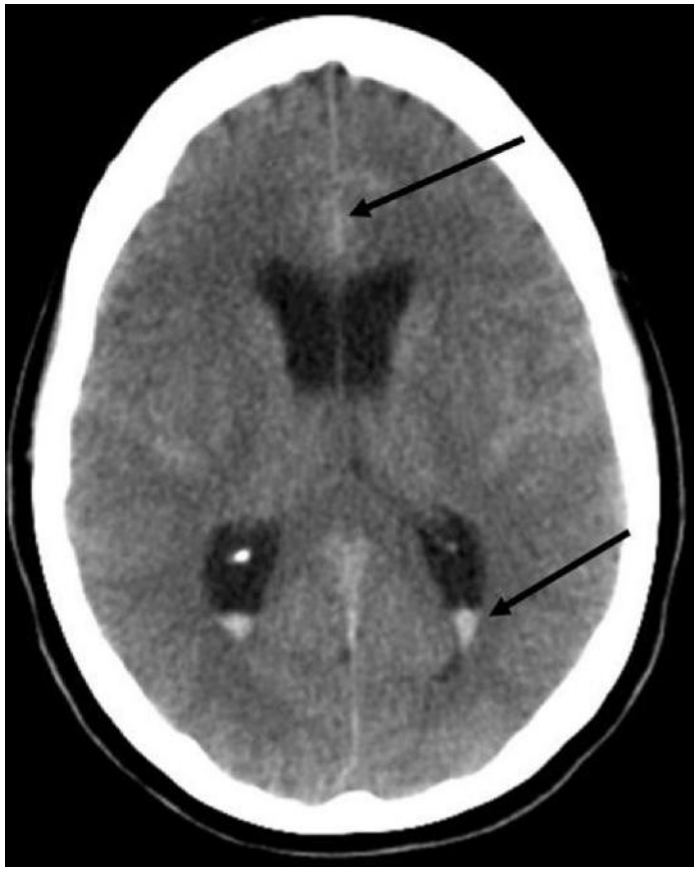

FIGURE 166-1. Diffuse subarachnoid hemorrhage with associated ventricular hemorrhage. *Top arrow* indicates blood in interhemispheric fissure. *Bottom arrow* indicates blood in lateral ventricle. [Image used with permission of James Anderson, MD, Department of Radiology, Oregon Health & Science University.]

Important consequences of this diagnostic pathway include the detection of incidental aneurysms, as opposed to clinically significant bleeds, with the background incidence of aneurysms in the population (2% to 6%) exceeding that of the morbidity and mortality associated with subarachnoid hemorrhages.[16] The major disadvantage of CT/CTA is ionizing radiation. The usefulness of MRI, particularly fluid-attenuated inversion recovery MRI sequences, is limited.[17] A negative MRI result would still need to be followed by an LP.[18] The major disadvantages of MRI/MRA at this time are availability, time to perform the examination, and cost.

Lumbar Puncture Most authorities recommend CSF analysis when a patient with suspected subarachnoid hemorrhage has a normal result on head CT.[19,20] Another advantage of LP is the ability to identify other causes of headache such as meningitis or idiopathic intracranial hypertension. The disadvantages of LP include post-LP headache and inability to perform the procedure in the patient with coagulopathy or thrombocytopenia.

The two CSF tests of greatest interest are the presence of xanthochromia and RBC count. **Xanthochromia** is a yellow appearance of the CSF due to the enzymatic breakdown of blood releasing bilirubin. Any exposure of the CSF to light prior to interpretation can increase the rate of bilirubin degradation, which decreases any xanthochromia present.[1] Similarly, a delay in processing the CSF specimen may result in the development of xanthochromia following a traumatic LP. CSF is evaluated for xanthochromia with visual inspection, the standard technique in most U.S. laboratories, or by spectrophotometry, which may have superior sensitivity but approximately 75% specificity, resulting in additional unnecessary diagnostics for false positives.[21] The utility of the

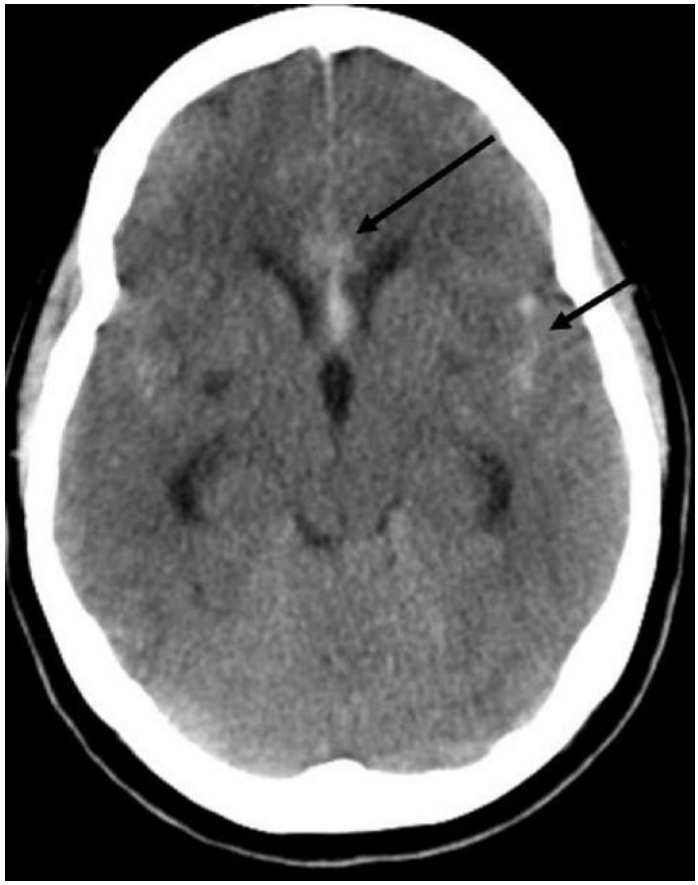

FIGURE 166-2. Scattered subarachnoid hemorrhages (*arrows*). [Image used with permission of James Anderson, MD, Department of Radiology, Oregon Health & Science University.]

test is further limited in that it takes approximately 12 hours for xanthochromia to develop in CSF.[22]

The RBC count in the third or fourth tube of CSF is commonly used to identify subarachnoid hemorrhage. Several issues can make interpreting CSF results challenging. The number of RBCs that constitutes a "positive" LP result has never been clearly defined, nor has the number of RBCs that may be attributed to a "traumatic" LP. One study showed that approximately 10% or 15% of LPs are traumatic, using cutoffs of 400 and 1000 RBCs, respectively.[23] A comparison of cell counts between consecutive tubes or between tubes 1 and 4 is sometimes used to differentiate subarachnoid hemorrhage from a traumatic LP. A small study, however, demonstrated that a 25% reduction in RBCs between tubes 1 and 4 may occur even in cases of confirmed subarachnoid hemorrhage.[24] Another small study found that RBCs <100 in the final tube effectively ruled out subarachnoid hemorrhage, whereas an RBC count of >10,000 in the final tube was associated with an increase in the odds of subarachnoid hemorrhage by a factor of 6.[25]

In general, **normal findings on head CT, the absence of xanthochromia, and zero or few RBCs ($<5 \times 10^6$ RBCs/L) in the CSF help reliably exclude subarachnoid hemorrhage**.[26] A normal head CT result with a positive finding of xanthochromia or elevated RBC count should be considered diagnostic of subarachnoid hemorrhage. **Unfortunately, the literature remains unclear on the precise threshold number of RBCs needed in the CSF to be considered diagnostic of subarachnoid hemorrhage.**

Subarachnoid Hemorrhage Grading Scales Many different subarachnoid hemorrhage grading scales exist. Those most widely used include the Hunt and Hess scale and the World Federation of Neurosurgical Societies scale (**Table 166-3**). A higher grade on either scale indicates a higher likelihood of poor outcome.

TREATMENT

Medical management of the subarachnoid hemorrhage patient in the ED should occur in a monitored critical care area and should target the prevention of complications. Check the Glasgow Coma Scale and pupillary responses regularly because a decrease of 1 Glasgow Coma Scale point can indicate the onset of complications.[1] Intracerebral and extracerebral complications of subarachnoid hemorrhage include rebleeding, vasospasm, cerebral infarction, cerebral edema, hydrocephalus, intracranial hypertension, fluid status and electrolyte abnormalities, respiratory failure, myocardial dysfunction, thromboembolism, and sepsis.[27]

The risk of rebleeding is greatest in the first 24 hours and can be reduced by adequate blood pressure control; however, the ideal target blood pressure and antihypertensive agent remain unclear. If known, maintain the patient's prehemorrhage blood pressure; otherwise, a mean arterial pressure of <140 mm Hg is a reasonable target while avoiding hypotension.[28] Because blood pressure may fluctuate through the course of the disease, a titratable IV antihypertensive is preferred. **Labetalol** and **nicardipine** are most often used, with neither showing clear superiority. **Avoid nitroprusside and nitroglycerin** because they increase cerebral blood volume and intracranial pressure.[29,30] Pain medications and antiemetics also play an important role in maintaining the alert patient's comfort and blood pressure. There is debate regarding the use of antifibrinolytics to prevent rebleeding after subarachnoid hemorrhage, with evidence supporting short- but not long-term use, although generally, these are not used because there is a risk of increased cerebral ischemia.[31]

Vasospasm is most common 2 days to 3 weeks after subarachnoid hemorrhage. A modest protective benefit is seen with administration of nimodipine, 60 milligrams PO every 4 hours, and this therapy should be initiated within 96 hours of symptom onset unless contraindicated due to allergy, nonfunctioning GI tract, or hepatic disease. Clinical trials of other novel treatments, including statins, magnesium, and endothelin receptor antagonist, have not demonstrated significant reductions in mortality.[32-36]

Delayed cerebral ischemia is associated with hypothermia, hyperthermia, and hyperglycemia. Prevent these conditions with the appropriate use of warming or cooling blankets, antipyretics, or insulin when indicated.

TABLE 166-3 Grading Scales for Subarachnoid Hemorrhage

Grade	Hunt-Hess Scale	World Federation of Neurosurgical Societies Scale
1	Mild headache, normal mental status, no cranial nerve or motor findings	GCS of 15, no motor deficits
2	Severe headache, normal mental status, may have cranial nerve deficit	GCS of 13 or 14, no motor deficits
3	Somnolent, confused, may have cranial nerve or mild motor deficit	GCS of 13 or 14, with motor deficits
4	Stupor, moderate to severe motor deficit, may have intermittent reflex posturing	GCS of 7–12, with or without motor deficits
5	Coma, reflex posturing or flaccid	GCS of 3–6, with or without motor deficits

Abbreviation: GCS = Glasgow Coma Scale score.

(*Source:* Reproduced with permission from Hemphill JC: Neurologic critical care, in Fauci AS, Braunwald E, Kasper DL, et al (eds): *Harrison's Principles of Internal Medicine, 17th ed.* © McGraw-Hill Inc., New York, 2008.)

Approximately 5% to 20% of patients with subarachnoid hemorrhage have at least one seizure. Consideration of seizure prophylaxis is currently supported by several clinical guidelines; however, this topic remains controversial and should be determined in conjunction with the intensivist or neurosurgeon who will manage the patient.[37]

DISPOSITION AND FOLLOW-UP

Admit all patients diagnosed with subarachnoid hemorrhage to an intensive care unit in consultation with a neurosurgeon. In the absence of another indication for admission, patients who have normal findings on head CT and CSF analysis within 2 weeks of occurrence of initial symptoms may be safely discharged from the ED.[1,38] Consider consultation with a neurosurgeon for patients who present >2 weeks after the sudden onset of a severe headache causing suspicion for subarachnoid hemorrhage if the initial workup yields normal findings.[1]

INTRACEREBRAL HEMORRHAGE

EPIDEMIOLOGY

Spontaneous intracerebral hemorrhage causes 8% to 11% of all acute strokes and is twice as common as subarachnoid hemorrhage. Like subarachnoid hemorrhage, intracerebral hemorrhage carries a high morbidity and mortality. Seven-day mortality is approximately 30%, 1-year mortality about 55%, and 10-year mortality approximately 80%.[39] Among those who survive, only one in five will be functionally independent at 1 year. There has been no recent change in mortality after intracerebral hemorrhage. This may be because the increased use of anticoagulation for atrial fibrillation to prevent ischemic stroke contributes to poorer outcomes in those patients taking anticoagulants who develop intracerebral hemorrhage.[39] Intracerebral hemorrhage occurs more than two times more frequently in blacks than in whites, which may be related to the higher prevalence of hypertension in blacks.[40] Anticoagulation with warfarin is a significant risk factor for intracerebral hemorrhage, with an annual intracerebral hemorrhage incidence of 0.3% to 0.6% in those taking the drug, and plays a role in 6% to 16% of all cases of intracerebral hemorrhage. Among patients taking warfarin, the risk of intracerebral hemorrhage nearly doubles for each 0.5 increase in international normalized ratio above 4.5. Intracerebral hemorrhage occurs in approximately 3% to 9% of patients treated with tissue plasminogen activator for acute ischemic stroke.[28] Current information suggests that major bleeding events occur at a similar rate with warfarin and direct thrombin inhibitors.[41]

PATHOPHYSIOLOGY

Risk factors for intracerebral hemorrhage include long-standing hypertension, arteriovenous malformations, arterial aneurysm, anticoagulant therapy, use of sympathomimetic drugs (particularly cocaine and phenylpropanolamine), intracranial tumors, and amyloid angiopathy in the elderly. Current smoking and increased frequency of smoking also raise the risk of intracerebral hemorrhage, but the etiology of this increased risk has not been as well defined as in ischemic stroke.[42]

CLINICAL FEATURES

Intracerebral hemorrhage may be clinically indistinguishable from cerebral infarction, subarachnoid hemorrhage, and ischemic stroke. In intracerebral hemorrhage, headache, nausea, and vomiting often precede the neurologic deficit, and in contrast to subarachnoid hemorrhage, the headache onset is usually more insidious. **In hypertensive intracerebral hemorrhage, bleeding is usually localized to the putamen, thalamus, pons, or cerebellum (in decreasing order of frequency)**, and clinical examination findings may be relatable to those areas. **Cerebellar hemorrhage** is commonly associated with dizziness, vomiting, marked truncal ataxia, gaze palsies, and depressed level of consciousness. Patients with cerebellar hemorrhage are more likely to have rapidly progressive symptoms and may require more aggressive intervention than patients with other forms of intracerebral hemorrhage.

DIAGNOSIS AND IMAGING

The differential diagnosis of intracerebral hemorrhage is similar to that of subarachnoid hemorrhage. The history, rapidity of progression of symptoms, and other clinical features may suggest that intracerebral hemorrhage is more likely than subarachnoid hemorrhage or ischemic stroke, but these features are not adequate alone to make a clinical diagnosis. CT and MRI each have areas of superiority in evaluating a patient for intracerebral hemorrhage. **CT is optimal for demonstrating hemorrhage extension into the ventricles, whereas MRI is superior for demonstrating underlying structural lesions.** Either modality is considered acceptable as the initial study for diagnosing intracerebral hemorrhage.[28] Widespread availability of CT makes a noncontrast CT the initial study of choice in most EDs (**Figure 166-3**). The addition of contrast may allow identification of masses or aneurysms.

Cerebral angiography may be useful in selected patients in stable condition who do not require urgent surgery, particularly those in whom no obvious cause of bleeding is identified and those younger than 45 years of age without hypertension.[43]

Additional tests should be performed to exclude coexisting pathology or facilitate surgery, if necessary, including a complete blood count, electrolyte levels, creatinine level, glucose level, electrocardiogram, chest radiograph,

FIGURE 166-3. Large right-sided parietal intraparenchymal hemorrhage (*arrow*). [Image used with permission of James Anderson, MD, Department of Radiology, Oregon Health & Science University.]

TABLE 166-4 Suggested Guidelines for Treating Elevated Blood Pressure in Spontaneous Intracranial Hemorrhage

Clinical Circumstances	Management
SBP >200 mm Hg or MAP >150 mm Hg	Consider aggressive reduction of blood pressure with continuous IV infusion.
SBP >180 mm Hg or MAP >130 mm Hg and evidence or suspicion of elevated ICP	Consider monitoring ICP and reducing blood pressure using intermittent or continuous IV medications to keep cerebral perfusion pressure >60–80 mm Hg.
SBP >180 mm Hg or MAP >130 mm Hg and no evidence or suspicion of elevated ICP	Consider a modest reduction of blood pressure (e.g., MAP of 110 mm Hg or target blood pressure of 160/90 mm Hg) using intermittent or continuous IV medications.

Abbreviations: ICP = intracranial pressure; MAP = mean arterial pressure; SBP = systolic blood pressure.

coagulation studies, and blood type and screen. A urine pregnancy test and screen for drugs of abuse should be performed as appropriate.

TREATMENT

Treatment of patients with intracerebral hemorrhage should occur in a monitored critical-care area with appropriate urgency. Patients with cerebellar hemorrhage are at particularly high risk of rapid deterioration and may require rapid intervention.[44] Maintain close attention to the patient's airway, monitoring of neurologic status, management of hyperthermia with antipyretics, administration of antiepileptic medications if seizures occur, aggressive management of hyperglycemia (>160 milligrams/dL), blood pressure management, and reversal of coagulopathy (if present). Management of elevated intracranial pressure should include raising the head of the bed 30 degrees and providing appropriate analgesia and sedation. If more aggressive reduction of intracranial pressure is required—such as administration of osmotic diuretics or intubation with neuromuscular blockade and mild hyperventilation—invasive intracranial pressure monitoring is generally indicated. Current guidelines for blood pressure management are listed in **Table 166-4**.[28] **The INTERACT2 study demonstrated no reduction in the rate of death or severe disability among patients assigned to rapid (within 1 hr) reduction of blood pressure to <140 mm Hg; however the study showed better functional outcomes in those with rapid BP reduction.**[45]

Reverse Coagulopathy Given the complexity and variety of antiplatelet and anticoagulation agents in current use, institutional protocols should be available with clear algorithms listing the indications for, and dosing of, reversal agents (**Table 166-5**). If the coagulopathy is related to heparin use, administer protamine at approximately 1 milligram per 100 units of heparin, adjusted based on the time since the heparin was last given. For patients taking warfarin, provide reversal no matter what the value of the international normalized ratio. For further discussion, see chapter 239, Thrombotics and Antithrombotics. Several options exist for reversing warfarin-induced coagulopathy: vitamin K, fresh frozen plasma, recombinant factor VIIa, and prothrombin complex concentrates. Preferred route of administration of vitamin K is the PO route, since IV and SC routes can cause anaphylaxis. Vitamin K takes many hours to be effective. Fresh frozen plasma has a faster onset but contains variable amounts of clotting factors, and the dose of 15 mL/kg requires a large volume infusion that most patients cannot tolerate. **Fresh frozen plasma can be available for rapid administration as universal donor (AB+) without the need for type and cross-match.**

Recombinant factor VIIa does not improve survival or functional outcome after intracerebral hemorrhage.[46] **Prothrombin complex concentrates** are effective and rapidly reverse oral anticoagulants; however, morbidity and mortality remain high even when the coagulopathy is reversed.[47]

TABLE 166-5 Reversal of anticoagulation for Intracerebral Hemorrhage

Anticoagulant	Reversal Agent	Comment
Warfarin	Vitamin K 2.5–5 milligrams PO	Full effect in 24 h; IV can cause anaphylaxis; allergic reactions also reported with IM and SC dosing
	Fresh frozen plasma 2 units IV	Full dose 15 mL/kg limited by volume
	Prothrombin complex concentrate (PCC) 50 IU/kg IV	Dose-related risk of thromboembolism; available as 3- (II, IX, X) and 4- (II, VII, IX, X) factor PCC; use what is available in your institution
Aspirin and adenosine diphosphate receptor agonists	Obtain consultation if available when considering platelet infusion	CAUTION: platelet reversal may cause coronary or arterial thrombosis; use only if benefits outweigh risk
Unfractionated heparin (UFH)	1 milligram protamine/100 units of UFH; maximum dose, 50 milligrams; calculate last 3 h of heparin dose to determine protamine dose because heparin has short half-life	Infusion rate ≤5 milligrams/min; risk of hypersensitivity in patients with fish allergy or prior protamine exposure: premedicate with hydrocortisone 500 milligrams IV and diphenhydramine 50 milligrams IV
Low-molecular-weight heparin (LMWH)	If last dose within 8 h, give 1 milligram protamine/1 milligram LMWH; maximum dose, 50 milligrams If last dose 8–12 h ago, give 0.5 milligram protamine/1 milligram LMWH If last dose ≥12 h ago, do not give protamine	See above protamine cautions. Infusion rate ≤5 milligrams/min; higher infusion rates can cause hypotension or bradycardia
Direct thrombin inhibitor or factor Xa inhibitors	No effective reversal agent	Consult hematology While activated charcoal 1 gram/kg can bind apixaban, rivaroxaban, or dabigatran if these drugs were taken in last 2 h, risk of CNS deterioration and pulmonary aspiration typically prohibit use in CNS bleed

Manage intracerebral hemorrhage related to fibrinolytic therapy with standard intracerebral hemorrhage treatment along with platelet and cryoprecipitate infusions, although little evidence exists to guide therapy in these cases.[28]

DISPOSITION AND FOLLOW-UP

Admit all patients to an intensive care unit in consultation with a neurosurgeon.

CHAPTER 167

Stroke Syndromes

Steven Go
Daniel J. Worman

INTRODUCTION AND EPIDEMIOLOGY

In the United States, 795,000 people experience strokes annually (one stroke every 40 seconds).[1] Of these events, 77% are primary strokes, whereas 23% represent recurrent strokes.[1] In addition to the human costs, the financial implications of stroke are enormous—strokes accounted for an estimated $36.5 billion of total expenditures in the United States in 2010. Despite these grim statistics, from 2000 to 2010, the annual stroke death rate fell 35.8%.[2] With the growing use of stroke units, thrombolysis, and other new therapies, there is increased hope for patients with acute stroke who present to the ED.

PATHOPHYSIOLOGY

Stroke is generally defined as any disease process that interrupts blood flow to the brain. Injury is related to the loss of oxygen and glucose substrates necessary for high-energy phosphate production and the presence of mediators of secondary cellular injury. Subsequent factors, such as edema and mass effect, may exacerbate the initial insult.

ANATOMY

An understanding of the diagnosis and treatment of stroke begins with a working knowledge of the relevant vascular supply and neuroanatomy of the brain.

The arterial supply to the brain is illustrated in **Figures 167-1 and 167-2**.

The vascular supply is divided into anterior and posterior circulations. Clinical findings in stroke are determined by the location of the lesion(s) (**Table 167-1**), but the degree of collateral circulation may cause variations in the specific clinical symptoms and their severity.

STROKE TYPE

Stroke results from two major mechanisms: ischemia and hemorrhage. Ischemic strokes account for 87% of all strokes and are categorized by cause: thrombotic, embolic, or hypoperfusion related. Hemorrhagic strokes are subdivided into intracerebral (accounting for 10% of all strokes) and nontraumatic subarachnoid hemorrhage (accounting for 3% of all strokes)[1] (**Table 167-2**). The final common pathway for all of these mechanisms is altered neuronal perfusion. Neurons are exquisitely sensitive to changes in cerebral blood flow and die within minutes of complete cessation of perfusion—hence, the current treatment emphasis on rapid reperfusion strategies.

PREHOSPITAL CARE

The early detection of stroke must begin with the general public. In general, stroke knowledge among laypersons remains suboptimal and has led to several educational initiatives to raise stroke awareness.[3]

Three of the more commonly used prehospital tools are the Cincinnati Prehospital Stroke Scale,[4] the Los Angeles Prehospital Stroke Screen,[5] and the Melbourne Ambulance Stroke Screen (**Table 167-3**).[6]

Time is a critical component in the care of stroke patients. EMS personnel should quickly ascertain the time of onset of the patient's symptoms, giving particular attention to bystander accounts to clarify details, because stroke patients may be poor historians. Family members and/or witnesses to the event should be urged to come to the ED as soon as possible to provide further medical information to the treating physician. Time at the scene should be limited: EMS personnel should rapidly stabilize the patient's condition and transport the patient to a facility capable of optimally managing acute stroke, being sure to notify the receiving facility of the patient's condition and estimated time of arrival. In some cases, it may be necessary to bypass closer, but less capable, facilities in order to increase the chances of the patient receiving the best possible care.[7]

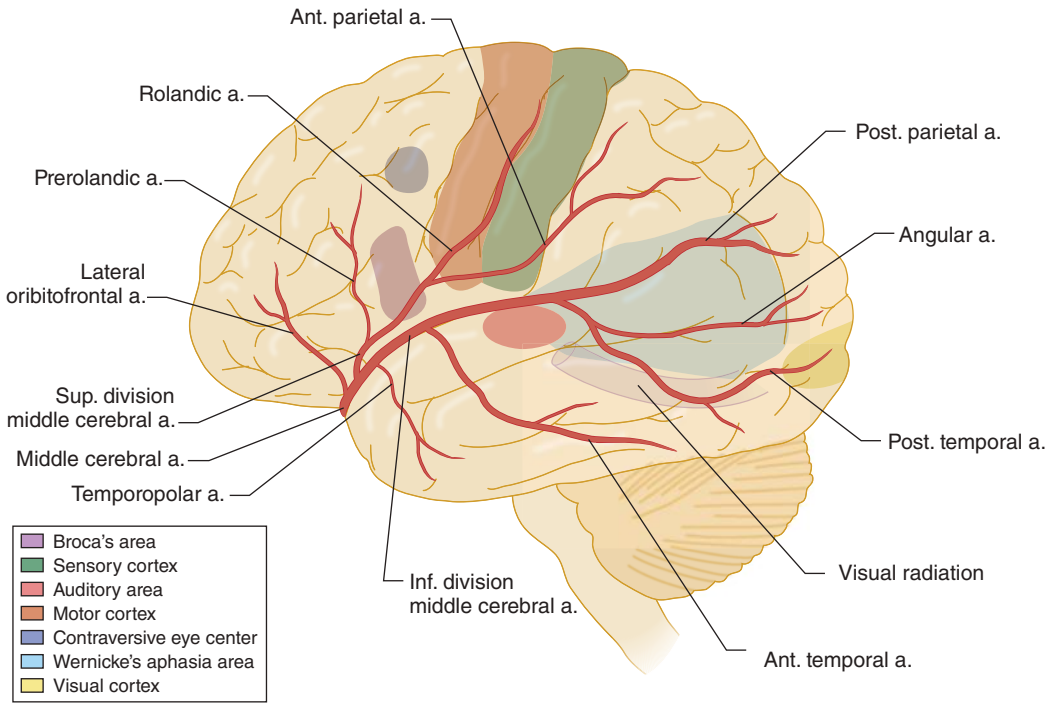

FIGURE 167-1. Cerebral hemisphere, lateral aspect. Note the branches and distribution of the middle cerebral artery and the principal regions of cerebral localization. CLINICAL FEATURES

The diagnosis of stroke in the ED rests on the bedrock of a focused, accurate history and physical examination.[8] The clinical presentation of stroke can range from the obvious (facial droop, arm drift, abnormal speech[8]) to the subtle (generalized weakness, lightheadedness, vague sensory changes, altered mental status). Women account for slightly more than half of new or recurrent strokes in the United States,[9] and modest gender differences exist in terms of presenting signs and symptoms.[10,11] In general, women tend to report diffuse, nontraditional symptoms and are less likely to report traditional symptoms when compared to men, but evidence of these distinctions is limited (**Table 167-4**).[10-12]

TABLE 167-1 Anterior and Posterior Circulation of the Brain

Circulation	Major Arteries	Major Regions of Brain Supplied
Anterior (internal carotid system)	Ophthalmic	Optic nerve and retina
	Anterior cerebral	Frontal pole
		Anteromedial cerebral cortex
		Anterior corpus callosum
	Middle cerebral	Frontoparietal lobe
		Anterotemporal lobe
Posterior (vertebral system)	Vertebral	Brainstem
	Posteroinferior cerebellar	Cerebellum
	Basilar	Thalamus
	Posterior cerebral	Auditory/vestibular structures
	Medial temporal lobe	Visual occipital cortex

HISTORY

The timing of symptom onset, the presence of associated symptoms, and the medical history may point toward a particular mechanism of stroke. For example, sudden onset of symptoms suggests an embolic or hemorrhagic stroke, whereas a stuttering or waxing and waning deficit suggests a thrombotic or hypoperfusion-related stroke. A history of Valsalva maneuver immediately preceding a thunderclap headache or sudden onset of symptoms suggests a ruptured cerebral aneurysm, whereas a recent history of neck trauma or manipulation suggests cervical artery dissection. Risk factors for vessel thrombus include hypertension, diabetes mellitus, and coronary atherosclerotic disease. In contrast, atrial fibrillation, valvular replacement, or recent myocardial infarction suggests embolism. Transient neurologic deficits occurring in the same vascular distribution suggest underlying vascular disease consistent with a thrombotic stroke, whereas transient deficits involving different vascular distributions suggest embolism. Although adjunctive history can be helpful in determining the type of stroke, exhaustive or unduly prolonged attempts to elicit nonessential history should not delay therapy.

Accurately determine the time of symptom onset. Time of onset is frequently misreported as the time a patient was *discovered* with symptoms or the time of awakening (if symptoms were noted upon awakening). For the purposes of thrombolysis, if a patient awakens with the symptoms of stroke, **the time of onset is the last known time when the patient's condition was at baseline.**[7]

Exclude as many **stroke mimics** as possible (**Table 167-5**).[7,8,13] After stroke mimics are excluded, if acute stroke is still the most likely diagnosis and if the symptom onset is within the recommended time limits for thrombolytic therapy, elicit information pertaining to inclusion and exclusion criteria for thrombolytic therapy (see Table 167-11[7,14] and Table 167-12[7,15] for the criteria for administration of recombinant tissue plasminogen activator [rtPA] in acute ischemic stroke).

TABLE 167-2 Stroke Classification

Stroke Type	Mechanism	Major Causes	Clinical Notes
Ischemic			
Thrombotic	Narrowing of a damaged vascular lumen by an in situ process—usually clot formation	Atherosclerosis Vasculitis Arterial dissection Polycythemia Hypercoagulable state Infection (human immunodeficiency virus infection, syphilis, trichinosis, tuberculosis, aspergillosis)	Symptoms often have gradual onset and may wax and wane. Common cause of transient ischemic attack.
Embolic	Obstruction of a normal vascular lumen by intravascular material from a remote source	Valvular vegetations Mural thrombi Paradoxical emboli Cardiac tumors (myxomas) Arterial-arterial emboli from proximal source Fat emboli Particulate emboli (IV drug use) Septic emboli	Typically sudden in onset. Account for 20% of ischemic strokes.
Hypoperfusion	Low–blood flow state leading to hypoperfusion of the brain	Cardiac failure resulting in systemic hypotension	Diffuse injury pattern in watershed regions. Symptoms may wax and wane with hemodynamic factors.
Hemorrhagic			
Intracerebral	Intraparenchymal hemorrhage from previously weakened arterioles	Hypertension Amyloidosis Iatrogenic anticoagulation Vascular malformations Cocaine use	Intracranial pressure rise causes local neuronal damage. Secondary vasoconstriction mediated by blood breakdown products or neuronal mechanisms (diaschisis) can cause remote perfusion changes. Risks include advanced age, history of stroke, and tobacco or alcohol use. More common in those of Asian or African descent.
Nontraumatic subarachnoid	Hemorrhage into subarachnoid space	Berry aneurysm rupture Vascular malformation rupture	May be preceded by a sentinel headache ("warning leak").

PHYSICAL EXAMINATION

Airway, breathing, and circulation are the top priorities. Next, the goals of examination are to confirm the diagnosis of stroke, exclude stroke mimics, and identify comorbidities. Fever should prompt an investigation for potential infection. CNS infections (meningitis, encephalitis) may mimic a stroke, or an infection such as aspiration pneumonia or a urinary tract infection may be a complication of the stroke. Look for meningismus, signs of emboli (Janeway lesions and Osler nodes), and bleeding diatheses (ecchymoses or petechiae). A funduscopic examination may identify signs of papilledema (suggesting a mass lesion, cerebral vein thrombosis, or hypertensive crisis) or preretinal hemorrhage (consistent with subarachnoid hemorrhage).

TABLE 167-3 Prehospital Stroke Scales

Cincinnati Prehospital Stroke Scale (If *any* of the three items is abnormal, sensitivity = 66%, specificity = 87% for acute stroke.)	1. Facial droop (abnormal: one side of face does not move as well as other side) 2. Arm drift (abnormal: one arm does not move or one arm drifts down compared with the other) 3. Speech (abnormal: slurred, inappropriate words or mute)
Los Angeles Prehospital Stroke Screen (If answers to *all* items 1–6 are "Yes" or "Unknown," sensitivity = 91% [95% confidence interval (CI) 76%–98%], specificity = 97% [95% CI 93%–99%] for acute stroke.)	1. Age >45 y 2. No history of seizure disorder 3. New onset of neurologic symptoms in last 24 h 4. Patient ambulatory at baseline (prior to event) 5. Blood glucose level of 60–400 milligrams/dL 6. Obvious asymmetry in *any* of the following examinations: facial smile/grimace, grip, arm strength
Melbourne Ambulance Stroke Screen (If answers to *all* items 1-4 are "Yes" PLUS at least one of 5-8 is present, sensitivity = 90% [95% CI: 81%-96%), specificity = 74% [95% CI: 53%-88%] for acute stroke.)	1. Age > 45 y 2. No history of seizure/epilepsy 3. Not wheelchair-bound/bedridden at baseline 4. Blood Glucose 50-400 mg/dL 5. Unilateral facial droop 6. Unilateral hand grip weakness 7. Unilateral arm drift 8. Abnormal speech

TABLE 167-4 Selected Stroke Symptoms

Traditional symptoms	Sudden numbness or weakness of face, arm, or leg—especially unilateral*
	Sudden altered mental status†
	Sudden aphasia
	Sudden memory deficit or spatial orientation or perception difficulties
	Sudden visual deficit or diplopia*
	Sudden dizziness, gait disturbance, or ataxia*
	Sudden severe headache with no known cause
Nontraditional symptoms	Loss of consciousness or syncope
	Generalized weakness†
	Shortness of breath
	Sudden pain in the face, chest, arms, or legs
	Seizure
	Falls or accidents
	Sudden hiccups
	Sudden nausea
	Sudden fatigue
	Sudden palpitations
	Altered mental status

*More common in men.

†More common in women.

Look for findings suggestive of possible cardiac or vascular disease, such as rales, an S_3 gallop, or carotid bruit.

The National Institutes of Health Stroke Scale (NIHSS) is the standard tool for documenting the severity of a stroke. The **NIHSS** is an 11-category (15-item) neurologic evaluation (score range of 0 to 42) that is quick to use (5 to 10 minutes), yields reproducible results, has a high interrater reliability, and provides a score that correlates with infarct volume[16] (**Table 167-6**).[17,18] An Adobe Acrobat (pdf) file of the NIHSS, as well as detailed instructions for its use, are readily available for download from the National Institute of Neurological Disorders and Stroke (NINDS) Web site (http://www.ninds.nih.gov/doctors/nih_stroke_scale.pdf). In addition, NIHSS calculators are available on the Internet[19] and for use with mobile devices.[20,21] A modified NIHSS, which omits the redundant and least reliable items, produces clinical results similar to those for the full NIHSS[18] and is easier to use (score range of 0 to 31). An important caveat is that the NIHSS is weighted toward the detection of anterior circulation strokes as opposed to posterior circulation strokes.[22] This is because common symptoms of posterior strokes (cranial nerve deficits and ataxia) receive fewer points, and ataxia is often scored as absent by raters if weakness is present. For example, one study[23] found that the NIHSS score associated with a favorable outcome was ≤5 for posterior circulation strokes and ≤8 for anterior circulation strokes. In addition, the NIHSS has a bias toward detection of dominant hemisphere strokes.[24]

ISCHEMIC STROKE SYNDROMES

ANTERIOR CEREBRAL ARTERY INFARCTION

Occlusion of the anterior cerebral artery is uncommon (0.5% to 3% of all strokes[25]), but when unilateral occlusion occurs, it can cause contralateral sensory and motor symptoms in the lower extremity, with sparing of the hands and face. In addition, a left-sided lesion is typically associated with akinetic mutism and transcortical motor aphasia (repetition ability retained), whereas right-sided infarction can result in confusion and motor hemineglect. Bilateral occlusion can cause a combination of the above symptoms, but was particularly associated with mutism, incontinence, and poor outcome in one small series.[26]

TABLE 167-5 Stroke Mimics

Disorder	Distinguishing Clinical Features
Seizures/postictal paralysis (Todd's paralysis)	Transient paralysis following a seizure, which typically disappears quickly; can be confused with transient ischemic attack. Seizures can be secondary to a cerebrovascular accident.
Syncope	No persistent or associated neurologic symptoms.
Meningitis/encephalitis	Fever, immunocompromised state may be present, meningismus, detectable on lumbar puncture.
Complicated migraine	History of similar episodes, preceding aura, headache.
Brain neoplasm or abscess	Focal neurologic findings, signs of infection, detectable by imaging.
Epidural/subdural hematoma	History of trauma, alcoholism, anticoagulant use, bleeding disorder; detectable by imaging.
Subarachnoid hemorrhage	Sudden onset of severe headache.*
Hypoglycemia	Can be detected by bedside glucose measurement, history of diabetes mellitus.
Hyponatremia	History of diuretic use, neoplasm, excessive free water intake.
Hypertensive encephalopathy	Gradual onset; global cerebral dysfunction, headache, delirium, hypertension, cerebral edema.
Hyperosmotic coma	Extremely high glucose levels, history of diabetes mellitus.
Wernicke's encephalopathy	History of alcoholism or malnutrition; triad of ataxia, ophthalmoplegia, and confusion.
Labyrinthitis	Predominantly vestibular symptoms; patient should have no other focal findings; can be confused with cerebellar stroke.
Drug toxicity (lithium, phenytoin, carbamazepine)	Can be detected by particular toxidromes and elevated blood levels. Phenytoin and carbamazepine toxicity may present with ataxia, vertigo, nausea, and abnormal reflexes.
Bell's palsy	Neurologic deficit confined to isolated *peripheral* seventh nerve palsy; often associated with younger age.
Ménière's disease	History of recurrent episodes dominated by vertigo symptoms, tinnitus, deafness.
Demyelinating disease (multiple sclerosis)	Gradual onset. Patient may have a history of multiple episodes of neurologic findings in multifocal anatomic distributions.
Conversion disorder	No cranial nerve findings, nonanatomic distribution of findings (e.g., midline sensory loss), inconsistent history or examination findings.

*Although subarachnoid hemorrhage is a type of stroke, it has special considerations in terms of diagnosis and management. See chapter 166, "Spontaneous Subarachnoid and Intracerebral Hemorrhage."

MIDDLE CEREBRAL ARTERY INFARCTION

The middle cerebral artery is the vessel most commonly involved in stroke, and clinical findings can be quite variable, depending on exactly where the lesion is located and which brain hemisphere is dominant. (In right-handed patients and in up to 80% of left-handed patients, the left hemisphere is dominant.) A middle cerebral artery stroke typically presents with hemiparesis, facial plegia, and sensory loss contralateral to the affected cortex. These deficits variably affect the face and upper extremity more than the lower extremity. If the dominant hemisphere is involved, aphasia (receptive, expressive, or both) is often present. If the nondominant hemisphere is involved, inattention, neglect, extinction on double-simultaneous stimulation, dysarthria without aphasia, and constructional apraxia (difficulty in drawing complex two-dimensional or three-dimensional figures) may occur. A homonymous hemianopsia and gaze preference toward the side of the infarct may also be seen, regardless of the side of the infarction.

POSTERIOR CEREBRAL ARTERY INFARCTION (DISTAL POSTERIOR CIRCULATION)

The classic symptoms and signs of posterior circulation strokes include ataxia, nystagmus, altered mental status, and vertigo, but presentation

TABLE 167-6 National Institutes of Health Stroke Scale (NIHSS)

Instructions	Scale Definition
1a. Level of consciousness (LOC)* The investigator must choose a response if a full evaluation is prevented by such obstacles as an endotracheal tube, language barrier, or orotracheal trauma/bandages. A 3 is scored only if the patient makes no movement (other than reflexive posturing) in response to noxious stimulation.	0 = Alert; keenly responsive. 1 = Not alert, but arousable by minor stimulation to obey, answer, or respond. 2 = Not alert; requires repeated stimulation to attend, or is obtunded and requires strong or painful stimulation to make movements (not stereotyped). 3 = Responds only with reflex motor or autonomic effects or is totally unresponsive, flaccid, and areflexic.
1b. LOC questions The patient is asked the month and his or her age. The answer must be correct—there is no partial credit for being close. Aphasic and stuporous patients who do not comprehend the questions are given a score of 2. Patients unable to speak because of endotracheal intubation, orotracheal trauma, severe dysarthria from any cause, language barrier, or any other problem not secondary to aphasia are given a score of 1. It is important that only the initial answer be graded and that the examiner not "help" the patient with verbal or nonverbal cues.	0 = Answers both questions correctly. 1 = Answers one question correctly. 2 = Answers neither question correctly.
1c. LOC commands The patient is asked to open and close the eyes and then to grip and release the nonparetic hand. Substitute another one-step command if the hands cannot be used. Credit is given if an unequivocal attempt is made but not completed due to weakness. If the patient does not respond to command, the task should be demonstrated to him or her (pantomime) and the result scored (i.e., follows no, one, or two commands). Patients with trauma, amputation, or other physical impediments should be given suitable one-step commands. Only the first attempt is scored.	0 = Performs both tasks correctly. 1 = Performs one task correctly. 2 = Performs neither task correctly.
2. Best gaze Only horizontal eye movements are tested. Voluntary or reflexive (oculocephalic) eye movements are scored, but caloric testing is not done. If the patient has a conjugate deviation of the eyes that can be overcome by voluntary or reflexive activity, the score is 1. If a patient has an isolated peripheral nerve paresis (cranial nerve III, IV, or VI), the score is 1. Gaze is testable in all aphasic patients. Patients with ocular trauma, bandages, preexisting blindness, or other disorder of visual acuity or fields should be tested with reflexive movements, and a choice made by the investigator. Establishing eye contact and then moving about the patient from side to side will occasionally clarify the presence of a partial gaze palsy.	0 = Normal. 1 = Partial gaze palsy; gaze is abnormal in one or both eyes, but forced deviation or total gaze paresis is not present. 2 = Forced deviation, or total gaze paresis not overcome by the oculocephalic maneuver.
3. Visual Visual fields (upper and lower quadrants) are tested by confrontation, using finger counting or visual threat, as appropriate. Patients may be encouraged, but if they look at the side of the moving fingers appropriately, this can be scored as normal. If there is unilateral blindness or enucleation, visual fields in the remaining eye are scored. Score 1 only if a clear-cut asymmetry, including quadrantanopia, is found. If the patient is blind from any cause, score 3. Double simultaneous stimulation is performed at this point. If there is extinction, patient receives a score of 1, and the results are used to respond to item 11.	0 = No vision loss. 1 = Partial hemianopia. 2 = Complete hemianopia. 3 = Bilateral hemianopia (blind including cortical blindness).
4. Facial palsy* Ask—or use pantomime to encourage—the patient to show teeth or raise eyebrows and close eyes. Score symmetry of grimace in response to noxious stimuli in the poorly responsive or noncomprehending patient. If facial trauma/bandages, orotracheal tube, tape, or other physical barriers obscure the face, these should be removed to the extent possible.	0 = Normal symmetric movements. 1 = Minor paralysis (flattened nasolabial fold, asymmetry on smiling). 2 = Partial paralysis (total or near-total paralysis of lower face). 3 = Complete paralysis of one or both sides (absence of facial movement in the upper and lower face).
5. Motor arm The limb is placed in the appropriate position: extend the arms (palms down) 90 degrees (if sitting) or 45 degrees (if supine). Drift is scored if the arm falls before 10 s. The aphasic patient is encouraged using urgency in the voice and pantomime, but not noxious stimulation. Each limb is tested in turn, beginning with the nonparetic arm. Only in the case of amputation or joint fusion at the shoulder, the examiner should record the score as untestable (UN) and clearly write the explanation for this choice. 5a. Left arm 5b. Right arm	0 = No drift; limb holds 90 (or 45) degrees for full 10 s. 1 = Drift; limb holds 90 (or 45) degrees, but drifts down before full 10 s; does not hit bed or other support. 2 = Some effort against gravity; limb cannot get to or maintain (if cued) 90 (or 45) degrees, drifts down to bed, but has some effort against gravity. 3 = No effort against gravity; limb falls. 4 = No movement.
6. Motor leg The limb is placed in the appropriate position: hold the leg at 30 degrees (the patient is always tested supine). Drift is scored if the leg falls before 5 s. The aphasic patient is encouraged using urgency in the voice and pantomime, but not noxious stimulation. Each limb is tested in turn, beginning with the nonparetic leg. Only in the case of amputation or joint fusion at the hip, the examiner should record the score as untestable (UN) and clearly write the explanation for this choice. 6a. Left leg 6b. Right leg	0 = No drift; leg holds 30-degree position for full 5 s. 1 = Drift; leg falls by the end of the 5-s period but does not hit bed. 2 = Some effort against gravity; leg falls to bed by 5 s, but has some effort against gravity. 3 = No effort against gravity; leg falls to bed immediately. 4 = No movement.

(*Continued*)

TABLE 167-6 National Institutes of Health Stroke Scale (NIHSS) (*Continued*)

Instructions	Scale Definition
7. Limb ataxia* This item is aimed at finding evidence of a unilateral cerebellar lesion. Test with the patient's eyes open. In case of visual defect, ensure that testing is done in the intact visual field. The finger-nose-finger and heel-shin tests are performed on both sides, and ataxia is scored only if present out of proportion to weakness. Ataxia is absent in the patient who cannot understand or is paralyzed. Only in the case of amputation or joint fusion, the examiner should record the score as untestable (UN) and clearly write the explanation for this choice. In case of blindness, test by having the patient touch the nose from an extended arm position.	0 = Absent. 1 = Present in one limb. 2 = Present in two limbs.
8. Sensory† Sensation or grimace to pinprick when tested, or withdrawal from a noxious stimulus in the obtunded or aphasic patient. Only sensory loss attributed to stroke is scored as abnormal, and the examiner should test as many body areas (arms [not hands], legs, trunk, face) as needed to check accurately for hemisensory loss. A score of 2, "severe or total sensory loss," should be given only when a severe or total loss of sensation can be clearly demonstrated. Stuporous and aphasic patients will therefore probably score 1 or 0. The patient with brainstem stroke who has bilateral loss of sensation is scored 2. If the patient does not respond and is quadriplegic, score 2. Patients in a coma (item 1a score = 3) are automatically given a 2 on this item.	0 = Normal; no sensory loss. 1 = Mild-to-moderate sensory loss; patient feels pinprick is less sharp or is dull on affected side, or there is loss of superficial pain with pinprick, but patient is aware of being touched. 2 = Severe to total sensory loss; patient is not aware of being touched on face, arm, and leg.*
9. Best language A great deal of information about comprehension is obtained during the preceding sections of the examination. For this scale item, the patient is asked to describe what is happening in the test picture, to name the items on the test naming sheet, and to read from the test list of sentences. Comprehension is judged from responses here as well as responses to all of the commands in the preceding general neurologic examination. If vision loss interferes with the tests, ask the patient to identify objects placed in the hand, repeat, and produce speech. The intubated patient should be asked to write. The patient in a coma (item 1a score = 3) automatically scores 3 on this item. The examiner must choose a score for the patient with stupor or limited cooperation, but a score of 3 should be used only if the patient is mute and follows no one-step commands.	0 = No aphasia; normal. 1 = Mild-to-moderate aphasia; some obvious loss of fluency or facility of comprehension, without significant limitation on ideas expressed or form of expression. However, reduction of speech and/or comprehension makes conversation about provided materials difficult or impossible. For example, in conversation about provided materials, examiner can identify picture or naming card content from patient's response. 2 = Severe aphasia; all communication is through fragmentary expression; great need for inference, questioning, and guessing by listener. Range of information that can be exchanged is limited; listener carries burden of communication. Examiner cannot identify materials provided from patient's response. 3 = Mute, global aphasia; no usable speech or auditory comprehension.
10. Dysarthria* If the patient is thought to be normal, an adequate sample of speech must be obtained by asking the patient to read or repeat words from the test list. If the patient has severe aphasia, the clarity of articulation of spontaneous speech can be rated. Only if the patient is intubated or has other physical barriers to producing speech, the examiner should record the score as untestable (UN) and clearly write an explanation for this choice. Do not tell the patient why he or she is being tested.	0 = Normal. 1 = Mild-to-moderate dysarthria; patient slurs at least some words and, at worst, can be understood with some difficulty. 2 = Severe dysarthria; patient's speech is so slurred as to be unintelligible in the absence of or out of proportion to any dysphasia, or is mute/anarthric.
11. Extinction and inattention Sufficient information to identify neglect may be obtained during the prior testing. If the patient has a severe vision loss preventing visual double simultaneous stimulation and the responses to cutaneous stimuli are normal, the score is 0. If the patient has aphasia but does appear to attend to both sides, the score is 0. The presence of visual spatial neglect or anosognosia may also be taken as evidence of abnormality. Because the abnormality is scored only if present, the item is never scored as untestable.	0 = No abnormality. 1 = Visual, tactile, auditory, spatial, or personal inattention or extinction to bilateral simultaneous stimulation in one of the sensory modalities. 2 = Profound hemi-inattention or extinction in more than one modality; patient does not recognize own hand or orients to only one side of space.

*Shaded cells indicate items not included in the modified NIHSS.[18]

†Scale for item 8 is compressed to two elements (0 = normal; 1 = abnormal) for modified NIHSS.[18]

Source: National Institute of Neurological Disorders and Stroke (NINDS) Web site (http://www.ninds.nih.gov/doctors/nih_stroke_scale.pdf). Accessed January 18, 2014.

can sometimes be rather subtle.[27] Crossed neurologic deficits (e.g., ipsilateral cranial nerve deficits with contralateral motor weakness) may indicate a brainstem lesion. According to an analysis of a large stroke registry,[28] symptoms of posterior cerebral artery involvement include unilateral limb weakness, dizziness, blurry vision, headache, and dysarthria. Common presenting signs include visual field loss, unilateral limb weakness, gait ataxia, unilateral limb ataxia, cranial nerve VII signs, lethargy, and sensory deficits.[28] Visual field loss, classically described as contralateral homonymous hemianopsia and unilateral cortical blindness, is thought to be specific for distal posterior circulation stroke because the visual centers of the brain are supplied by the posterior cerebral artery. Light-touch and pinprick sensation deficits, loss of ability to read (alexia) without agraphia, inability to name colors, recent memory loss, unilateral third nerve palsy, and hemiballismus have also been reported. Motor dysfunction, although common, is typically minimal, which can keep some patients from realizing they have had a stroke.

BASILAR ARTERY OCCLUSION (MIDDLE POSTERIOR CIRCULATION)

Occlusion of the basilar artery most commonly presents with symptoms of unilateral limb weakness, dizziness, dysarthria, diplopia, and headache.[28] The most common presenting signs are unilateral limb weakness, cranial nerve VII signs, dysarthria, Babinski sign, and oculomotor signs.[28] Dysphagia, nausea or vomiting, dizziness, and Horner's syndrome are positively correlated with basilar artery occlusion.[28] Basilar artery occlusion can also rarely cause **locked-in syndrome**, which occurs with bilateral pyramidal tract lesions in the ventral pons and is characterized by complete muscle paralysis except for upward gaze and blinking. Basilar artery occlusions have a high risk of death and poor outcomes.[29]

VERTEBROBASILAR INFARCTION (PROXIMAL POSTERIOR CIRCULATION)

Patients with vertebrobasilar infarction most commonly present with symptoms of dizziness, nausea or vomiting, headache, dysphagia, unilateral limb

weakness, and unilateral cranial nerve V symptoms.[28] Common presenting signs include unilateral limb ataxia, nystagmus, gait ataxia, cranial nerve V signs, limb sensory deficit, and Horner's syndrome.[28] For further discussion of vertigo, see chapter 170, "Vertigo."

CEREBELLAR INFARCTION

Patients with cerebellar infarction can present with very nonspecific symptoms and frequently present with dizziness (with or without vertigo), nausea and vomiting, gait instability, headache, limb ataxia, dysarthria, nystagmus, and cranial nerve abnormalities.[30] Mental status may vary from alert to comatose. Because CT is inadequately sensitive for posterior fossa lesions, **obtain a diffusion-weighted MRI (DWI-MRI) when this diagnosis is suspected**. A CT angiogram or magnetic resonance angiogram is useful to characterize any vascular lesion once the diagnosis is made. The clinical presentation and course of cerebellar infarction can be frustratingly difficult to predict, but the clinician must remain vigilant to the possibility of rapid deterioration secondary to increased brainstem pressure caused by cerebellar edema. Therefore, extremely close serial examinations (especially looking for gaze palsy and altered mental status) and prompt neurologic and neurosurgical bedside consultations are needed. **Obtain early neurosurgical consultation for patients with cerebellar infarction.** Cerebellar edema can lead to rapid deterioration with herniation, and consultation is required to determine the need for emergency posterior fossa decompression in these patients. Acute **obstructing hydrocephalus** requires treatment of elevated intracranial pressure and emergent surgical decompression.[30]

LACUNAR INFARCTION

Lacunar infarcts are pure motor or sensory deficits caused by infarction of small penetrating arteries and are commonly associated with chronic hypertension and increasing age. The presentation is variable based on the location and size of the lesions. The prognosis is generally considered more favorable than for other stroke syndromes.

CAROTID AND VERTEBRAL ARTERY DISSECTION

Carotid or vertebral artery dissection is an uncommon but important cause of stroke (10% to 25% of cases), especially in young and middle-aged patients.[31] A history of neck trauma in the days to weeks prior to presentation is a prominent risk factor. The trauma is usually minor[32] (e.g., manipulative therapy of the neck[33] or sport-related trauma[34]). Other risk factors include connective tissue disease,[35] history of migraine,[36] large vessel arteriopathies,[37] and hypertension.[38]

The typical first symptom of patients with carotid or vertebral artery dissection is unilateral **headache** (68%), neck pain (39%), or face pain (10%),[39-41] which can precede other symptoms by hours to days (median, 4 days).[42] New-onset headache or neck pain of unclear etiology is such an important symptom that imaging of the neck vessels is recommended by some as part of initial evaluation.[41] **Symptoms may be transient or persistent.** The median time between an initial presentation of neck pain and the development of other neurologic symptoms is 14 days, but if headache is the first symptom, other neurologic symptoms follow within a median time of 15 hours.[42]

Carotid Artery Dissection The headache is most commonly in the frontotemporal region and, due to its variable quality and severity, may mimic subarachnoid hemorrhage (i.e., "thunderclap" headache), temporal arteritis, or preexisting migraine. A partial Horner's syndrome (miosis and ptosis) has traditionally been linked to carotid artery dissection, but in reality, it occurs in only about 25% of patients and is a sign accompanying other disorders besides stroke.[43] Associated cranial nerve palsies have been reported in 12% of carotid artery dissections.[44] Carotid dissection can progress to cause cerebral ischemia or, rarely, retinal infarction.

Vertebral Artery Dissection Vertebral artery dissection commonly presents with neck pain (66%) and headache (65%), both of which can be unilateral or bilateral.[40] The headache is typically occipital, but can rarely present with pain on an entire side of the head or in the frontal region.[39] Other symptoms and signs may include unilateral facial paresthesia, dizziness, vertigo, nausea/emesis, diplopia and other visual disturbances, ataxia, limb weakness, numbness, dysarthria, and hearing loss. Cervical radiculopathy (typically a peripheral motor deficit at the C5 level) is a rare presentation (1%) and can also involve multiple levels and sensory findings.[45] Untreated vertebral artery dissection may result in infarction in regions of the brain supplied by the posterior circulation.

MRI/magnetic resonance angiography and CT/CT angiography are the diagnostic modalities of choice for suspected carotid, vertebral, or basilar artery dissection.[46] Choice of study is usually determined by consultation with the neurologist and radiologist.[47] Color duplex US may not detect important vascular lesions.[48,49]

Treatment of Carotid and Vertebral Artery Dissection In the absence of contraindications, carotid and vertebral artery dissection has been traditionally treated with IV heparin followed by warfarin (to maintain an INR of 2.0 to 3.0). This treatment has persisted despite the absence to date of published, high-quality randomized controlled trials comparing anticoagulation with other potentially more effective treatment modalities.[50] In 2012, the nonrandomized arm (88 patients) of the Cervical Artery Dissection in Stroke Study was published along with a meta-analysis of previous trials.[51] These preliminary results showed no difference between anticoagulation and antiplatelet therapy in terms of prevention of stroke after cervical artery dissection. Nonrandomized data regarding endovascular approaches to cervical artery dissection have been published, but no randomized controlled trial has been published yet. Therefore, pending the availability of new randomized controlled trial data, administer either anticoagulant or antiplatelet therapy in the ED in conjunction with appropriate specialist consultation.

HEMORRHAGIC STROKE SYNDROMES

INTRACEREBRAL HEMORRHAGE

Intracerebral hemorrhage may be clinically indistinguishable from ischemic infarction, but the two conditions are distinct clinical entities in terms of management, with higher levels of morbidity and mortality for hemorrhage than for ischemic infarction.[52,53] Therefore, perform imaging to differentiate between the two. Headache, nausea, and vomiting often precede the neurologic deficit, and the patient's condition may quickly deteriorate (see chapter 166, "Spontaneous Subarachnoid and Intracerebral Hemorrhage").

CEREBELLAR HEMORRHAGE

Cerebellar hemorrhage may be clinically indistinguishable from cerebellar infarction. The same clinical presentation and management considerations detailed earlier in this chapter apply (see "Cerebellar Infarction").

SUBARACHNOID HEMORRHAGE

Subarachnoid hemorrhage is typically characterized by a severe occipital or nuchal headache. Patient history includes the recent sudden onset of a maximal-intensity headache in many cases. Careful history taking may reveal activities associated with a Valsalva maneuver, such as defecation, sexual activity, weight lifting, or coughing, at stroke onset. For further information, see chapter 166.

STROKE DIAGNOSIS

Mimics (Table 167-5)[7,8,13] can often be distinguished from stroke by careful history taking and physical examination, bedside tests, observation, and appropriate imaging. However, it can be difficult to distinguish conditions with focal transient symptoms (e.g., seizure) from transient ischemic attack (TIA).

INITIAL DIAGNOSTIC EVALUATION

The classic mantra, "**time is brain**,"[54] explains the current American Heart Association/American Stroke Association (AHA/ASA) stroke

guidelines Class IB recommendation to enact "an organized protocol for the emergency evaluation of patients with suspected stroke" in which "the goal is to evaluate and to decide treatment within 60 minutes of the patient's arrival in an ED."[7] Creation of a multidisciplinary "stroke team" is encouraged, and the culture of the institution should be aligned to encourage rapid diagnosis and treatment of stroke. Train triage personnel to suspect stroke and to quickly activate a stroke critical pathway that includes specific standing orders and procedures. Implement the critical pathway immediately upon that patient's arrival, beginning in the triage area. Notify the emergency physician, the ED charge nurse, and the CT and laboratory technicians immediately when acute stroke is suspected. Do not delay the workup because ED beds are overcrowded or the emergency physician is currently otherwise engaged, and move the patient to a monitored bed as soon as feasible.

Concurrent with focused history taking and physical examination, perform a prioritized group of interventions and diagnostic studies rapidly in the ED when acute stroke is suspected (**Table 167-7**).

Nonessential testing should NOT delay performing brain imaging **within 25 minutes of the patient's arrival (Table 167-8)**.[7]

TABLE 167-8 AHA/ASA Time Recommendations for Acute Ischemic Stroke

Intervention	Time Goal (from ED arrival)
Begin ED physician evaluation	10 min
Activation of stroke team	15 min
Begin head CT	25 min
Complete head CT interpretation	45 min
Begin rtPA administration	1 h
Admission to stroke unit	3 h

Abbreviations: AHA/ASA = American Heart Association/American Stroke Association; rtPA = recombinant tissue plasminogen activator.

IMAGING

Brain Imaging Obtain emergency non–contrast-enhanced CT for suspected acute stroke. **Most acute ischemic strokes are not visualized by a noncontrast brain CT in the early hours of a stroke.**[8] Therefore, the utility of the first brain CT is primarily to exclude intracranial bleeding, abscess, tumor, and other stroke mimics, as well as to detect current contraindications to thrombolytics (e.g., evidence of more than one-third middle cerebral artery territory involvement).

The CT scan should be reviewed by the most expert interpreter available within 45 minutes of patient arrival, especially if thrombolytic therapy is being considered.[7] The identification of subtle hemorrhage, infarctions involving more than one third of the middle cerebral artery territory, and early cerebral infarction requires expertise. Telemedicine consultation is an excellent option, because reports indicate

TABLE 167-7 Core ED Interventions for Suspected Acute Stroke

Intervention/Evaluation	Rationale/Discussion
All patients	
Assessment of *a*irway, *b*reathing, *c*irculation	Immediate life threats must be addressed before other interventions are undertaken. Actively manage airway if necessary.
Establishment of IV access	IV access is necessary for possible thrombolytic therapy.
Oxygen administration (if hypoxia is present)	Routine oxygen supplementation is not indicated in mild to moderate stroke,[55] and should only be given to keep oxygen saturation >94%.[7]
Cardiac monitoring	Dysrhythmias, especially atrial fibrillation, are not infrequent in acute stroke and may predict 3-month mortality.[56,57] Prophylactic administration of antiarrhythmic agents is not indicated.
Bedside glucose determination	To rapidly rule out hypoglycemia mimicking stroke. Treat hypoglycemia (<60 milligrams/dL) with IV dextrose. **This is the only laboratory test result required prior to thrombolytic therapy**[7] *unless* the patient is taking/possibly taking oral anticoagulation therapy or heparin, or if there is a suspicion of thrombocytopenia or other bleeding diatheses (Table 167-11).
Pulse oximetry	To detect hypoxia.
ECG	Acute coronary syndrome, dysrhythmias (atrial fibrillation, in particular), ECG changes, and elevated troponin T levels are frequently associated with acute stroke.[58] ECG abnormalities may also predict 3-mo mortality.[56] A large study (n = 9180) of consecutive stroke patients revealed that 2.3% suffered a subsequent myocardial infarction with 64.9% morbidity/mortality compared with 35.8% in the entire cohort.[59]
Noncontrast brain CT or MRI	To exclude intracerebral hemorrhage, frank hypodensity (especially more than one third of the middle cerebral artery territory) (CT) or hyperdensity of ischemia (MRI),[7] abscess, and tumor. (See discussion in "Imaging" section of this chapter.)
CBC including platelet count	To detect polycythemia, thrombocytosis, or thrombocytopenia.
Coagulation studies	To detect preexisting coagulopathy in hemorrhagic stroke or when thrombolytics are being considered (Table 167-11).
Electrolyte levels	To detect electrolyte-imbalance stroke mimics (particularly Na^+ and Ca^{2+}).
Cardiac enzyme levels	See "ECG" earlier in this table.
Nothing by mouth (NPO) order	To protect against aspiration.
Strict bedrest in the ED	To protect against falls and seizures (in the period immediately after stroke). In patients who can maintain oxygenation, supine position has been recommended to possibly improve cerebral blood flow[7,60]; however, this remains controversial.[61] Head of bed elevation to 15 to 30 degrees may be used in patients at risk for hypoxia, airway compromise, aspiration, or suspected increased intracranial pressure.[7]
Selected patients	
Urinalysis and/or chest radiograph (if infection suspected)	To detect infectious stroke mimics or stroke-associated infections. Routine chest radiography is not recommended.[7]
Pregnancy test (if female of childbearing age)	Pregnancy influences diagnosis and management considerations.
Toxicology screen and/or blood alcohol level (if ingestion suspected)	To detect stroke mimics as well as potential causes of stroke such as ingestion of a sympathomimetic (e.g., cocaine, methamphetamine, phencyclidine).
Lumbar puncture (if infection or subarachnoid hemorrhage suspected)	To detect stroke mimics. Thrombolytics should not be given before or after a lumbar puncture because of increased risk of post–lumbar puncture epidural hematoma.

excellent interobserver agreement in CT readings between telemedicine stroke neurologists and neuroradiologists.[62]

Diffusion-weighted MRI is superior to non–contrast-enhanced CT or other types of MRI (T1/T2 weighted, fluid-attenuated inversion recovery) in the detection of acute infarction.[63,64] However, at this time, the ED role of MRI for acute stroke is limited because of MRI's uncertain accuracy in detecting acute hemorrhage,[65] lack of rapid availability,[66] patient-specific contraindications (lack of cooperation, claustrophobia, metallic implants or pacemakers, and diminished access to the patient), relative inexperience in some practitioners in interpreting MRI scans in acute stroke, and cost-effectiveness. In addition, thrombolytic inclusion/exclusion criteria were originally developed using CT findings,[67] although the use of MRI-based rtPA selection criteria continues to be explored.[68,69] Postthrombolysis diffusion-weighted MRI may be useful in differentiating stroke from other diagnoses such as TIA and stroke mimics (including coronary artery disease) in patients who have received rtPA.[70]

Despite these caveats, the current AHA/ASA acute ischemic stroke guidelines recommend either non–contrast-enhanced CT or MRI as the initial imaging in the acute stroke patient.[7] However, **in the vast majority of EDs, a non–contrast-enhanced CT is the most readily available imaging study and is the *only* imaging study necessary prior to administration of rtPA**.[71]

Vascular Imaging The current AHA/ASA acute ischemic stroke guidelines state that vascular imaging is "strongly recommended" only in patients eligible for endovascular therapies, but these studies should not delay rtPA administration.[7] With the advent of endovascular therapies (intra-arterial thrombolysis and clot retrieval/disruption), identifying the presence of intracranial large-vessel stenosis or occlusion is important for therapeutic decisions. CT angiography, digital subtraction angiography, or magnetic resonance angiography can detect intracranial arterial stenosis.[72] Some centers perform CT angiography after non–contrast-enhanced CT to identify lesions amenable to endovascular treatment.[71]

Perfusion Studies In acute ischemic stroke, the area of irreversible brain infarct (core) is surrounded by ischemic tissue that may potentially be salvageable, regardless of the time of onset of symptoms. The size of this penumbra region cannot be ascertained clinically, so perfusion CT and MRI can be used to measure the size of the penumbra and to guide further therapy for patients who fall outside the time ranges for thrombolysis or where the time of symptom onset is unclear.[73] To date, the impact of perfusion studies on therapy is mixed.[74,75]

GENERAL TREATMENT OF ACUTE ISCHEMIC STROKE

STANDARD TREATMENT

Initial ED stabilization and interventions are listed in Table 167-7. Many of these interventions are consensus based. Not all patients will be eligible for systemic rtPA, so it is important to follow general treatment principles whether or not rtPA is given.

DEHYDRATION

Dehydration can contribute to poor stroke outcomes secondary to increased blood viscosity, hypotension, renal impairment, and venous thromboembolism.[76] Correct dehydration with IV isotonic crystalloid.[7] Routine volume expansion and hemodilution do not appear to improve outcomes in stroke patients[77] and should probably not be done except perhaps in patients with hyperviscous states. For euvolemic patients, provide maintenance fluids.

HYPOXIA

The 2013 AHA/ASA consensus guidelines recommend oxygen administration to patients in stable condition only as necessary to maintain oxygen saturation >94% and to maintain normoxia.[7] Routine normobaric oxygen administration does not appear to improve short- or long-term outcomes in mild to moderate stroke,[55,78] and oxygen administration has been associated with increased stroke mortality.[79] Hyperbaric oxygenation is not currently recommended.[7]

HYPERPYREXIA

Fever is associated with increased morbidity and mortality in stroke, possibly due to increased metabolic demand and free radical production.[80] Identify the source of fever and treat with acetaminophen.[7]

HYPERTENSION

Based on consensus opinion, the current AHA/ASA acute stroke guidelines[7] dichotomize recommendations for hypertensive therapy based on the potential for acute reperfusion intervention. **For patients who are not candidates for thrombolytics or reperfusion measures, the guidelines call for *permissive hypertension*, with no active attempts made to lower blood pressure unless the systolic blood pressure is >220 mm Hg or the diastolic blood pressure is >120 mm Hg or if the patient has another medical condition that would benefit from lowering blood pressure. If the decision has been made to initiate blood pressure control, a suggested target is a 15% reduction in systolic blood pressure for the first 24 hours.**[7]

Conversely, blood pressure control is essential prior to, during, and after thrombolytic therapy. A systolic blood pressure >185 mm Hg or a diastolic blood pressure >110 mm Hg is a contraindication to the use of rtPA[15,67] because elevated blood pressure is associated with hemorrhagic transformation of ischemic stroke.[81] **Therefore, if a patient is a candidate for rtPA, actively attempt to lower blood pressure to meet these entry parameters.** An approach to management of arterial hypertension is detailed in **Table 167-9**[7] and **Table 167-10**.[7] If the target arterial blood pressures for rtPA administration cannot be reached with these measures, **then the patient is no longer a candidate for rtPA therapy**.

HYPERGLYCEMIA

The current AHA/ASA guidelines recommend the maintenance of blood glucose from 140 milligrams/dL (7.77 mmol/L) to 180 milligrams/dL (9.99 mmol/L).[7] Avoid, and treat, hypoglycemia (<60 milligrams/dL [3.33 mmol/L]).

Hyperglycemia is common in acute stroke,[82] and glycemic control has been recommended based on data that associate less favorable outcomes with hyperglycemia.[83] However, glycemic control must avoid hypoglycemia, which in itself can result in brain dysfunction.[84]

TABLE 167-9 Management of Hypertension before Administration of Recombinant Tissue Plasminogen Activator (rtPA)

If the patient is a candidate for rtPA therapy, the target arterial blood pressures are: **systolic blood pressure ≤185 mm Hg and diastolic blood pressure ≤110 mm Hg**

Drug	Comments
Labetalol, 10–20 milligrams IV over 1–2 min, may repeat ×1	Use with caution in patients with severe asthma, severe chronic obstructive pulmonary disease, congestive heart failure, diabetes mellitus, myasthenia gravis, concurrent calcium channel blocker use, hepatic insufficiency. May cause dizziness and nausea. Pregnancy category C (D in second and third trimesters).
or	
Nicardipine infusion, 5 milligrams/h, titrate up by 2.5 milligrams/h at 5- to 15-min intervals; maximum dose: 15 milligrams/h; when desired blood pressure attained, reduce to 3 milligrams/h	Use with caution in patients with myocardial ischemia, concurrent use of fentanyl (hypotension), congestive heart failure, hypertrophic cardiomyopathy, portal hypertension, renal insufficiency, hepatic insufficiency (may need to adjust starting dose). Contraindicated in patients with severe aortic stenosis. Can cause headache, flushing, dizziness, nausea, reflex tachycardia. Pregnancy category C.

If the target arterial blood pressures for rtPA administration cannot be reached with these initial measures, then *the **patient is no longer a candidate for rtPA therapy***.

TABLE 167-10 Management of Hypertension during and after Administration of Recombinant Tissue Plasminogen Activator (rtPA)

Blood Pressure Monitoring Frequencies	
Time after Start of rtPA Infusion	**Frequency of Blood Pressure Monitoring**
0–2 h	Every 15 min
3–8 h	Every 30 min
9–24 h	Every 60 min
Drug Treatment of Hypertension during and after Administration of rtPA	
If systolic blood pressure is >180–230 mm Hg or diastolic blood pressure is >105–120 mm Hg	Labetalol, 10 milligrams IV followed by infusion at 2–8 milligrams/min. *or* Nicardipine infusion, 5 milligrams/h, titrate up by 2.5 milligrams/h at 5- to 15-min intervals; maximum dose 15 milligrams/h.
If blood pressure is not controlled by above measures or if diastolic blood pressure >140 mm Hg	Consider sodium nitroprusside infusion (0.5–10 microgram/kg/min). Continuous arterial monitoring advised; use with caution in patients with hepatic or renal insufficiency. Increases intracranial pressure. Pregnancy category C.

ASPIRIN

The current AHA/ASA guidelines recommend the oral administration of aspirin (initial dose is 325 milligrams) within 24 to 48 hours after stroke onset.[7] However, no antiplatelet agent (including aspirin) should be given within 24 hours of rtPA therapy. In addition, some experts recommend that oral aspirin therapy be deferred until swallowing studies can be done to avoid potential aspiration.[7] When the results of the International Stroke Trial[85] and the Chinese Acute Stroke Trial[86] are combined (40,000 patients), these studies demonstrate significant reduction in mortality and morbidity rates (at 4 weeks and 6 months) when aspirin is administered to acute ischemic stroke patients within 48 hours.[87] The benefit seems due mainly to reduction of recurrent stroke. The number needed to treat is 100, but aspirin is cost-effective and adds no risk to the outcome of ischemic stroke.[87]

THROMBOLYSIS BACKGROUND

NINDS STUDY

The National Institutes of Health/NINDS study[67] was a randomized double-blind trial comparing IV rtPA with placebo. The drug was administered within 3 hours of symptom onset, with approximately one half of patients treated within 90 minutes. Outcomes were measured using four different neurologic outcome scales (including the NIHSS) and a global statistic. Although there was no difference in the treatment and control groups at 24 hours, at 3 months, the odds ratio (OR) for a favorable outcome in patients treated with rtPA was 1.7 (95% confidence interval [CI] 1.2 to 2.61; $P = .008$), an 11% to 13% absolute risk reduction benefit (number needed to treat = 8 to 9, for tPA <3 hours). Put another way, 31% to 50% of the patients receiving rtPA (depending on the scale used) had a favorable outcome at 3 months compared with 20% to 38% of patients given placebo. Benefit was found regardless of ischemic stroke subtype and was sustained 1 year after therapy. Symptomatic intracerebral hemorrhage attributable to rtPA occurred in 6.4% of patients in the rtPA group (45% mortality), whereas symptomatic intracerebral hemorrhage occurred in 0.6% of those in the placebo group (50% mortality). Despite this increased rate of intracerebral hemorrhage, the mortality rate at 3 months was not significantly different for the treatment and placebo groups (17% vs. 21%, respectively; $P = .30$), and the percentage of patients left severely disabled was lower among those receiving rtPA.[67] The NINDS trial represented the first randomized placebo-controlled trial that showed benefit of IV rtPA in acute stroke. Prior trials using different thrombolytic agents, different dosing of rtPA, or different treatment windows failed to show benefit or showed harm. **Based largely on the NINDS data, in 1996 the U.S. Food and Drug Administration approved the use of IV rtPA in acute ischemic stroke within 3 hours of stroke onset.** As of this writing, although the European Medicines Agency has approved rtPA use from 3 to 4.5 hours after symptom onset, the Food and Drug Administration has denied approval for this application.[107] Confidentiality regulations have prevented the release of the rationale for these decisions.[7]

Concerns have been raised about the NINDS trial results.[108] The NINDS trial, although well designed, was relatively small and studied 624 patients total, 312 of whom received rtPA. As a result of chance, there existed an imbalance in baseline stroke severity between the two groups that apparently favored the rtPA group. Therefore, the NINDS investigators commissioned an independent reanalysis of the data[109] in 2004 that took this imbalance into account. This reanalysis found that, despite the imbalance, the originally described benefit of rtPA held. The authors concluded that "these findings support the use of tPA to treat patients with acute ischemic stroke within 3 hours of onset."[109] However, they did concede the need to collect further data to determine which particular stroke subgroups would benefit from or be harmed by rtPA. In 2009, a graphic reanalysis of the NINDS trial data set was published,[110] which showed very small differences in the treatment and placebo group outcomes, with a slight favoring of rtPA treatment. Therefore, the authors concluded that the reported NINDS results could have resulted from confounding alone. However, the methodology of this reanalysis was challenged in a subsequent graphic reanalysis of the NINDS data that supported the original results,[111] although these critiques have also been challenged in turn.[112]

SUBSEQUENT THROMBOLYTIC TRIALS

The European Cooperative Acute Stroke Study III (ECASS III) demonstrated efficacy with an expansion of the rtPA treatment window to 4.5 hours.[15] The OR favored patients treated with rtPA (OR = 1.34; 95% CI 1.02 to 1.76), and the post hoc analysis, which adjusted for confounding variables, yielded similar statistical results (OR = 1.42; 95% CI 1.02 to 1.98). Although the incidence of intracerebral hemorrhage was higher in the rtPA group than the placebo group (27% vs. 17%) and the incidence of symptomatic hemorrhage was also higher in the rtPA group (2.4% vs. 0.2%; 7.9% vs. 3.5% when the NINDS definition of symptomatic hemorrhage was used), mortality was similar in both groups (7.7% in the rtPA group and 8.4% in the control group). The number needed to treat for benefit was 14. Based on these data, AHA/ASA issued a 2009 scientific advisory[113] that recommended rtPA should be administered to eligible patients who present between 3 and 4.5 hours of an acute stroke, as long as they meet the ECASS III criteria. However, rtPA administration >3 hours after symptom onset is still considered "off label" in the United States because the Food and Drug Administration has declined approval[107] (see Table 167-12).

In 2012, the third International Stroke Trial (IST-3)[114] was published, making it the largest (3035 patients) rtPA in ischemic stroke randomized controlled trial to date. Patients in the treatment group were given the standard dose of rtPA up to 6 hours after stroke onset, with 72% of them receiving rtPA after 3 hours. The exclusion criteria were loosened, including eliminating any upper age limit and the broadening of the acceptable blood pressure range prior to rtPA (systolic 90 to 220 mm Hg; diastolic 40 to 130 mm Hg).[115] The trial showed no difference at 6 months in the primary outcome measure, Oxford Handicap Score (0 to 2; alive and independent): 37% versus 34% (OR = 1.13; 95% CI 0.95 to 1.35; $P = .181$) in the treatment versus control groups, respectively. However, a secondary ordinal analysis showed a favorable shift in Oxford Handicap Score scores (indicating less disability) in the treatment group at 6 months. Although symptomatic intracranial hemorrhage occurred in 7% of rtPA patients versus 1% of controls ($P <.0001$) and 11% of deaths occurred within 7 days in rtPA patients versus 7% in controls ($P <.001$), mortality at 6 months was the same (27%) in both treatment and control groups. The favorable shift in Oxford Handicap Score in rtPA patients appeared to last at least 18 months and was associated with higher overall self-reported health, with no increased mortality.[116] Interestingly, a subgroup analysis in IST-3 revealed that patients receiving thrombolytics between 3 and 4.5 hours after symptom onset actually had a nonstatistical trend toward a *worse*

functional outcome compared with controls than those receiving rtPA less than 3 hours and from 4.5 to 6 hours after symptom onset.[114]

Finally, in a 2012 systematic review and meta-analysis that included **12 randomized controlled trials of rtPA** in ischemic stroke (7012 patients), the authors concluded that rtPA-treated stroke patients were more likely to have favorable outcomes than controls and that early treatment was better than late treatment, with possible benefit up to 6 hours after symptom onset.[117]

THROMBOLYSIS: INDICATIONS, EXCLUSIONS, DOSAGE, AND COMPLICATIONS

The decision to administer rtPA must be made rapidly and accurately. There must be careful identification of the time of symptom onset, defined as the **last moment the patient was known to be at baseline**. Taking the patient and family chronologically through the events immediately prior to the stroke is particularly helpful in unclear cases. **Thrombolytic use in stroke is not recommended when the time of onset cannot be reliably determined**. As of this writing, strokes recognized upon awakening (up to 29.6% of strokes[118]) should be clocked from the time at which the patient was last known to be without symptoms. Preliminary studies of thrombolysis in these so-called "wake-up" strokes have been published[119-121] that suggest some of these patients might benefit from rtPA, but these results await confirmation by randomized controlled trials.

The patient must be evaluated carefully for indications and exclusions for rtPA therapy (**Table 167-11** and **Table 167-12**), and the findings must be documented meticulously, preferably on preprinted assessment forms. The decision to administer rtPA is made by assessing multiple factors, including the numerical NIHSS score. A score between 4 and 22 is commonly used as one of the criteria for rtPA administration. However, some patients may have a lower NIHSS score, yet have a potentially disabling condition (e.g., aphasia, hemianopia, gait disturbance). Some studies have also shown poor outcomes for untreated minor strokes.[122-124] Thus, interpret an NIHSS score in the total context of the individual patient when making treatment decisions.

In the previous AHA/ASA stroke guidelines,[14,113] the exclusion criteria hewed very closely to those published by the NINDS and ECASS III trials. However, in the current recommendations,[7] several of the previous exclusion criteria have been reclassified as **"relative exclusion criteria"** on the basis of "recent experience." The guidelines urge that the risks versus anticipated benefits of proposed rtPA therapy should be carefully considered if any of the relative contraindications are present prior to administration of the drug. When faced with such patients, obtain emergency consultation with a physician with acute stroke expertise, whether on site or via telemedicine,[125,126] because local treatment varies and patient care decisions should be individualized.

A bedside blood glucose is required prior to rtPA; however, do not withhold rtPA because other laboratory results are still pending unless there is reason to suspect a pathologic or iatrogenic coagulopathy. Administer rtPA to eligible patients even if endovascular therapies are being considered.[7]

The total dose of rtPA is 0.9 milligram/kg IV, with a maximum dose of 90 milligrams; administer 10% of the dose as a bolus over 1 minute, with the remaining amount infused over 60 minutes. Perform blood pressure and neurologic checks every 15 minutes for 2 hours after starting the infusion. Table 167-10 outlines the emergent management of hypertension during and after administration of thrombolytics. **Do not give anticoagulants or antiplatelet agents in the initial 24 hours following treatment**,[7] because only rtPA trials without early aspirin have shown benefit. Admit patients to a specialized stroke unit (if available) or an intensive care unit familiar with the use of thrombolytic drugs and neurologic monitoring. If post-rtPA bleeding is suspected, halt further rtPA administration and perform an emergent CT. Order a CBC with platelet count, coagulation studies, fibrinogen level, and typing and cross-match for packed red blood cells, cryoprecipitate or fresh frozen plasma, and platelets. Emergent neurology, neurosurgery, and hematology consultations, as needed, are appropriate. Be prepared to treat the possible rtPA side effect of angioedema.

OTHER TREATMENT MODALITIES

Therapeutic hypothermia, induced hypertension, endovascular therapies, carotid endarterectomy/stenting, and emergency hemicraniectomy for massive infarcts are modalities that are being studied, but as of this writing, benefits are unproven.

Mild **therapeutic hypothermia** is associated with improved neurologic outcomes in comatose patients who survive cardiopulmonary arrest.[88] Consequently, there is much interest in the potential benefit of induced hypothermia in acute stroke, but evidence-based data about effectiveness are not available at this time.[89]

Animal data[90] and preliminary trials have suggested that implementing **drug-induced hypertension** in an effort to increase blood flow to the ischemic penumbra may benefit outcomes from acute ischemic stroke.[91,92] However, there are insufficient data to recommend this modality at this time.[7]

There is intense interest in **endovascular therapies**, primarily intra-arterial thrombolysis and mechanical clot disruption/extraction. Potential advantages of endovascular therapies include an expanded treatment window, a treatment for patients with non–time-based contraindications to IV rtPA, an ability to specifically evaluate the occluded vascular territory, use of lower total doses of thrombolytic drugs, and the possibility of mechanical clot disruption. However, indications, timing, and exclusions have yet to be established. Endovascular treatments are still considered investigational,[93] but they may be considered in patients ineligible for rtPA.

The Interventional Management of Stroke III (IMS III) trial[94] was designed to compare IV rtPA followed by endovascular treatment (including mechanical clot extraction devices) versus IV rtPA alone, but this study was terminated in 2012 after 656 subjects were enrolled due to lack of power to find statistical significance.[95] The Systemic Thrombolysis for Acute Ischemic Stroke (SYNTHESIS Expansion) trial[96] showed no difference between endovascular therapy versus IV rtPA. The Mechanical Retrieval and Recanalization of Stroke Clots Using Embolectomy (MR RESCUE) trial[74] showed no benefit to endovascular therapy in patients chosen by presence of ischemic penumbra.

In TIA patients with medically treated high-grade internal carotid artery lesions, **carotid endarterectomy** should be performed promptly, because surgical benefit is greatest within 2 weeks of the TIA.[97] The Carotid Revascularization Endarterectomy versus Stenting Trial (CREST)[98] and the International Carotid Stenting Study (ICSS)[99] suggest that **carotid stenting** is a viable alternative to endarterectomy, especially in patients <70 years old[98] or in patients with higher surgical risks.[99] The evidence-based role of carotid endarterectomy/stenting in acute stroke, on the other hand, is still not currently defined.[7,100]

Patients with a massive middle cerebral artery infarct are not candidates for thrombolytic therapy and have an 80% mortality rate. A pooled analysis of data from three European trials (Decompressive Surgery for the Treatment of Malignant Infarction of the Middle Cerebral Artery [DECIMAL], Decompressive Surgery for the Treatment of Malignant Infarction of the Middle Cerebral Artery [DESTINY], and Hemicraniectomy After Middle Cerebral Artery Infarction With Life-Threatening Edema Trial [HAMLET]) showed that decompressive hemicraniectomy was associated with better outcomes than medical therapy.[101] However, the Hemicraniectomy and Durotomy upon Deterioration Infarction-Related Swelling (HeADDFIRST) pilot trial[102] revealed less mortality at 180 days (40%) in patients with medical treatment than previously reported (50% to 70%).[103] In addition, there was no statistical difference between the medically managed patients in this trial and the patients who underwent hemicraniectomy plus medical treatment (36%).[102] These results may suggest a possible benefit to standardized medical management in these patients. At this time, the decision to perform surgery must be made on an individual basis; therefore, evidence-based indications for decompressive surgery in acute stroke have not yet been established.

There are currently insufficient data to recommend the use of dipyridamole, ticlopidine, or clopidogrel (either alone or in combination with aspirin) in early acute stroke. Antiplatelet therapy is contraindicated in acute hemorrhagic stroke.

TABLE 167-11 American Heart Association (AHA)/American Stroke Association (ASA) 2013 Inclusion/Exclusion Criteria for IV Recombinant Tissue Plasminogen Activator (rtPA) in Acute Ischemic Stroke

Inclusion Criteria	
Measurable diagnosis of acute ischemic stroke	Use of NIHSS score recommended. Major strokes (NIHSS score >22) are more likely to have poor outcomes.
Onset of symptoms <3 h prior to rtPA administration	Must be *well established* and is defined as the time of the witnessed onset of symptoms or the time the patient was last known at baseline.
Age ≥18 y	No clear upper age limit.
Exclusion Criteria	
Significant head trauma or prior stroke in previous 3 mo	
Symptoms suggest subarachnoid hemorrhage	
Arterial puncture at noncompressible site ≤7 d ago	
History of previous intracranial hemorrhage	
Intracranial neoplasm, arteriovenous malformation, or aneurysm*	
Seizure with postictal residual neurologic impairments thought to be due to the seizure	
Recent intracranial or intraspinal surgery*	
Pretreatment systolic blood pressure >185 mm Hg *or* diastolic blood pressure >110 mm Hg despite therapy (see Table 167-9)	
Active internal bleeding*	
Platelet count <100,000/mm^3	If patient has no history of thrombocytopenia, rtPA may be given before this lab result is available; however, rtPA should be stopped if the platelet count is <100,000/mm^3.
Use of heparin within preceding 48 h *and* a prolonged activated partial thromboplastin time (aPTT) greater than upper limit of normal	
International normalized ratio (INR) >1.7 or partial thromboplastin time (PTT) >15 s	Oral anticoagulant use in and of itself is not a contraindication to rtPA. If patient is not taking oral anticoagulant or heparin, rtPA may be given before this lab result is available; however, rtPA should be stopped if these lab tests come back elevated above normal limits.
Current use of direct thrombin inhibitors or direct factor Xa inhibitors with elevated sensitive laboratory tests (such as aPTT, INR, platelet count, and ecarin clotting time [ECT]; thrombin time [TT]; or appropriate factor Xa activity assays)*	
Blood glucose level <50 milligrams/dL (2.7 mmol/L)	
Non–contrast-enhanced CT (NECT) demonstrates multilobar infarction (hypodensity >1/3 cerebral hemisphere)	Do not give rtPA if CT shows acute intracranial hemorrhage or neoplasm.
Relative Exclusion Criteria	
Only minor or rapidly improving stroke symptoms (clearing spontaneously)	Some patients may have a lower NIHSS score but have a potentially disabling condition (e.g., aphasia, hemianopia). Some studies have shown poor outcomes for untreated minor strokes.[122-124]
Pregnancy	No randomized controlled trials have been published regarding safety or efficacy of rtPA for ischemic stroke in pregnancy. Case series have reported mixed results.[127-129]
Seizure at onset with postictal residual neurologic impairments	rtPA can be given if the residual impairments are thought to be secondary to the stroke as opposed to the seizure.[7,130]
Major surgery or serious trauma within preceding 14 d†	
Previous GI or urinary tract hemorrhage within preceding 21 d†	
Previous myocardial infarction within preceding 3 mo†	Rationale for this criterion was a statement indicating that myocardial rupture can result if rtPA is given within a few days of acute myocardial infarction.[14]
Former Exclusion Criteria from 2007 AHA/ASA Guidelines[14]	
Evidence of acute trauma (fracture)	
Failure of the patient or responsible party to understand the risks and benefits of, and alternatives to, the proposed treatment after a full discussion	

*New exclusion criteria for 2013 AHA/ASA guidelines.

†Changed from absolute contraindication from 2007 AHA/ASA guidelines.

Abbreviation: NIHSS = National Institutes of Health Stroke Scale.

DISPOSITION

Admit all acute stroke patients to monitored care units familiar with the care of stroke patients, preferably to specialized stroke units at designated stroke centers. The use of stroke units has been associated with decreased complications and length of stay, improved daily function, decreased rate of discharge to long-term care facilities, and increased likelihood of being able to live at home in the long term—with the benefit being independent of thrombolytic use.[104-106] If a patient with acute stroke presents to a facility that lacks these resources, consider transferring the patient to a higher level of care after the patient's condition has stabilized and IV rtPA has been given, as indicated—the "drip and ship" model. Emergent, early consultation with an experienced stroke physician at the accepting institution is desirable in these circumstances.

TABLE 167-12 American Heart Association (AHA)/American Stroke Association (ASA) 2013 Additional Inclusion/Exclusion Criteria for IV Recombinant Tissue Plasminogen Activator (rtPA) in Acute Ischemic Stroke for Patients Presenting within 3 to 4.5 Hours after Onset

Additional Inclusion Criteria
Measurable diagnosis of acute ischemic stroke
Onset of stroke symptoms 3–4.5 h before initiation of rtPA administration
Additional Exclusion Criteria
Age >80 y
Severe stroke as assessed clinically (e.g., NIHSS score >25) or by appropriate imaging techniques (i.e., involving >1/3 of middle cerebral artery territory)
Taking an oral anticoagulant regardless of international normalized ratio
History of previous ischemic stroke and diabetes mellitus
Exclusion Criterion from ECASS III Not Included in Current AHA/ASA Guidelines
Blood glucose >400 milligrams/dL

Abbreviation: ECASS III = European Cooperative Acute Stroke Study III; NIHSS = National Institutes of Health Stroke Scale.

TABLE 167-13 ABCD² Score to Predict Very Early Stroke Risk after Transient Ischemic Attack

Criteria	Points
*A*ge ≥60 y	0 = Absent 1 = Present
*B*lood pressure ≥140/90 mm Hg	0 = Absent 1 = Present
*C*linical features	0 = Absent 1 = Speech impairment without unilateral weakness 2 = Unilateral weakness (with or without speech impairment)
*D*uration	0 = Absent 1 = 10–59 min 2 = ≥60 min
*D*iabetes	0 = Absent 1 = Present
Total Score: 0–7	

ANTIPLATELET THERAPY

STROKE

The current AHA/ASA guidelines recommend the oral administration of aspirin (initial dose is 325 milligrams) within 24 to 48 hours after stroke onset.[7] However, no antiplatelet agent (including aspirin) should be given within 24 hours of rtPA therapy. In addition, some experts recommend that oral aspirin therapy be deferred until swallowing studies can be done to avoid potential aspiration.[7] When the results of the International Stroke Trial[85] and the Chinese Acute Stroke Trial[86] are combined (40,000 patients), these studies demonstrate significant reduction in mortality and morbidity rates (at 4 weeks and 6 months) when aspirin is administered to acute ischemic stroke patients within 48 hours.[87] The benefit seems mainly due to reduction of recurrent stroke. The number needed to treat is 100, but aspirin is cost-effective and adds no risk to the outcome of ischemic stroke.[87]

There are currently insufficient data to recommend the use of dipyridamole, ticlopidine, or clopidogrel (either alone or in combination with aspirin) in early acute stroke. Antiplatelet therapy is contraindicated in acute hemorrhagic stroke.

TRANSIENT ISCHEMIC ATTACK (TIA)

TIA is defined as follows: "a transient episode of neurological dysfunction caused by focal brain, spinal cord, or retinal ischemia, without acute infarction."[131] This tissue-based definition recognizes that although TIA symptoms typically last less than 1 to 2 hours, duration of symptoms is an unreliable discriminator between TIA and infarction. A TIA should be viewed as analogous to unstable angina—that is, an ominous harbinger of a potential future vascular event. In fact, the adjusted OR for stroke <1 month after TIA is 30.4 (95% CI 10.4 to 89.4)[132] and the overall 90-day stroke risk after TIA is about 9.2% to 9.5%.[133-135] Some data suggest that 50% of these subsequent events occur within 2 days after presentation to the ED.[133] Published risk factors associated with increased risk for subsequent stroke include hypertension, diabetes mellitus, symptom duration of ≥10 minutes, weakness, and speech impairment.[133] A study of admitted patients found increased risk with male sex, age ≥65 years, hyperlipidemia, and dysarthria.[136]

TIA DIAGNOSIS

View TIAs as ominous signs of cerebral vascular disease indicating a high risk of stroke in the near future.[131] In 2007, the ABCD² scoring system was intended to replace two previous scoring scales (California score and ABCD score) (**Table 167-13**).[137]

Johnston et al[137] initially reported a 2-day risk of subsequent stroke as: 1% (ABCD² score 0 to 3), 4.1% (score 4 to 5), and 8.1% (score 6 to 7). The 7-day risk of stroke was 1.2% (ABCD² score 0 to 3), 5.9% (score 4 to 5), and 11.7% (score 6 to 7).

Based on these data, it was hoped that the ABCD² score could be used to risk-stratify low-risk patients for outpatient workup of TIA. However, subsequently published studies have produced conflicting conclusions as to the ABCD² score's predictive value for subsequent stroke after TIA.[138,139] A meta-analysis (>16,000 patients)[140] found inadequate positive and negative likelihood ratios (1 to 2 and 0.5 to 1, respectively) to be of practical use when deciding stroke risk in a given patient. Overall, the ABCD² score identified high-risk patients poorly and had only modest success in predicting low-risk patients, and the study author's cautioned against solely relying on the ABCD² score to risk-stratify patients.[140] In an attempt to improve accuracy of ABCD², the presence of two or more TIA events at 7 days (ABCD³) and diffusion-weighted MRI (ABCD³-I) have been added to the scoring system. Although one study demonstrated the superiority of these new scales to predict stroke,[141] the addition of these two data points limits the usefulness of these scales in the ED during initial presentation.

In summary, although the ABCD² score has been recommended for use by major guidelines,[131] definitive evidence-based admissions thresholds have yet to be determined. Therefore, some experts recommend that most TIA patients be hospitalized to monitor and educate them, begin antiplatelet therapy (unless contraindicated), rapidly treat subsequent stroke, assess stroke risk factors, implement preventative measures, and perform endarterectomy in appropriate patients.[131] Others recommend beginning the workup in the ED, starting antiplatelet therapy in appropriate patients, educating the patient and family regarding risk modification, and giving explicit return precautions.[142] The specific approach to a patient must be individualized and may depend not only on medical factors, but also available healthcare resources and the patient's social situation.

TIA TREATMENT

Antiplatelet Agents After TIA, the use of aspirin to prevent vascular events is historically well accepted. Current practice includes dipyridamole plus aspirin (reasonable as a first choice), clopidogrel, and aspirin alone. The selection of a particular antiplatelet regimen is a multifactorial decision based on comorbid conditions, bleeding risk, prior drug use, and cost.

A very large meta-analysis (>88,000 patients)[143] concluded that aspirin plus dipyridamole was superior to aspirin alone for prevention of vascular events after stroke or TIA. Aspirin plus dipyridamole was associated with more hemorrhagic events than dipyridamole (relative risk = 1.83; 95% CI 1.17 to 2.81), but was associated with fewer hemorrhagic

events than aspirin and clopidogrel (relative risk = 0.38; 95% CI 0.25 to 0.56). However, a trial of 5170 patients found that the combination of clopidogrel and aspirin was superior to aspirin alone for reducing the risk of stroke in the first 90 days without increasing the risk of hemorrhage.[144] A trial (the Platelet-Oriented Inhibition in New TIA and Minor Ischemic Stroke [POINT] trial) is currently in progress to investigate this comparison as well.[145]

Anticoagulation Adjusted-dose oral anticoagulation with warfarin has been the historical therapy of choice for stroke prevention in patients with nonvalvular atrial fibrillation and TIA; however, an assessment of warfarin anticoagulation for stroke prevention in the United States demonstrated a dismal rate of optimal anticoagulation control.[146] This has led to multiple randomized controlled trials of novel anticoagulants, which have been shown to have equivalent efficacy but with less risk of intracranial hemorrhage compared to warfarin.[147] The risk of recurrent stroke in the presence of atrial fibrillation without anticoagulation is low, probably <5% over the next 48 hours; moreover, the risk of hemorrhagic transformation of an acute stroke is also greatest in the first 48 hours. Consequently, **in the setting of acute atrial fibrillation, anticoagulation therapy typically should not be started in the ED but should be initiated in the inpatient setting.**

Multiple studies have demonstrated that, although unfractionated heparin may help prevent recurrent stoke, its potential benefits are outweighed by the increased risk of intracranial hemorrhage. Multiple studies of low-molecular-weight heparin and heparinoids have found similarly disappointing results. A Cochrane systematic review of 24 randomized trials (23,748 patients) found no net benefit of anticoagulants in acute stroke.[148] In addition, a meta-analysis of seven trials focused specifically on anticoagulant use in acute cardiothrombotic stroke and found no overall benefit.[149] **Therefore, the use of unfractionated heparin, low-molecular-weight heparin, or heparinoids for emergent treatment of a specific stroke subtype or TIA cannot be recommended based on available evidence, even in the presence of atrial fibrillation.**[150]

SPECIAL POPULATIONS

STROKE OR TIA WITH CONCURRENT ACUTE MYOCARDIAL INFARCTION

The co-occurrence of acute myocardial infarction and acute stroke has implications for acute treatment in the ED. There is little published information on co-occurrence of the two conditions, and treatment must be extrapolated. Troponin T elevation in acute stroke is likely to be related to acute myocardial infarction if renal failure and symptomatic heart failure are excluded and is associated with worse clinical outcomes.[151] However, the newer highly sensitive troponin assays do not appear to add additional prognostic information if a fourth-generation troponin assay is normal.[152] Although anticoagulation with heparin is not recommended for the treatment of acute stroke, heparin does reduce extension or reinfarction in the setting of acute myocardial infarction (relative risk = 0.40; number needed to treat = 33).[153] However, the risk of mortality, the need for revascularization procedures, major or minor bleeding, and recurrent angina appear to be similar with and without heparin. Weigh the risks when requested to initiate heparin therapy by the cardiologist and when advised by the neurologist that heparin may induce hemorrhagic transformation. Consider the patient's baseline cardiac and neurologic status. The balance often swings to the preservation of cardiac status.

SICKLE CELL DISEASE

Stroke afflicts both adults and children with sickle cell disease, with an overall prevalence of 3.8%,[154] compared to the overall prevalence of 2.8% (age ≥20 years) in the general population in the United States.[1] Sickle cell disease is the most common cause of ischemic stroke in children. Patients homozygous for hemoglobin S have the highest incidence of stroke (0.61 in 100 patient-years), but all genotypes are at increased risk.[154] The highest incidence of hemorrhagic stroke in these patients occurs from ages 20 to 29.[154]

Cerebral aneurysms and arterial abnormalities also occur with increased frequency in patients with sickle cell disease, and careful evaluation for subarachnoid hemorrhage is mandated for patients presenting with headache and neurologic findings. Initial management is similar to that for stroke patients without sickle cell disease, but care should also be taken to treat the underlying sickle cell disease with oxygen administration, hydration, and pain control, if necessary. Although evidence is limited, expert consensus recommends exchange transfusion in sickle cell patients with acute ischemic stroke, with the goal of reducing hemoglobin S levels to <30%.[155,156] The same therapy has been recommended in hemorrhagic stroke in order to reduce vasospasm and secondary ischemic infarction.[155] Sickle cell disease is not currently considered a contraindication to rtPA therapy in eligible adults. In any event, emergent consultation with a hematologist and a stroke neurologist is in order, and admission to a stroke unit setting is indicated.

YOUNG ADULTS

Exercise particular care when evaluating young adults (age 15 to 50 years) with acute stroke. In this group, **cervical arterial dissection** accounts for 20% of all ischemic strokes and may often be preceded by only minor trauma. The young adult with a cardioembolic event may have mitral valve prolapse, rheumatic heart disease, or paradoxical embolism as the originating cause. Migrainous stroke (infarction associated with typical migraine attack, among those with established recurrent migraines) is also a possibility in this age group. Some members of this population are at risk for ischemic stroke from substance abuse. Heroin, cocaine, amphetamines, and other sympathomimetic drugs are often implicated. Human immunodeficiency virus is also a risk factor for stroke in young adults.[157]

PREGNANT WOMEN

Women are at increased risk of ischemic and hemorrhagic stroke during pregnancy and the postpartum period (up to 6 weeks after birth). Potential contributors to this increased risk include the presence of preeclampsia or eclampsia, hypertension, diabetes,[158] sickle cell disease, and drug abuse, as well as the venous stasis, edema, and hypercoagulable state that naturally occur.[9] Following birth, decreases in blood volume, alterations in hormonal status, and the potential for amniotic fluid embolism also contribute.[159] The number of antenatal strokes is approximately 34 per 100,000 deliveries,[160] with an adjusted relative risk in one series of 2.4 compared with nonpregnant females.[161] Interestingly, the overall risk for all types of stroke is far greater during 6 weeks postpartum than during pregnancy itself, with adjusted relative risks versus nonpregnant females of 8.7 and 28.3 for ischemic and hemorrhagic stroke, respectively.[161] Presentation of acute stroke is similar to that in nonpregnant patients, although pregnant patients are particularly susceptible to cerebral venous thrombosis, especially during delivery or the postpartum period, and may present primarily with a headache. MRI is generally considered the safest brain imaging study,[162] but the benefits of an emergent non–contrast-enhanced CT clearly outweigh the risks to the fetus in this setting if MRI is not immediately available. A head CT exposes the fetus to <1 rad. For further discussion, see chapter 99, "Comorbid Disorders in Pregnancy." rtPA does not cross the placenta, and there are reports of successful IV rtPA use for stroke in pregnant patients.[128,163-165] ED treatment of stroke in pregnant women should ideally involve early consultation with obstetricians, stroke neurologists, and neonatologists, as appropriate.

CHAPTER 168

Altered Mental Status and Coma

J. Stephen Huff

INTRODUCTION

Disorders of consciousness may be divided into processes that affect either *arousal* or *content of consciousness*, or a combination of both. Arousal behaviors include wakefulness and basic alerting. Anatomically, neurons responsible for these arousal functions reside in the reticular activating system, a collection of neurons scattered through the midbrain, pons, and medulla. The neuronal structures responsible for the content of consciousness reside in the cerebral cortex. Content of consciousness includes self-awareness, language, reasoning, spatial relationship integration, emotions, and the myriad complex integration processes that make us human. One simplistic model holds that dementia is failure of the content portions of consciousness with relatively preserved alerting functions. Delirium is arousal system dysfunction with the content of consciousness affected as well. Coma is failure of both arousal and content functions. Psychiatric disorders and altered mental states may share features such as hallucinations or delusion. Some distinctions between the different states are summarized in **Table 168-1**.

Mental status is the clinical state of emotional and intellectual functioning of the individual. The mental status evaluation may be divided into six areas (**Table 168-2**). Testing the mental status is done both formally and informally in patient evaluation by emergency physicians.[1] Assessment of higher mental or cognitive functions requires specific tests. Screening tests are described in the Diagnosis subsections under Delirium, Dementia, and Coma.

DELIRIUM

INTRODUCTION

Delirium, acute confusional state, acute cognitive impairment, acute encephalopathy, altered mental status, and other synonyms all refer to a transient disorder with impairment of attention and cognition. The patient has difficulty focusing, shifting, or sustaining attention. Confusion may fluctuate (**Table 168-1**).

The incidence of delirium in ED populations is not clear. It is estimated that 10% to 25% of elderly hospitalized patients have delirium at the time of admission.[2,3] The literature suggests that up to one quarter of all ED patients aged 70 years or older have impaired mental status or delirium and contends that routine evaluation is not satisfactory to identify many of these patients.[4,5]

TABLE 168-1 Features of Delirium, Dementia, and Psychiatric Disorder

Characteristic	Delirium	Dementia	Psychiatric Disorder
Onset	Over days	Insidious	Sudden
Course over 24 h	Fluctuating	Stable	Stable
Consciousness	Reduced or hyperalert	Alert	Alert
Attention	Disordered	Normal	May be disordered
Cognition	Disordered	Impaired	May be impaired
Orientation	Impaired	Often impaired	May be impaired
Hallucinations	Visual and/or auditory	Often absent	Usually auditory
Delusions	Transient, poorly organized	Usually absent	Sustained
Movements	Asterixis, tremor may be present	Often absent	Absent

TABLE 168-2 Six Elements of Mental Status Evaluation

Appearance, behavior, and attitude
Is dress appropriate?
Is motor behavior at rest appropriate?
Is the speech pattern normal?
Disorders of thought
Are the thoughts logical and realistic?
Are false beliefs or delusions present?
Are suicidal or homicidal thoughts present?
Disorders of perception
Are hallucinations present?
Mood and affect
What is the prevailing mood?
Is the emotional content appropriate for the setting?
Insight and judgment
Does the patient understand the circumstances surrounding the visit?
Sensorium and intelligence
Is the level of consciousness normal?
Is cognition or intellectual functioning impaired?

PATHOPHYSIOLOGY

Pathologic mechanisms producing delirium are complex and are thought to involve widespread neuronal or neurotransmitter dysfunction. There are four general causes[6]:

1. Primary intracranial disease
2. Systemic diseases secondarily affecting the CNS
3. Exogenous toxins
4. Drug withdrawal

CLINICAL FEATURES

Delirium or acute confusional state generally develops over days. Attention, perception, thinking, and memory are all altered. Alertness is reduced as manifested by difficulty maintaining attention and focusing concentration. The patient may appear quite awake, but attention is impaired. Activity levels may be either increased or decreased. The patient may fluctuate rapidly between hypoactive and hyperactive states. **Symptoms may be intermittent, and it is not unusual for different caregivers to witness completely different behaviors within a brief time span.** The sleep-wake cycles are often disrupted, with increased somnolence during the day and agitation at night, or "sundowning." Tremor, asterixis, tachycardia, sweating, hypertension, and emotional outbursts may be present. Hallucinations tend to be visual, although auditory hallucinations can also occur.[2,3,7]

DIAGNOSIS

Both historical and physical examination findings indicating delirium are necessary to confirm the diagnosis. Obtaining a history from caregivers, spouse, or other family members is the primary method for diagnosing delirium.[2,3,7] **The acute onset of attention deficits and cognitive abnormalities fluctuating in severity throughout the day and worsening at night is virtually diagnostic of delirium.** Examine medication history, including over-the-counter medications taken and prescribed medications, in detail. Check for drug interactions. Assess for an underlying process, such as pneumonia or urinary tract infection. Ancillary testing should include serum electrolyte levels, hepatic and renal studies, urinalysis, CBC, and a chest radiograph. Order a head CT if a mass lesion such as subdural hematoma is suspected; follow this by performing a lumbar puncture if meningitis or subarachnoid hemorrhage is considered.

One key tool for detecting delirium is the mental status examination and other cognitive screening instruments.[8-12] These tests are valuable in directing the physician to study aspects of attention and memory that might not otherwise be formally tested. Parts of the Mini-Mental State Examination are sometimes used in the ED.[8-10] The complete test takes 7 to 10 minutes to administer, but copyright restrictions limit reproduction and use.[11] Age, education, chronic cognitive impairment, and verbal abilities all may affect scores. The Mini-Mental State Examination does not detect mild impairment. The median positive and negative likelihood ratios for the test are 6.3 and 0.19, respectively.[11] Several other shorter evaluation tools have been proposed.[9-12] The **Quick Confusion Scale** has been tested in ED patients, yields scores that correlate well with those on the Mini-Mental State Examination ($r = 0.61$ in one study[10] and 0.783 in another[9]), and takes <3 minutes to administer. The patient does not need to read, write, or draw to complete the test[10] (**Table 168-3**).

Depression may resemble hypoactive delirium, with withdrawal, slowed speech, and poor results on cognitive testing present in both conditions. However, rapid fluctuation of symptoms is common in delirium but generally absent in depression. In addition, clouding of consciousness is absent in patients with depression. **Patients with depression are oriented and able to perform commands.**

TABLE 168-3 The Quick Confusion Scale

Item	Score (Number Correct)	¥ (Weight)	=	(Total)
What year is it now?	0 or 1 (Score 1 if correct, 0 if incorrect)	×2	=	_____
What month is it?	0 or 1	×2	=	_____
(Present memory phrase): Repeat this phrase after me and remember it: "John Brown, 42 Market Street, New York."				
About what time is it? (Answer correct if within 1 h.)	0 or 1	×2	=	_____
Count backward from 20 to 1.	0, 1, or 2	×1	=	_____
Say the months in reverse.	0, 1, or 2	×1	=	_____
Repeat the memory phrase (each underlined portion correct is worth 1 point).	0, 1, 2, 3, 4, or 5	×1	=	_____
Final score is the sum of the totals.			=	_____

Notes:

15 is the top score; a score <15 may indicate the need for additional assessment.	
Scores highest number in category indicates correct response; lower scoring indicates increased number of errors.	
Item 1. What year is it now?	Score 1 if answered correctly, 0 if incorrect.
Item 2. What month is it?	Score 1 if answered correctly, 0 if incorrect.
Item 3. About what time is it?	Answer considered correct if within 1 h; score 1 if correct, 0 if incorrect.
Item 4. Count backward from 20 to 1.	Score 2 if correctly performed; score 1 if one error, score 0 if two or more errors.
Item 5. Say the months in reverse.	Score 2 if correctly performed; score 1 if one error, score 0 if two or more errors.
Item 6. Repeat memory phrase: "John Brown, 42 Market Street, New York."	Each underlined portion correctly recalled is worth 1 point in scoring; score 5 if correctly performed; each error drops score by 1.
Final score is the sum of the weighted totals; items 1, 2, and 3 are multiplied by 2 and summed with the other item scores to yield the final score.	

TABLE 168-4 Important Medical Causes of Delirium

Infectious	Pneumonia Urinary tract infection Meningitis or encephalitis Sepsis
Metabolic/toxic	Hypoglycemia Alcohol ingestion Electrolyte abnormalities Hepatic encephalopathy Thyroid disorders Alcohol or drug withdrawal
Neurologic	Stroke or transient ischemic attack Seizure or postictal state Subarachnoid hemorrhage Intracranial hemorrhage CNS mass lesion Subdural hematoma
Cardiopulmonary	Congestive heart failure Myocardial infarction Pulmonary embolism Hypoxia or carbon dioxide narcosis
Drug related	Anticholinergic drugs Alcohol or drug withdrawal Sedatives-hypnotics Narcotic analgesics Selective serotonin or serotonin-norepinephrine reuptake inhibitors Polypharmacy

An unusual cause of confusional state, but one that is suspected to be underrecognized, is **nonconvulsive status epilepticus**, or **complex partial status epilepticus**. This twilight state may persist for hours or even months. Suspicion and electroencephalography are required for recognition.[10] (See chapter 171, Seizures, for further discussion of nonconvulsive status epilepticus.)

TREATMENT

Direct treatment at the underlying cause. Common medical causes of delirium are listed in **Table 168-4**. Multiple causes may be present in a given patient.

Environmental manipulations such as adequate lighting, psychosocial support, and mobilization may be helpful in enhancing the patient's ability to interpret the surroundings correctly.[2,6,7] Sedation may be needed. Haloperidol is a frequent initial choice at a dose of 5 to 10 milligrams PO, IM, or IV with reduced dosing of 1 to 2 milligrams in the elderly. Repeat at 20- to 30-minute intervals as needed. Benzodiazepines such as lorazepam, 0.5 to 2.0 milligrams PO, IM, or IV, may be used in combination with haloperidol in doses of 1 to 2 milligrams, with the dose varying widely depending on the age and size of the patient and the degree of agitation. Chapter 287, Acute Agitation, provides further discussion on management of agitation.

DISPOSITION AND FOLLOW-UP

Admit the patient into the hospital for further treatment and additional diagnostic testing unless a readily reversible cause for the acute mental status change is discovered and treatment initiated. This decision is individualized with consideration of patient characteristics, the resources in the home or healthcare facility, and the patient's safety.

DEMENTIA

INTRODUCTION

Dementia implies a loss of mental capacity. Psychosocial level and cognitive abilities deteriorate, and behavioral problems develop. The largest categories of dementia are idiopathic dementia (Alzheimer's disease) and vascular dementia, which are essentially diagnoses of exclusion. However, other, more treatable disorders may cause or simulate dementia.

The typical course of dementia is slow with insidious symptom onset. The abrupt onset of symptoms or rapidly progressive symptoms should prompt a search for other diagnoses. Presentation to the ED is usually precipitated by some sentinel event. Hallucinations, delusions, repetitive behaviors, and depression are all common.

PATHOPHYSIOLOGY

Most cases of dementia in the United States are due to Alzheimer's disease, a neurodegenerative disorder of unknown etiology. The pathophysiology is complex, with a reduction in neurons in the cerebral cortex, increased amyloid deposition, and the production of neurofibrillary tangles and plaques. Other neurodegenerative diseases have their own unique pathologies. Vascular dementia accounts for the next largest number of dementia cases. The pathology is that of cerebrovascular disease with multiple infarctions. A listing of different types of dementia is provided in **Table 168-5**.

TABLE 168-5 Classification of Dementia by Cause

Degenerative
Alzheimer's disease
Huntington's disease
Parkinson's disease
Vascular
Multiple infarcts
Hypoperfusion (cardiac arrest, profound hypotension, others)
Subdural hematoma
Subarachnoid hemorrhage
Infectious
Meningitis (sequelae of bacterial, fungal, or tubercular)
Neurosyphilis
Viral encephalitis (herpes, human immunodeficiency virus), Creutzfeldt-Jakob disease
Inflammatory
Systemic lupus erythematosus
Demyelinating disease, others
Neoplastic
Primary tumors and metastatic disease
Carcinomatous meningitis
Paraneoplastic syndromes
Traumatic
Traumatic brain injury
Subdural hematoma
Toxic
Alcohol
Medications (anticholinergics, polypharmacy)
Metabolic
Vitamin B_{12} or folate deficiency
Thyroid disease
Uremia, others
Psychiatric
Depression (pseudodementia)
Hydrocephalic
Normal-pressure hydrocephalus (communicating hydrocephalus)
Noncommunicating hydrocephalus

CLINICAL FEATURES

Impairment of memory, particularly recent memory, is gradual and progressive. Remote memories are often preserved. Impairment of memory and orientation with preservation of motor and speech abilities is said to be characteristic of the onset of dementia associated with Alzheimer's disease. Degenerative dementias are divided into early, middle, and late stages. Early in the disease, complaints of memory loss, naming problems, or forgetting of items is common. The middle stage shows progression of these problems plus loss of reading, decreased performance in social situations, and loss of direction. The late stage of the illness may include extreme disorientation, inability to perform self-care tasks, and personality change. Clinical features may include affective symptoms such as depression and anxiety, behavioral disorders, and speech difficulties.

Patients with vascular or multi-infarct dementia often show similar symptoms, but may have findings on physical examination of exaggerated or asymmetric deep tendon reflexes, gait abnormalities, or weakness of an extremity.

DIAGNOSIS

General physical examination does not determine the diagnosis of dementia but may be helpful in identifying associated causes.[13] The presence of focal neurologic signs may suggest vascular dementia or a mass lesion. Increased motor tone and other extrapyramidal signs such as rigidity or a movement disorder may suggest Parkinson's disease. Perform mental status testing as outlined earlier.

Laboratory assessment typically includes a CBC, comprehensive metabolic profile, urinalysis, thyroid function tests, serum vitamin B_{12} level, and serologic testing for syphilis (in patients at risk).[14,15] Other helpful laboratory tests may include erythrocyte sedimentation rate, serum folate level, human immunodeficiency virus testing, and chest radiography. Consider CT or MRI imaging in every patient at some point in the diagnostic evaluation. Perform lumbar puncture if the diagnosis is not readily apparent.

Diagnosis of probable vascular dementia requires signs of cerebrovascular disease. The relationship between stroke and cognitive decline must be temporally related, with dementia within 3 months of the stroke or abrupt deterioration in memory and other cognitive abilities. A fluctuating, stepped course suggests vascular dementia.[16]

The possibility of a concurrent medical condition suddenly causing cognitive functioning to deteriorate should be strongly considered and often is the thrust of investigation in the ED. Urinary tract infection, congestive heart failure, and hypothyroidism are just a few of the conditions that may cause a mildly demented but functioning individual to show rapid decline. The symptoms overlap with those of delirium as discussed earlier in the Clinical Features section under Delirium, and the two conditions may overlap.[3,7] Consider depression imitators, the so-called treatable causes of dementia (included in **Table 168-5**), in the differential diagnosis.

Depression may coexist with dementia, and also consider depression-imitating dementia (pseudodementia). Arrange appropriate inpatient or outpatient follow-up for further behavioral health evaluation. If depression is severe, consider hospital admission.

TREATMENT

All types of dementia are treatable, at least to some degree, by environmental or psychosocial interventions. Antipsychotic drugs are used to manage psychotic and nonpsychotic behaviors, but adverse drug effects complicate treatment. Reserve antipsychotic drugs for patients with persistent psychotic features or those with extreme disruptive or dangerous behaviors.[3,17] Coordinate treatment with caregivers who are in a position to monitor the patient's behavior patterns over time.

Treatment of vascular dementia is limited to treatment of risk factors, including hypertension.

Normal-pressure hydrocephalus is suggested by the presence of excessively large ventricles on head CT and can prompt consideration of a trial of lumbar puncture with cerebrospinal fluid drainage or ventricular shunting. **Consider normal-pressure hydrocephalus if urinary incontinence and gait disturbance develop early in the disease process.**

DISPOSITION AND FOLLOW-UP

A new diagnosis of dementia may be entertained in the ED, but the depth of the required diagnostic evaluation usually exceeds the time available during the ED visit. A decision to admit or to arrange an outpatient diagnosis is the usual disposition after the major differential diagnostic possibilities have been eliminated. Direct attention toward the presence of delirium or a treatable cause of dementia. Consider hospital admission if comorbid medical problems, a rapidly progressive or atypical clinical course, or an unsafe or uncertain home situation exists.

COMA

INTRODUCTION

Coma is a state of reduced alertness and responsiveness from which the patient cannot be aroused.[18,19] The Glasgow Coma Scale (**Table 168-6**; see also chapter 257, Head Trauma) is a widely used clinical scoring system for alterations in consciousness. Advantages are the simplicity of the scoring system and assessment of separate verbal, motor, and eye-opening functions. Disadvantages include lack of acknowledgment of hemiparesis or other focal motor signs and lack of testing of higher cognitive functions. Interrater variability has been noted in assessments using the **Glasgow Coma Scale**.[20] Another coma scale, the FOUR (*F*ull *O*utline of *UnR*esponsiveness) score, has been used in intensive care units and has the advantages of assessing simple brainstem functions and respiratory patterns, as well as eye and motor responses.[21] Causes of coma likely to be encountered in the ED are noted in **Table 168-7**.

PATHOPHYSIOLOGY

The pathophysiology of coma is complex. Coma can result from deficiency of substrates needed for neuronal function (as with hypoglycemia or hypoxia). With systemic causes, the brain is globally affected, and signs that localize dysfunction to a specific area of the brainstem or cortex are usually lacking. With primary CNS causes, coma may result from a brainstem disorder such as hemorrhage or from bilateral cortical dysfunction. Signs localizing to specific areas of CNS dysfunction such

TABLE 168-7 Differential Diagnosis of Coma

	1	None	None	

as hemiparesis or cranial nerve abnormalities may be present. Unilateral hemispheric disease, such as stroke, should not alone result in coma. The function of the brainstem and/or both hemispheres must be impaired for unresponsiveness to occur.

The herniation syndromes are models for alterations of consciousness, but their mechanisms are unknown. In **uncal herniation syndrome**, the medial temporal lobe shifts to compress the upper brainstem, which results in progressive drowsiness followed by unresponsiveness.[19,22] The ipsilateral pupil is sluggish, eventually becoming dilated and nonreactive as the third cranial nerve is compressed by the medial temporal lobe. Hemiparesis may develop ipsilateral to the mass from compression of the descending motor tracts in the opposite cerebral peduncle. **Central herniation syndrome** is characterized by progressive loss of consciousness, loss of brainstem reflexes, decorticate posturing, and irregular respiration.[19] Because midline shift without herniation, as demonstrated by neuroimaging, seems to correlate with a decreased level of consciousness, vascular compression due to local cerebral edema or local increased intracranial pressure (ICP) may be an underlying mechanism for these syndromes.

A diffuse increase in ICP can cause diffuse CNS dysfunction. Cerebral blood flow is constant at mean arterial pressures (MAPs) of 50 to 100 mm Hg due to the process of cerebral autoregulation. At MAPs outside this range, cerebral blood flow may be reduced, and diffuse ischemia may develop. **Cerebral perfusion pressure is equal to the MAP minus the ICP (cerebral perfusion pressure = MAP – ICP).** In extreme uncontrolled elevation of the ICP, cerebral perfusion pressure is diminished as the ICP approaches the MAP, which causes brain ischemia.

Particularly in unresponsive patients with a history of seizures, the possibility of ongoing nonconvulsive seizures must be considered. Subtle status epilepticus or ictal coma may represent transformed generalized convulsive status epilepticus. Electrical seizures may continue in the absence of clinical seizures.[23]

CLINICAL FEATURES

The clinical features of coma vary with both the depth of coma and the cause. For example, a patient in a coma with a hemispheric hemorrhage and midline shift may have decreased muscle tone on the side of the hemiparesis. The eyes may conjugately deviate toward the side of the hemorrhage. **With expansion of the hemorrhage and surrounding edema, increase in ICP, or brainstem compression, unresponsiveness may progress to a complete loss of motor tone and loss of the ocular findings as well.**

A variety of abnormal breathing patterns may be seen in the comatose patient.[19] They offer little information in the acute setting. Pupillary findings, the results of other cranial nerve evaluation, hemiparesis, and response to stimulation are all part of the clinical picture that need assessment. These findings can assign the cause of the coma into a probable general category—diffuse CNS dysfunction (toxic-metabolic coma) or focal CNS dysfunction (structural coma). A further division of structural coma into hemispheric (supratentorial) or posterior fossa (infratentorial) coma is often possible at the bedside.

Toxic-Metabolic Coma Many different toxic and metabolic conditions cause coma. The diffuse CNS dysfunction is reflected by the lack of focal physical examination findings that point to a specific region of brain dysfunction. For example, in toxic-metabolic coma, if the patient demonstrates either spontaneous movements or reflex posturing, the movements are symmetric without evidence of hemiparesis. Muscle stretch reflexes, if present, are symmetric. Pupillary response is generally preserved in toxic-metabolic coma. Typically the pupils are small but reactive. If extraocular movements are present, they are symmetric. If extraocular movements are absent, however, this sign is of no value in differentiating toxic-metabolic from structural coma. A notable exception is severe sedative poisoning as from barbiturates; the pupils may be large, extraocular movements absent, muscles flaccid, and the patient apneic, which simulates the appearance of brain death.

Coma from Supratentorial Lesions Coma caused by lesions of the hemispheres, or supratentorial masses, may present with progressive hemiparesis or asymmetric muscle tone and reflexes. The hemiparesis may be suspected with asymmetric responses to stimuli or asymmetric extensor or flexor postures. Uncal herniation syndrome, as described earlier in Pathophysiology, is an example of a supratentorial syndrome. Frequently, however, large acute supratentorial lesions are seen without the features consistent with temporal lobe herniation. Coma without lateralizing signs may result from decreased cerebral perfusion secondary to increased ICP. Reflex changes in blood pressure and heart rate may be observed with increased ICP or brainstem compression. Hypertension and bradycardia in a comatose patient may represent the Cushing reflex from increased ICP.

Coma from Infratentorial Lesions Posterior fossa or infratentorial lesions comprise another structural coma syndrome. **An expanding lesion, such as cerebellar hemorrhage or infarction, may cause abrupt coma, abnormal extensor posturing, loss of pupillary reflexes, and loss of extraocular movements.** The anatomy of the posterior fossa leaves little room for accommodating an expanding mass. Early brainstem compression with loss of brainstem reflexes may develop rapidly. Another infratentorial cause of coma is pontine hemorrhage, which may present with the unique signs of pinpoint-sized pupils.

Pseudocoma Pseudocoma or psychogenic coma is occasionally encountered and may present a perplexing clinical problem. Adequate history taking and observation of responses to stimulation reveal findings that differ from those in the syndromes described in the previous sections. Pupillary responses, extraocular movements, muscle tone, and reflexes are shown to be intact on careful examination. Tests of particular value include responses to manual eye opening (there should be little or no resistance in the truly unresponsive patient) and extraocular movements. Specifically, if avoidance of gaze is consistently seen with the patient always looking away from the examiner, or if nystagmus is demonstrated with caloric vestibular testing, this is strong evidence for nonphysiologic or feigned unresponsiveness.

DIAGNOSIS

In the approach to the comatose patient, perform stabilization, diagnosis, and treatment actions simultaneously. Examination, laboratory procedures, and neuroimaging allow differentiation between structural and metabolic causes of coma in almost all patients in the ED. History and physical examination findings allow that initial assignment in many patients, but liberal use of CT scanning is encouraged because exceptions to the tentative clinical diagnosis are frequent.

Address airway, breathing, and circulation immediately. Consider reversible causes of coma, such as hypoglycemia or opiate overdose. Access all available historical sources (EMS personnel, caregivers, family, witnesses, medical records, etc.) to aid in diagnosis.

The tempo of onset of the coma is of great diagnostic value. Abrupt coma suggests abrupt CNS failure with possible causes such as catastrophic stroke or seizures. A slowly progressive onset of coma may suggest a progressive CNS lesion such as tumor or subdural hematoma. Metabolic causes, such as hyperglycemia, may also develop over several days.

Address general examination and measurement of vital signs (including oxygen saturation and temperature) following stabilization and resuscitation. General examination may reveal signs of trauma or suggest other diagnostic possibilities for the unresponsiveness. For example, a toxidrome may be present that suggests diagnosis and treatment, such as the opiate syndrome with hypoventilation and small pupils.

Neurologic testing deviates from the standard examination. Fine tests of weakness, such as testing for pronator drift of the outstretched upper extremities, are not possible in the unresponsive patient. However, asymmetric findings on examination of cranial nerves through pupillary examination, assessment of corneal reflexes, and testing of oculovestibular reflexes may suggest focal CNS lesions. Abnormal extensor or flexor postures are nonspecific for localization or cause of coma but suggest profound CNS dysfunction. Asymmetric muscle tone or reflexes raise the suspicion of a focal lesion. **The goal of the physician is to rapidly determine if the CNS dysfunction is from diffuse impairment of the brain or if signs point to a focal (and perhaps surgically treatable) region of CNS dysfunction.**

CT is the neuroimaging procedure of choice. Acute hemorrhage is readily identified, as is midline shift and mass lesions. Consider lumbar puncture if CT scan findings are unremarkable and subarachnoid hemorrhage

or CNS infection is suspected. Suspect basilar artery thrombosis in a comatose patient with "normal" results on head CT, in which the only finding may be a hyperdense basilar artery.[24] MRI or cerebral angiography is needed to make the diagnosis of basilar artery thrombosis.

SPECIAL CONSIDERATIONS IN COMA

If trauma is suspected, maintain stabilization of the cervical spine during assessment. If protection of the airway is in doubt or the coma state is likely prolonged, then protect the airway by intubating the patient. Rapid-sequence intubation techniques are discussed at length in chapter 29, Intubation and Mechanical Ventilation. **ingestions, infections, and child abuse in the appropriate clinical setting.**

Patients who have had generalized seizures and remain unresponsive may be in a continuing state of electrical seizures without corresponding motor movements. This is called **nonconvulsive status epilepticus** or **subtle status epilepticus** and can be described as electromechanical dissociation of the brain and body. **If the motor activity of the seizure stops and the patient does not awaken within 30 minutes, then consider nonconvulsive status epilepticus.** Obtain neurologic consultation and electroencephalography.[23]

TREATMENT

Treatment of coma involves identification of the cause of the brain failure and initiation of specific therapy directed at the underlying cause. Attend to airway, ventilation, and circulation. Evaluate and treat for readily reversible causes of coma, such as hypoglycemia and opioid toxicity.

Antidotes Rapid point-of-care glucose determination can identify the need for dextrose. Although thiamine should be administered before glucose infusion in patients with a suspected history of alcohol abuse or malnutrition, thiamine is not necessary for all patients. Routine use of flumazenil in coma of unknown cause is not recommended.[25] Naloxone, the opiate antagonist, is useful in coma because typical signs of opiate overdose may be absent.

Increased Intracranial Pressure If history, physical examination, or neuroimaging findings suggest increased ICP, specific steps can reduce or ameliorate any further rise in ICP. Any noxious stimulus, including "bucking" the ventilator, can increase ICP, so use paralytic and sedative agents. A general recommendation is to keep the head elevated about 30 degrees and at midline to aid in venous drainage. **Mannitol** (0.5 to 1.0 gram/kg IV) can decrease intravascular volume and brain water and may transiently reduce ICP. In cases of brain edema associated with tumor, dexamethasone, 10 milligrams IV, reduces edema over several hours. Hyperventilation with reduction of partial pressure of arterial carbon dioxide can reduce cerebral blood volume and transiently lower ICP. Current recommendations are to avoid excessive hyperventilation (partial pressure of arterial carbon dioxide ≤35 mm Hg) during the first 24 hours after brain injury. Brief hyperventilation may be necessary for refractory intracranial hypertension. Data to recommend specific therapy are lacking, and preferences among individuals and institutions vary greatly, so communicate early with consultants and admitting physicians.

DISPOSITION AND FOLLOW-UP

Patients with readily reversible causes of coma, such as insulin-induced hypoglycemia, may be discharged if home care and follow-up care are adequate and a clear cause for the episode is suspected. Admit patients with persistent altered consciousness. Most institutions depend on emergency physicians to stabilize the patient's condition and correctly assign a tentative diagnosis so that the patient may be admitted to the proper specialty service. If the appropriate service is not available, then consider transfer to another hospital after patient stabilization.

CHAPTER 169

Ataxia and Gait Disturbances

J. Stephen Huff

INTRODUCTION

Ataxia and gait disturbances may be symptoms of many disease processes and generally are not themselves diagnoses. **Ataxia** is uncoordinated movement. A **gait disorder** is an abnormal pattern or style of walking. The presenting problem may be articulated by the patient or family as weakness, dizziness, stroke, falling, or another nonspecific chief complaint. Such symptoms must always be viewed in the context of the patient's overall clinical picture. This chapter reviews the more common causes of acute ataxia and gait disorders (**Table 169-1**).

PATHOPHYSIOLOGY

Clinicians erroneously tend to think that ataxia and gait disorders result primarily from cerebellar lesions. However, such disorders result from many systemic or focal conditions that affect different elements of the central and peripheral nervous systems. Cerebellar lesions may indeed cause ataxia, but isolated lesions of the cerebellum are not the most common cause of these complaints. Ataxias are classified as either motor (cerebellar) or sensory.

TABLE 169-1 Common Etiologies of Acute Ataxia and Gait Disturbances

- **Systemic conditions**
  - Intoxications with diminished alertness
    - Ethanol
    - Sedative-hypnotics
  - Intoxications with relatively preserved alertness (diminished alertness at higher levels)
    - Phenytoin
    - Carbamazepine
    - Valproic acid
    - Heavy metals—lead, organic mercurials
  - Other metabolic disorders
    - Hyponatremia
    - Inborn errors of metabolism
    - Wernicke's disease
- **Disorders predominantly of the nervous system**
  - Conditions affecting predominantly one region of the CNS
    - Cerebellum
      - Hemorrhage
      - Infarction
      - Degenerative changes
      - Abscess
    - Cortex
      - Frontal tumor, hemorrhage, or trauma
      - Hydrocephalus
    - Subcortical
      - Thalamic infarction or hemorrhage
      - Parkinson's disease
      - Normal pressure hydrocephalus
    - Spinal cord
      - Cervical spondylosis and other causes of spinal cord compression
      - Posterior column disorders
    - Conditions affecting predominantly the peripheral nervous system
      - Peripheral neuropathy
      - Vestibulopathy

MOTOR ATAXIAS

Motor ataxias (also referred to as **cerebellar ataxias**) are usually caused by disorders of the cerebellum. The sensory receptors and afferent pathways are intact, but integration of the proprioceptive information is faulty. Involvement of the lateral cerebellum (one of the cerebellar hemispheres) may lead to a motor ataxia of the ipsilateral limb. Lesions affecting primarily the midline portion of the cerebellum often cause problems with axial muscle coordination, which is reflected in difficulty maintaining a steady upright standing or sitting posture.

There are many reports of lesions in what would seem to be unlikely locations producing motor ataxia. Supratentorial infarctions, particularly small, deep infarctions, and lacunae of the posterior limb of the internal capsule have been reported to cause isolated hemiataxia. It is postulated that interruption of either ascending or descending cerebellar to cortical pathways are the cause of this motor-type ataxia.[1] Small infarctions or hemorrhages in thalamic nuclei may produce a clinical picture of motor- or cerebellar-like ataxia with hemisensory loss. These effects are seen contralateral to the lesion.[2] Lesions affecting the frontal lobe, such as tumor or cystic masses, may cause a motor ataxia of the contralateral extremities through poorly understood mechanisms.[3] Nontraumatic spinal cord compression may present with gait ataxia or abnormality.[4]

SENSORY ATAXIAS

Sensory ataxias are due to failure of transmission of proprioception or position sense information to the CNS. Failure may arise from disorders affecting the peripheral nerves, spinal cord, or cerebellar input tracts. Coordinated motor performance is faulty, even though motor systems and the cerebellum are intact. Sensory ataxias may be somewhat compensated by visual sensory information. Loss of visual information leads to the observation that sensory ataxias often worsen in poor lighting conditions and may be brought out during examination.

GAIT DISORDERS

No organized classification scheme exists for gait disorders, and different authors categorize abnormal gaits in descriptive terms. A **cerebellar or motor ataxic gait** is widely based with unsteady and irregular steps, and compensation to barriers in the environment may be lacking. The **gait of sensory ataxia** resulting from loss of proprioception is notable for abrupt movement of the legs and slapping impact of the feet with each step. A variety of other terms are used to describe abnormal gaits.

An **apraxic gait** is one in which the patient seemingly has lost the ability to initiate the process of walking, an "ignition failure." This may occur with right or nondominant hemispheric lesions. Frontal lobe dysfunction may result in a similar gait and may be seen in normal pressure hydrocephalus.[5]

The term **festinating gait** is used to describe narrowly based miniature shuffling steps and is common in Parkinson's disease. An abnormal gait with outward swinging or circumabduction of the leg suggests a mild **hemiparesis** reflecting the asymmetric weakness of the proximal lower extremity muscles. Bilateral weakness of the trunk and pelvic girdle muscles may result in a **waddling gait** from failure to maintain the normal position of the pelvis relative to the lower extremities.

A functional gait disorder is one in which the patient is unable to walk normally, although all motor pathways, sensory pathways, and cerebellar functions may be demonstrated to be functioning normally. The underlying problem is often a conversion disorder. Functional gaits may be bizarre, at times resembling a person balancing on a tightrope and seemingly threatening to fall but not falling. A dramatic functional gait with flailing movements without falling actually demonstrates that strength, balance, and coordination are intact.

A unifying concept defines gait disorders according to the level of processing of neurologic information (**Table 169-2**).[6,7] The classification scheme is not ideal but does allow a thoughtful approach to patient diagnosis.

TABLE 169-2 Classification of Gait Disorders

Low-level gait disorders
Musculoskeletal problems
Arthritic gait or other joint or skeletal problems
Muscle weakness
Peripheral sensory problems
Sensory ataxic gait
Vestibular problems
Middle-level gait disorders
Hemiplegia
Paraplegia
Motor or cerebellar ataxia
Parkinson's disease
Dystonia, chorea, other movement disorders
High-level gait disorders
Senile gait (cautious gait)
Frontal ataxic gait
Apraxic gait (gait ignition failure)
Frontal disequilibrium

Low-level gait disturbance refers to disorders of proprioception or dysfunction of the musculoskeletal system. **Middle-level gait disturbance** causes distortion of appropriate interaction of postural and motor processes or synergies. This might include stroke with paralysis, cerebellar dysfunction, or diseases of the basal ganglia such as Parkinson's disease. **High-level gait disturbances** seemingly involve structures or processes that choose the appropriate responses for the support surface, body position in space, and intention of the patient. Cautious gait, apraxic gait, and the frontal gait disorder conceptually fall into this group with pathology that correlates with lesions in the frontal cortex or thalamus. This latter group is the least understood and the source of clinical confusion.

CLINICAL FEATURES

HISTORY

Collect historical information about the entire symptom constellation, and ask about headache, nausea, fever, weakness, or numbness. A history of fever, review of medication history, or family history of ataxia may lead to the diagnosis in individual cases. The nature of onset of symptoms and the time course of the process guide the pace of investigations. For example, abrupt onset of gait difficulty in a patient with severe headache, drowsiness, nausea, and vomiting should suggest an acute process within the CNS, possibly a hemorrhage into the cerebellum. The possible consequences of that diagnosis are severe and may require immediate attention. At the other extreme, a patient without significant medical history who is brought to the ED with a stumbling gait after an episode of binge drinking requires examination but may need nothing other than observation unless history or physical examination suggest trauma or some alternative cause for the symptoms.

PHYSICAL EXAMINATION

The following discussion of the neurologic examination assumes that the gait disorder is the dominating abnormality. Physical examination including testing of cranial nerves, mental status, sensation, and the motor system is necessary and may yield findings that lead to an unanticipated diagnosis.

General physical examination of a patient with ataxia or gait disturbance should include determination of orthostatic vital signs. Orthostatic hypotension may be present in hypovolemia, diabetic neuropathy, and other neurologic syndromes. Especially in the elderly, fluid replacement for simple hypovolemia may correct many symptoms of unsteadiness.

Gait testing is one of the most important parts of the directed neurologic examination. Observe the patient sitting upright in the stretcher, and then have the patient rise, stand, walk, and turn around. The patient should be asked to walk at a normal speed, then walk on the heels, and then the toes. Tandem gait is toe-to-toe walking and also tests many elements of the nervous system. **Do not assume a normal examination without observing ambulation.**

Cerebellar functions are tested by asking the patient to perform smooth voluntary movements and rapidly alternating movements. Dyssynergia (breakdown of movements into parts), dysmetria (inaccurate fine movements), or dysdiadochokinesia (clumsy rapid movements) may indicate a lateral cerebellar lesion. The rapid thigh-slapping test particularly examines rapidly alternating movements. This is correctly performed by asking the patient to pat the thigh with the palm then the back of the same hand in alternating fashion, making a sound with each rapid slap. The maneuver is performed with each hand in turn. The finger-to-nose test may be helpful in distinguishing between cerebellar and posterior column (proprioceptive) lesions. Performing this test with the eyes closed tests proprioception in the upper extremity. A test for cerebellar function that emphasizes the lower extremities is the heel-to-shin test. In cerebellar disease, the heel may initially overshoot the other shin or knee, and the action is done with a series of jerky movements. In posterior column disease, there may be difficulty locating the knee, and the movement down the shin typically weaves from side to side or falls off. Another test commonly used for cerebellar function is the Stewart-Holmes rebound sign (with sudden release of the flexed forearm, the individual fails to check the movement). Another example of rebound phenomena is when a tapped outstretched arm oscillates back and forth for several cycles.

The Romberg test is primarily a test of sensation, and if positive may distinguish sensory from motor ataxia. While standing with arms outstretched and eyes open, observe the patient for signs of unsteadiness. The feet should be narrowly spaced, and the posture should be easily maintained. The inability to maintain a steady standing posture (or, in extreme cases, a seated position) confirms that an ataxia is present but does not yet give any information about the type of ataxia. Then ask the patient to close the eyes, to eliminate visually orienting information. If the ataxia worsens with the loss of visual input, then the Romberg sign is present or positive, suggesting sensory ataxia with a problem of proprioceptive input (posterior column, vestibular dysfunction), or a peripheral neuropathy. Further neurologic examination is indicated to confirm the suspicion of sensory ataxia. In patients who show little or no change in unsteadiness with eye closure (Romberg test–negative), a motor ataxia is suggested, with possible localization of that problem to the cerebellum. Note that many normal individuals will have some small increase in unsteadiness with eye closure.

Historically, tabes dorsalis (neurosyphilis) was a common cause of sensory ataxia. In tabes dorsalis, the posterior columns and posterior spinal roots degenerate, primarily in the lumbosacral region. The loss of proprioceptive information from the lower extremities renders the patient dependent on visual cues for correct gait. The classic description is that of a patient who walks slowly with wide gait while staring at the ground. In darkness or with interruption of vision, the patient is unable to walk. The gait in this condition is peculiar, with the foot first raised and then slapped to the ground with each step. These abnormalities reflect the loss of proprioceptive information from the posterior roots and posterior columns. Consider vitamin B_{12} deficiency in patients with evidence of posterior column disease. If the deficiency is left untreated, an initial unsteady gait may progress to weakness, spasticity, and ataxia. The finding of a megaloblastic anemia may be a clue, but the neuropathy may precede the anemia.

Sensory examination in a patient with unsteady gait or movements should include position or vibration testing (posterior columns), as well as testing sensation to pinprick. Testing of the deep tendon reflexes will serve largely to discover asymmetry or spasticity that might suggest an alternative diagnosis. Acute cerebellar injury may result in muscle hypotonia for a few days or weeks.[8]

Nystagmus is seen in many different disorders due to lesions in a variety of different locations of the CNS, but the presence of nystagmus does suggest that the pathologic process is intracranial (CNS or vestibular) and not in the spinal cord or peripheral nervous system (see chapter 170, Vertigo).

DIAGNOSIS

Assuming a primary complaint of ataxia, the first task is to determine whether the ataxia is sensory or motor and whether the primary process is systemic or within the nervous system. If the ataxia is thought to result from problems within the nervous system, the next question is one of localization to the peripheral nervous system versus the CNS and perhaps to a more specific anatomic location. Finally, the tempo of the illness, comorbid diseases, and other clinical findings guide investigations and may allow a disease-specific diagnosis.

A patient with acute gait failure over hours to days needs thorough evaluation in the ED, often requiring CT scan and MRI, or lumbar puncture if cerebrospinal fluid infection is suspected. Acute ataxia or gait disturbance may also be evaluated by consultation if available, and possible admission, in contrast to a patient with gradual loss of abilities over weeks or months where outpatient referral and evaluation may be more appropriate.

SPECIAL POPULATIONS

THE GERIATRIC PATIENT

The gait changes with advancing age. A typical constellation includes gait slowing, shortening of the stride, and widening of the base. This results in the appearance of a guarded gait—that is, the gait of someone about to slip and fall. Many patients are aware of the loss of speed and adaptive balance and acknowledge the need to be careful. The nature of the senile gait is not fully understood but may represent a mild degree of neuronal loss, failing proprioception, slowing of corrective responses, or weakness of the lower extremities. Senile gait disorder is thought to exist in up to one fourth of the elderly population. Some authorities divide this disorder into components of gait ataxia with mild truncal instability and widened gait, and gait slowing with diminished spontaneous arm swing and bradykinesia.[9] However, elements of the senile gait are also found in neurodegenerative diseases, so consider the possible presence of a neurodegenerative disorder such as Parkinson's disease or normal pressure hydrocephalus in elderly patients with gait impairment.[9] Patients unable to walk or care for themselves, or with increasing falls at home need admission for supportive care.

THE ALCOHOLIC PATIENT

A history of alcoholism or malabsorption problem in the patient with ataxia or gait disorder raises the possibility of a potentially remedial nutritional problem. If acute motor ataxia is present with confusion or eye movement abnormalities, consider **Wernicke's disease** and administer IV thiamine.[10] The entity of alcoholic cerebellar degeneration (sometimes referred to as rostral vermis syndrome, because a portion of the cerebellar vermis is preferentially affected) may represent the same nutritional deficiency and not the direct toxic effects of alcohol.

CHILDREN

In evaluating children with acute ataxia or gait disorder, examination must exclude weakness and musculoskeletal disorders. The child may be awake, alert, and playful but is visibly unsteady or wobbly sitting on a stretcher. The differential diagnosis is extensive (**Table 169-3**). Acute or deteriorating presentation generally mandates an aggressive search for the underlying cause and will likely need inpatient management.[11]

Intoxications are a cause of ataxia in children, and the ingestion may be surreptitious. History should include queries about any medications in the household. Acute ataxia may follow immunizations, viral illnesses, or varicella and also has been rarely reported in the preeruptive phase of varicella.[12] Most children are in the 2- to 4-year-old range. Acute cerebellar ataxia of childhood is thought to be a postinfectious demyelinating disorder. The onset of gait ataxia is abrupt, and only occasionally is fever present at the time ataxia begins.

TABLE 169-3 Causes of Acute Ataxia in Children, Roughly in Order of Frequency

Cause	Example
Drug intoxication	Ethanol Isopropyl alcohol Phenytoin Carbamazepine Sedatives Lead, mercury
Idiopathic	Acute cerebellar ataxia of childhood
Infection and inflammation	Varicella Coxsackievirus A and B Mycoplasma Echovirus Postinfectious inflammation Postimmunization
Neoplasm	Neuroblastoma Other CNS tumors
Paraneoplastic	Opsoclonus-myoclonus syndrome
Trauma	Subdural or epidural posterior fossa hematoma
Congenital or hereditary	Pyruvate decarboxylase deficiency Friedreich's ataxia Hartnup disease
Hydrocephalus Cerebellar abscess Labyrinthitis/vestibular neuronitis Transverse myelitis Meningoencephalitis	

The latency from the prodromal illness to the onset of ataxia is from 2 days to 2 weeks. Other neurologic findings encountered included truncal ataxia, dysmetria, and, uncommonly, cranial nerve abnormalities. Patients with ataxia following varicella appear to have uniform excellent recovery compared with patients with acute cerebellar ataxia from other causes who may have some residual problems.[13] Little workup is needed if the ataxia occurs in the convalescent phase of varicella, and antiviral medications are not indicated. Otherwise, neuroimaging, lumbar puncture, and consultation are advisable. One study showed that although roughly half of the patients had cerebrospinal fluid inflammatory changes with pleocytosis or elevated immunoglobulin G index, MRI identified inflammatory changes in the cerebellum in only a minority of cases.[12] Another small report noted MRI abnormalities not only in the cerebellum, but also in other areas of the CNS. This "syndrome" may in fact consist of several subgroups, some of which involve transient demyelination.[14]

Posterior fossa mass lesions and other CNS masses may present with ataxia, although usually some abnormality of cranial nerves or strength will be discovered with careful examination. Attention is needed to exclude abnormalities on physical examination that might suggest problems not localized to the cerebellum. Abnormal ocular movements should increase the suspicion of a mass lesion. Acute ataxia associated with rapid chaotic eye movements (opsoclonus) and myoclonic extremity jerks of the head and extremities are the striking syndrome of opsoclonus-myoclonus. This may be a postviral syndrome but is often a paraneoplastic syndrome associated with a neuroblastoma located in the abdomen or chest.[10]

Unusual metabolic disorders such as pyruvate decarboxylase complex deficiency may present with ataxia. Family history may or may not suggest a metabolic disorder. Typically, the onset is gradual, but abrupt decompensations may occur. Other systemic or CNS abnormalities will be present.

CHAPTER 170

Vertigo

Brian Goldman

INTRODUCTION AND EPIDEMIOLOGY

Dizziness is a common complaint in patients >40 years old, leading to roughly 10 million visits to ambulatory care settings and 25% of ED visits.[1] Dizziness can lead to falls in elderly patients. The symptoms may persist and be incapacitating. Patients may use various terms for the complaint: dizziness may mean vertigo, syncope, presyncope, weakness, giddiness, anxiety, or a disturbance in mentation.

Vertigo is the perception of movement (rotational or otherwise) where no movement exists. **Syncope** is a transient loss of consciousness accompanied by loss of postural tone with spontaneous recovery. **Near-syncope** is light-headedness with concern for an impending loss of consciousness. **Psychiatric dizziness** is defined as a sensation of dizziness not related to vestibular dysfunction that occurs exclusively in combination with other symptoms as part of a recognized psychiatric symptom cluster.[2] **Disequilibrium** refers to a feeling of unsteadiness, imbalance, or a sensation of "floating" while walking.

Acute vestibular syndrome is a symptom complex consisting of vertigo, nausea and vomiting, intolerance to head motion, spontaneous nystagmus, unsteady gait, and postural instability caused by injury to peripheral or central vestibular structures. To be called acute vestibular syndrome, the associated vertigo must persist for at least 24 hours, thus excluding causes of transient vertigo such as benign paroxysmal positional vertigo (BPPV). Acute vestibular syndrome may be peripheral or central in origin. Clinical findings that distinguish central from peripheral causes include focal neurologic deficits such as hemiparesis, hemisensory loss, or gaze palsy. **The most common peripheral cause of acute vestibular syndrome is vestibular neuronitis. The most common central cause is ischemic stroke of the posterior fossa (brainstem or cerebellar), followed by demyelination. There is growing evidence that a significant number of patients with central acute vestibular syndrome are misdiagnosed in the ED.** A systematic review estimated that roughly 25% of patients presenting with acute vestibular syndrome have had a stroke.[3]

The time-honored paradigm of evaluating dizziness is based largely on the patient's subjective description. More recently, objective bedside physical examination has emerged as a more reliable way of arriving at the correct diagnosis.[4]

PATHOPHYSIOLOGY

The CNS coordinates and integrates sensory input from the visual, vestibular, and proprioceptive systems. Vertigo arises from a mismatch of information from two or more of the involved senses, caused by dysfunction in the sensory organ or its corresponding pathway.

Visual inputs provide spatial orientation. Proprioceptors help relate body movements and indicate the position of the head relative to that of the body. The vestibular system (via the otoliths) establishes the body's orientation with respect to gravity. The cupulae's sensors track rotary motion. The three semicircular canals sense orientation to movement and head tilts and are filled with a fluid called *endolymph*. The endolymphatic sac produces glycoproteins that create an osmotic

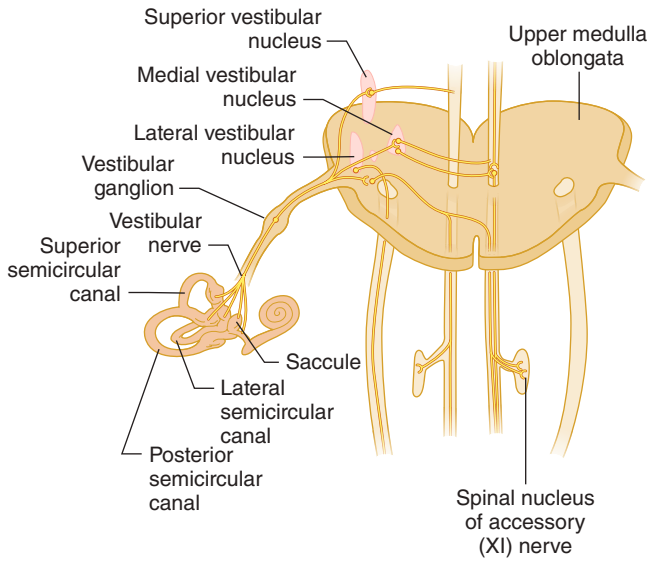

FIGURE 170-1. Vestibular innervation.

sink necessary to maintain flow. The movement of fluid in the semicircular canals causes specialized hair cells inside the canals to move, causing afferent vestibular impulses to fire. Sensory input from the vestibular apparatus travels to the nucleus of the eighth cranial nerve (**Figure 170-1**).

The medial longitudinal fasciculus, the red nuclei, the cerebellum, the parietal lobes, and the superior temporal gyrus of the cerebral cortex integrate the various sensory inputs. Connections between these structures and the oculomotor nuclei that drive the vestibulo-ocular reflex complete the system. The vestibulo-ocular reflex prevents visual blurring from head movements and body sway.

Balanced input from the vestibular apparatus on both sides is the norm. Unilateral lesions of the vestibular apparatus as well as excessive unilateral firing due to abnormal motion of the endolymph produce imbalanced activity and vertigo. Rapid head movements accentuate the imbalance. Symmetric bilateral damage does not usually produce vertigo but may lead to truncal or gait instability.

The most striking clinical sign associated with vertigo is **nystagmus**, a rhythmic movement of the eyes that has both a fast and a slow component, with direction named by its fast component. The slow component is due to the vestibulo-ocular reflex and is generated by excitation of the semicircular canal, producing eye movement away from that canal. The fast component of nystagmus is caused by the cortex, which exerts a quick corrective movement in the opposite direction. Vestibular disorders produce nystagmus that is provoked when the affected side is in the dependent position, and the characteristic pattern is vertical and rotational or horizontal. **Vertical nystagmus by itself usually indicates a brainstem abnormality.** However, an atypical pattern of nystagmus in the absence of other signs of CNS disease does not necessarily indicate central pathology.[5]

The prevalence of dizziness increases with age and is due to decreases in visual acuity, proprioception, and vestibular input, plus an increase in free-floating otoconia within the semicircular canals that cause BPPV. Older patients are also more likely to take medications that cause dizziness.

PHYSIOLOGIC VERTIGO

Physiologic vertigo results from a mismatch of visual, proprioceptive, and vestibular input. This may be the pathogenesis of motion sickness as well as the transient visual vertigo associated with watching a film that captures the visual sensation of motion, by attending complex visual environments, such as shopping malls, and by viewing complex floor or wallpaper patterns.

CLINICAL FEATURES

The conditions that cause acute undifferentiated vertigo are summarized in **Table 170-1**. Vertigo is usually categorized as "peripheral" or "central," and making the distinction between the two is the most important part of the evaluation. **Peripheral vertigo is caused by disorders affecting the vestibular apparatus and the eighth cranial nerve, whereas central vertigo is caused by disorders affecting central structures, such as the brainstem and the cerebellum.** Peripheral vertigo tends to cause distressing symptoms, but is seldom life threatening; the reverse tends to be true for central vertigo. Disorders causing central vertigo often require urgent diagnostic imaging or consultation with a neurologist or neurosurgeon.

Some of the features that distinguish peripheral causes from central causes (mainly cerebrovascular disease) are found in **Table 170-2**. **Note that many of the so-called distinguishing features of peripheral acute vestibular syndrome may also be found in some patients with cerebrovascular disease.**[6]

HISTORY

An approach to vertigo is shown in **Figure 170-2**. Try to obtain an unprompted description of the patient's "dizziness" and avoid leading questions that bias the patient's responses. However, the initial description may not be a reliable predictor of underlying pathology.[7]

Patients with acute vestibular syndrome have continuous vertigo or dizziness for more than 24 hours. Thus, the list excludes causes of brief transient episodes such as BPPV, Ménière's syndrome, and transient ischemic attack. If the patient has experienced true vertigo, determine whether the vertigo is of peripheral or central origin, and determine the temporal pattern and precipitating causes (**Table 170-3**). Peripheral vertigo is more likely than central vertigo to be intense and to be associated with nausea, vomiting, diaphoresis, tinnitus, hearing loss, and photophobia.

Headache is generally not a feature of peripheral causes of acute vestibular syndrome but is associated with central causes. Dizziness and

TABLE 170-1 Causes of Acute Undifferentiated Vertigo

Vestibular/otologic	Benign paroxysmal positional vertigo Traumatic: following head injury Infection: labyrinthitis, vestibular neuronitis, Ramsay Hunt syndrome
Systemic conditions with vestibular/otologic effects	Ménière's syndrome Neoplastic Vascular Otosclerosis Paget's disease Toxic or drug-induced: aminoglycosides
Neurologic	Vertebrobasilar insufficiency or vertebral artery dissection Lateral Wallenberg's syndrome Anterior inferior cerebellar artery syndrome Neoplastic: cerebellopontine angle tumors Cerebellar disorders: hemorrhage, degeneration Basal ganglion diseases Multiple sclerosis Infections: neurosyphilis, tuberculosis Epilepsy Migraine headaches Cerebrovascular disease
General	Hematologic: anemia, polycythemia, hyperviscosity syndrome Toxic: alcohol Chronic renal failure Metabolic: thyroid disease, hypoglycemia

TABLE 170-2 Differentiating Peripheral from Central Causes of Acute Undifferentiated Vertigo

	Peripheral	Central
Onset	Sudden or insidious	Sudden
Severity of vertigo	Intense spinning	Ill defined, less intense
Prodromal dizziness	Occurs in up to 25%; often single episode	Occurs in up to 25%; recurrent episodes suggest transient ischemic attacks
Intolerant of head movements/Dix-Hallpike maneuver	Yes	Sometimes
Associated nausea/diaphoresis	Frequent	Variable
Auditory symptoms	Points to peripheral causes	May be present
Proportionality of symptoms	Usually proportional	Often disproportionate
Headache or neck pain	Unusual	More likely
Nystagmus	Rotatory-vertical, horizontal	Vertical
CNS symptoms/signs	Absent	Usually present
Head impulse test	Abnormal	Usually normal
HINTS examination (combined horizontal head impulse test, nystagmus, and test of skew)	Normal on all three bedside tests	Abnormal on at least one of three bedside tests

headache suggest migraine but also occur with vertebral artery dissection or aneurysm.[8]

Head trauma and medications can precipitate episodes of dizziness or interfere with central adaptation. Recent head or neck trauma is a risk factor for **dissection of the vertebral artery**. In patients with acute vertigo, a recent history of trauma should spark concern for dissection even if pain is absent.

Evaluate the following groups for central vertigo: older patients, those with hypertension or cardiovascular disease, those with other risk factors for stroke, or those taking warfarin. Patients with acute vestibular syndrome and more than one vascular risk factor appear to be at increased risk of stroke. Although age is a known risk factor for stroke, patients age 50 and older with symptoms of acute vertigo and no neurologic signs are more likely to have vestibular neuronitis than stroke.[9] However, age per se does not rule out stroke as the cause of central acute vestibular syndrome. In a study of patients with cerebellar infarctions who were misdiagnosed on initial ED presentation, half of the patients misdiagnosed were younger then 50 years of age who presented with headache and vertigo. All of the patients misdiagnosed had either an incomplete or a poorly documented neurologic examination. Almost all of the patients had a CT scan of the brain that was initially interpreted as normal. The overall mortality was 40%; among survivors, 50% had disabling neurologic sequelae. This study underscores the need for a careful neurologic assessment in all such patients.[10]

PHYSICAL EXAMINATION

Perform complete ear, neurologic, and vestibular examinations in patients presenting with vertigo or dizziness. Examine the external auditory canal and tympanic membrane for evidence of otitis media, cholesteatoma, and other pathology. Test for hearing, and also perform Webber and Rinne testing. Hearing loss usually points to peripheral causes such as vestibular neuronitis and Ménière's syndrome. However, auditory symptoms and signs may also be due to ischemia of the inner ear associated with cerebrovascular disease.

When assessing patients with acute vestibular syndrome, keep the possibility of cerebrovascular disease in mind. The presence of focal neurologic deficits indicates a central etiology. However, focal deficits are not uniformly present in central vertigo. A systematic review found focal neurologic deficits in 80% of patients with acute vestibular syndrome caused by stroke.[3] In the **HINTS** study, neurologic (e.g., facial palsy, hemiparesis, limb ataxia) or oculomotor (e.g., internuclear ophthalmoplegia, gaze palsy, vertical nystagmus) abnormalities were reported in 51% of 76 patients with a central cause and none of 25 patients with a peripheral cause.[8] The presence of gait unsteadiness and severe truncal ataxia (inability to sit unaided with arms crossed) suggests vertigo due to stroke. A positive Romberg test is rarely found in patients with peripheral vertigo. The absence of focal neurologic deficits in some patients with central acute vestibular syndrome has led to growing interest in other methods of bedside testing.

HINTS Testing HINTS testing is an important advance in the rapid assessment of ED patients with acute vestibular syndrome. **HINTS** is an acronym that stands for horizontal head impulse test, nystagmus, and test of skew—three bedside tests that when taken together reliably help distinguish central (usually stroke) from peripheral acute vestibular syndrome.

The horizontal head impulse test is also known as the **Halmagyi head thrust** and, by itself, is the most helpful bedside test for distinguishing central from peripheral vertigo. The Halmagyi head thrust assesses the vestibulo-ocular reflex. Ask the patient to fixate on a visual target, while the examiner rotates the patient's head rapidly first from the center position to 40 degrees left and back again to the center position. Repeat the test on the right side. Carefully watch the patient's eyes for the response to the maneuver. The intact vestibulo-ocular reflex compensates for the rotational head thrust by rapidly and smoothly moving the eyes in the direction **opposite** to the head thrust. This is the normal physiologic response to a passive head thrust; an intact vestibulo-ocular reflex maintains fixation of the eyes with respect to the patient's environment. Thus, the patient will be able to maintain his or her gaze on the visual target throughout the head thrust.

If the vestibulo-ocular reflex is impaired, then the patient will not be able to maintain his or her gaze on the visual target, and the patient will exhibit a rapid simultaneous movement of both eyes (known as a **saccade**) in order to reacquire fixation upon the visual target. This is an abnormal response to the horizontal head impulse test.[11]

Thus, in a patient with no symptoms or signs of acute vestibular syndrome, a normal horizontal head impulse test (i.e., no corrective saccade) means that the vestibulo-ocular reflex is normal. **In a patient with acute vestibular syndrome, an abnormal response horizontal head impulse test (i.e., a corrective saccade) usually indicates a peripheral vestibular lesion, while no corrective saccade is highly suspicious for a stroke.**[12] In the HINTS study, the head impulse test had both a sensitivity and specificity comparable to that of MRI.[8]

The second part of HINTS testing that helps predict central acute vestibular syndrome is direction-changing horizontal nystagmus on lateral gaze. An abnormal response, which consists of right-beating nystagmus on right gaze and left-beating nystagmus on left gaze with or without nystagmus when the patient looks straight ahead, is believed to represent failure of gaze-maintaining structures located in the brainstem and the cerebellum. Direction-changing nystagmus has low sensitivity but high specificity for correctly identifying central causes of acute vestibular syndrome. The third part of HINTS testing is known as skew deviation or skew and refers to vertical ocular misalignment during the alternate cover test. Skew deviation only occurs in the presence of right-left imbalance in sensory inputs from the vestibular system to the oculomotor syndrome. As with direction-changing nystagmus, skew deviation is not sensitive but is highly specific for central acute vestibular syndrome.

All three bedside tests (horizontal head impulse test, nystagmus, and skew) have been combined into the HINTS battery of tests that define a clinical prediction rule for stroke. Just one finding specific for central acute vestibular syndrome on any of the three tests that make up the HINTS battery is considered 100% sensitive and 96% specific for stroke.[8] A cross-sectional study of patients with acute vestibular syndrome at high risk for stroke found that HINTS testing substantially outperformed ABCD2 risk scoring for stroke diagnosis in the ED and also outperformed MRI obtained within the first 2 days of symptom onset.[13] A current review concluded that with appropriate training in the

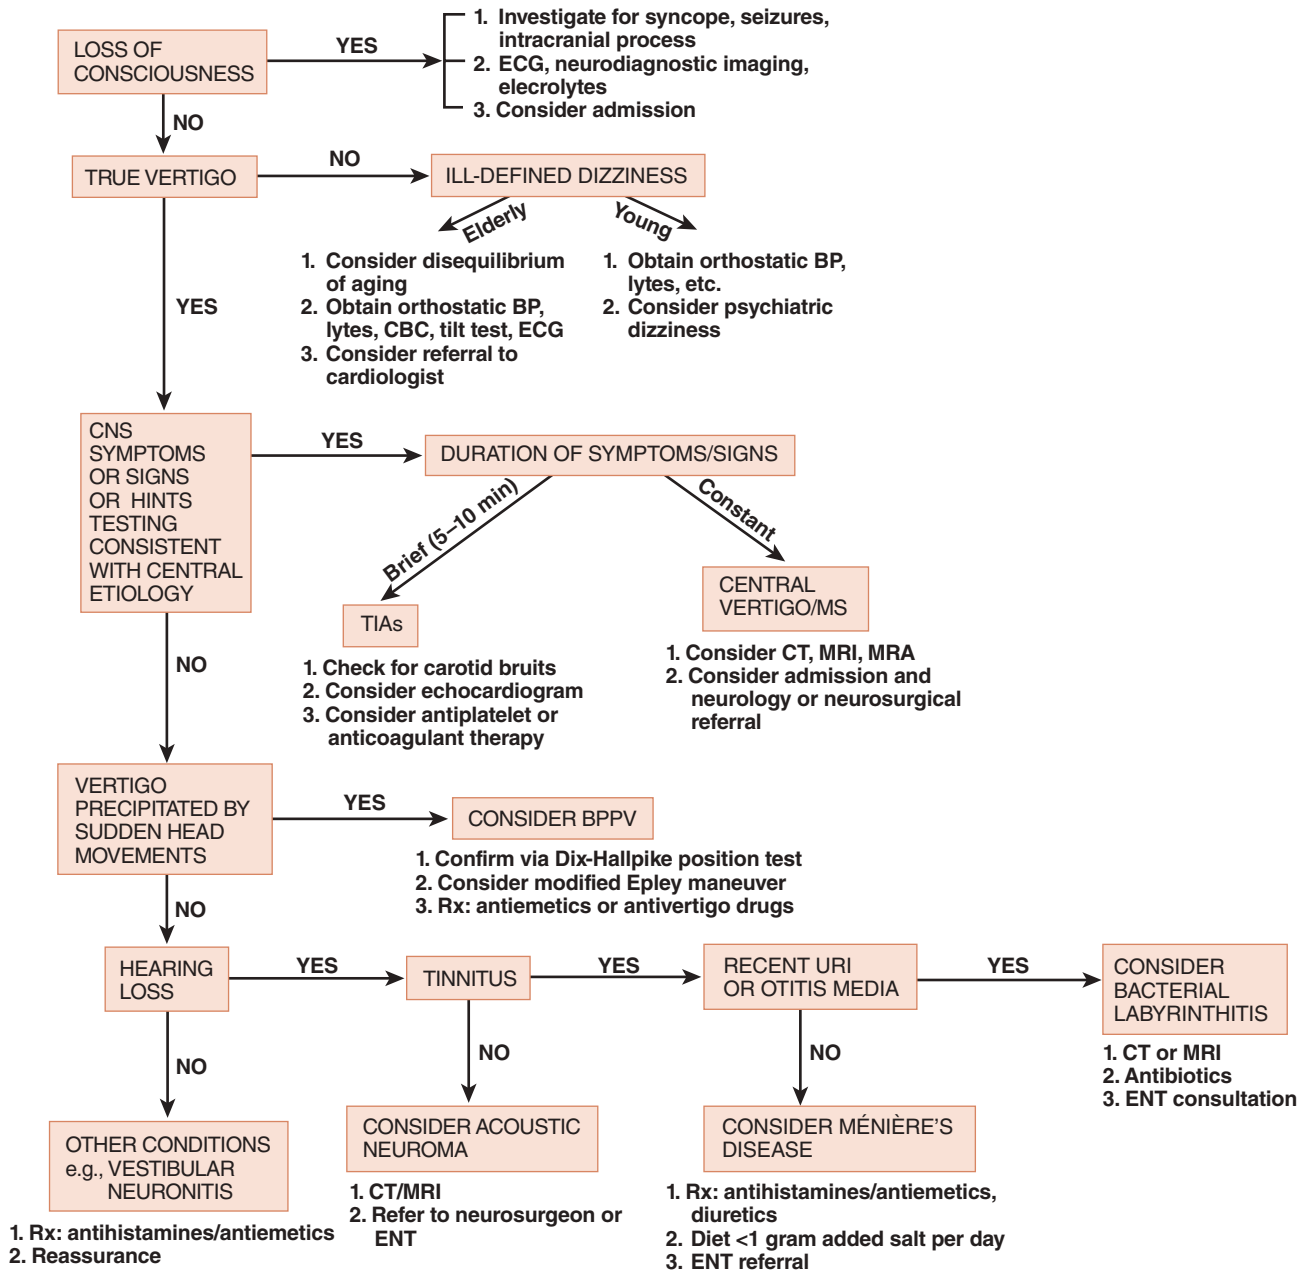

FIGURE 170-2. Guideline approach to vertigo. BP = blood pressure; BPPV = benign paroxysmal positional vertigo; CBC = complete blood count; CNS = central nervous system; ENT = ear, nose, and throat; MRA = magnetic resonance angiography; MS = multiple sclerosis; Rx = treatment; TIAs = transient ischemic attacks; URI = upper respiratory infection.

technique, it is reasonable to use HINTS testing as a tool to distinguish central from peripheral vertigo.[14]

Dix-Hallpike Maneuver **The diagnosis of BPPV involving the posterior canal is aided by the Dix-Hallpike position test.** Do not perform this test on patients with carotid bruits, a history of prior cerebrovascular disease, or risk factors or concern for vertebrobasilar insufficiency, because the Dix-Hallpike maneuver carries a theoretical risk of precipitating a stroke. In addition, use caution in patients with spinal injury or cervical spondylosis. The test may provoke vertigo. Pretreatment with 50 milligrams of dimenhydrinate IM or IV may make the test more tolerable but will not obliterate nystagmus. Have patients keep their eyes open at all times and stare at the examiner's nose or forehead. Start with the patient seated upright on the examining table. To test the right posterior semicircular canal, rotate the head 30 to 45 degrees to the right. Keeping the head in this position, rapidly bring the patient supine until the head is 20 degrees below the level of the examining table. Rotatory nystagmus following a latency of no more than 30 seconds is considered a positive test; the nystagmus exhibits rapid eye torsions toward the affected ear and lasts for 10 to 40 seconds. Return the patient to the upright sitting position, and repeat the test on the left side. **The side exhibiting the positive test is the side of the lesion.**[15]

TABLE 170-3 Temporal Patterns of Vertigo

Pattern	Conditions
Seconds	Benign paroxysmal positional vertigo, postural hypotension
Minutes	Transient ischemic attacks
Hours	Ménière's syndrome
More than 24 hours	Acute vestibular syndrome: peripheral or central

TABLE 170-4 Imaging and Ancillary Testing for Vertigo and Dizziness

Condition	Suggested Tests
Bacterial labyrinthitis	CBC, blood cultures, CT scan, or MRI for possible abscess; lumbar puncture if meningitis suspected
Vertigo associated with closed head injury	CT scan or MRI
Near-syncope	ECG, Holter monitor, CBC, glucose, electrolytes, renal function, table tilt testing
Cardiac dysrhythmias	ECG, Holter monitor
Suspected valvular heart disease	ECG, echocardiography
Nonspecific dizziness; disequilibrium of aging	CBC, electrolytes, glucose, renal function tests
Thyrotoxicosis	Thyroid-stimulating hormone, triiodothyronine, thyroxine
Cerebellar hemorrhage, infarction, or tumor	CT or MRI
Vertebral artery dissection	Cerebral angiogram to include neck vessels or MRA
Vertebrobasilar insufficiency	ECG, cardiac monitoring, echocardiogram, carotid Doppler, MRI, MRA

Abbreviation: MRA = magnetic resonance angiography.

DIAGNOSIS

IMAGING AND ANCILLARY TESTS

Patients with signs or symptoms concerning for central vertigo require emergent imaging and laboratory investigations (**Table 170-4**). CT alone is not adequate because it does not visualize the brainstem well.[16] MRI is more sensitive than CT.[17] For patients who may have vertebrobasilar insufficiency, MRI with magnetic resonance angiography of the head, neck vessels, and circle of Willis; duplex US of the carotid arteries; and neurologic consultation are indicated. Detailed cochleovestibular testing can be done by a specialist.

TREATMENT

SYMPTOMATIC TREATMENT FOR PERIPHERAL VERTIGO

Short-term treatment with antiemetic and vestibular suppressant pharmacotherapy is a mainstay for patients with peripheral vertigo (**Table 170-5**).[18] Withdraw such treatments as soon as possible to facilitate central vestibular compensation.[19]

DRUG THERAPY

Pharmacotherapy is used to treat specific conditions, reduce symptoms, or enhance vestibular compensation. Drugs with anticholinergic effects can be quite effective for vertigo. The agent of choice is transdermal scopolamine. H_1 antihistamines are commonly prescribed drugs for their anticholinergic effects. H_2 antihistamines are not effective. Calcium channel blockers (Table 170-5) possess antihistaminic and antidopaminergic activity and are indicated for the symptomatic relief of vertigo in patients not responding to scopolamine or antihistamines and are also indicated for vestibular migraine. Neuroleptics such as promethazine and metoclopramide reduce nausea and vomiting by blocking brainstem dopaminergic receptors. They too are indicated as second-line treatment. **Do not use prochlorperazine and chlorpromazine in vertigo caused by orthostatic hypotension.** Ondansetron, a serotonin 5-HT_3 receptor antagonist, has been used to treat intractable vertigo in brainstem disorders as well as vertigo due to multiple sclerosis.

Small doses of benzodiazepines such as diazepam and clonazepam may be used sparingly to relieve severe anxiety accompanying vertigo. However, these agents bind to γ-aminobutyric acid receptors in the CNS and thus may impair vestibular compensation. Benzodiazepines are given for central ocular motor disorders that cause nystagmus.

Methylprednisolone is indicated for vestibular neuronitis. However, the antiviral drug valacyclovir has not been proven to be efficacious in clinical trials. Anticonvulsant drugs are indicated for prophylaxis of vestibular migraine; gabapentin is indicated for dizziness associated with multiple sclerosis.

Antihistamines can cause sedation and anticholinergic adverse effects. Antidopaminergic neuroleptic agents can induce or exacerbate orthostatic hypotension. These drugs also cause somnolence and acute dystonia and can exacerbate anticholinergic adverse effects. Avoid using medications with overlapping anticholinergic and antidopaminergic effects in combination. Do not treat patients with nonvertiginous dizziness and disequilibrium of aging with antivertigo medications.

DISORDERS CAUSING PERIPHERAL VERTIGO

Peripheral vertigo produces an intense sensation of spinning or hurtling toward the ground or surrounding walls of abrupt onset. It is worsened by rapid movement and by changes in head position and is frequently associated with nausea, vomiting, diaphoresis, bradycardia, and hypotension.

BENIGN PAROXYSMAL POSITIONAL VERTIGO

BPPV is a mechanical disorder of the inner ear causing transient vertigo (with autonomic symptoms) and associated nystagmus that is precipitated by certain head movements. The lifetime prevalence of BPPV is 2.4% with a 1-year incidence of 0.6%, with women and patients over the age of 50 more likely to be affected. The mean duration of an episode is 2 weeks; 86% of patients affected seek medical attention.[20]

BPPV is believed to be caused by inappropriate activation of a semicircular canal, typically the posterior semicircular canal and typically unilateral, by the presence of free-floating particles or otoconia. The otoconia become displaced from the utricular macula by aging, head trauma, or labyrinthine disease. The particles tend to clump in the long arm of the posterior semicircular canal of the endolymph system. Once the clump reaches sufficient mass, changes in head position cause gravitation of the particles, which creates a plunger effect on the endolymph, causing the cupula to be displaced. This results in inadvertent neural firing, causing both vertigo and nystagmus.

The onset of BPPV is sudden and is precipitated by rolling over in bed, lying supine, leaning forward, looking up at the sky or ceiling, or turning the head. Because the symptoms fatigue, they tend to be worse in the morning. Patients may eliminate the offending activities. There is no associated hearing loss or tinnitus and no physical findings on examination of the external auditory canal.

Several findings support a diagnosis of BPPV (**Table 170-6**). There is a latency period of 1 to 5 seconds between assuming the offending head position and onset of vertigo and nystagmus. Both the vertigo and nystagmus crescendo to a peak of intensity and then subside within 5 to 40 seconds. Unlike vestibular neuronitis, the head thrust test in BPPV is normal and there is no spontaneous nystagmus. The Romberg test is negative, and the gait is normal. Posterior canal **BPPV can be diagnosed using the Dix-Hallpike test** (see "Physical Examination" section).[15] Symptoms disappear with repeated testing. The supine roll test (Pagnini-McClure test[21]) for horizontal canal BPPV is done as follows: place the patient supine, turn the head to the right and observe for nystagmus, and then turn the head back to neutral position. Repeat by turning the head to the left. The side with the most prominent nystagmus is the side of the affected canal.

BPPV involving the anterior semicircular canal is rare, and the Dix-Hallpike maneuver may elicit downbeating nystagmus with the affected ear up. However, any downbeating nystagmus should raise strong suspicion for a cerebellar or brainstem lesion (**Table 170-7**).[21] Patients with isolated BPPV often undergo many tests with little or no diagnostic yield.[22]

TABLE 170-5 Pharmacotherapy of Vertigo and Dizziness

Category	Drug	Dosage	Indications	Advantages	Disadvantages
Anticholinergics	Scopolamine	0.5 milligram transdermal patch (behind ear) three to four times a day	Vertigo, nausea	Useful if patient is vomiting	Sometimes difficult to obtain
Antihistamines	Dimenhydrinate	50–100 milligrams IM, IV, or PO every 4 h	Vertigo, nausea	Inexpensive	Drowsiness/anticholinergic effect
	Diphenhydramine	25–50 milligrams IM, IV, or PO every 4 h	Vertigo, nausea	Inexpensive	Drowsiness/anticholinergic effect
	Meclizine	25 milligrams PO two to four times a day	Vertigo, nausea		Drowsiness/anticholinergic effect
Antiemetics	Hydroxyzine	25–50 milligrams PO four times a day	Vertigo, nausea	Inexpensive	Drowsiness/anticholinergic effect
	Metoclopramide	10–20 milligrams IV, PO three times a day	Vertigo, nausea	Effective, versatile	Occasional extrapyramidal effect
	Ondansetron	4 milligrams IV two to three times a day; 8 milligrams PO twice a day			
	Promethazine	25 milligrams IM, PO, or PR three to four times a day	Vertigo, nausea	Useful if vomiting	Occasional extrapyramidal effect
Benzodiazepines	Diazepam	2–5 milligrams PO two to four times a day	Central vertigo, anxiety related to peripheral vertigo	Inexpensive	Dependency, may impair vestibular compensation
	Clonazepam	0.5 milligram PO two times a day	Central vertigo, anxiety related to peripheral vertigo	Inexpensive	Dependency, may impair vestibular compensation
Calcium antagonists	Cinnarizine	25 milligrams PO two to three times a day	Peripheral vertigo, vestibular migraine	Nonsedating	Lesser clinical experience
	Nimodipine	30 milligrams PO two times a day	Peripheral vertigo, vestibular migraine	Nonsedating	Lesser clinical experience
	Flunarizine	20 milligrams PO two times a day	Ménière's syndrome	Well tolerated	Not available in the United States
Vasodilators	Betahistine	48 milligrams PO three times a day for up to 6–12 mo	Ménière's syndrome	Well tolerated	Little evidence of efficacy for other causes of peripheral vertigo
Corticosteroids	Methylprednisolone	100 milligrams/d tapered by 20 milligrams/d every fourth day	Vestibular neuronitis	Well tolerated	Efficacy largely unproven; adverse effects associated with corticosteroids
Antivirals	Valacyclovir	1000 milligrams three times a day for 7 d	Vestibular neuronitis	Well tolerated	Efficacy largely unproven
Anticonvulsants	Carbamazepine	200–600 milligrams/d	Vestibular paroxysmia	Inexpensive	Monitor CBC and liver function tests
	Topiramate	50–100 milligrams/d	Vestibular migraine prophylaxis	Well tolerated	Not well evaluated; does not abort acute vertigo
	Valproic acid	300–900 milligrams/d	Vestibular migraine prophylaxis	Well tolerated	Not well evaluated; does not abort acute vertigo
	Gabapentin	300 milligrams four times per day	MS associated dizziness	Reduces acquired pendular nystagmus of multiple sclerosis	Known adverse effect profile
β-Blockers	Metoprolol	100 milligrams/d	Vestibular migraine prophylaxis	Long experience	Known adverse effect profile

Perform the particle-repositioning maneuver (or Epley maneuver) for patients with posterior canal BPPV in the ED.[23] **This maneuver uses gravity to induce the particles to move along the semicircular canals until they end up inside the utricle where unlikely to cause vertigo.** It is indicated in patients with suspected BPPV plus a positive Dix-Hallpike test (**Figure 170-3**). Do not perform these maneuvers in patients with neck or cervical spine abnormalities, or if carotid or vertebral dissection is suspected.

TABLE 170-6 Supportive Findings in Benign Paroxysmal Positional Vertigo

Latency period of <30 s between the provocative head position and onset of nystagmus.
The intensity of nystagmus increases to a peak before slowly resolving.
Duration of vertigo and nystagmus ranges from 5–40 s.
If nystagmus is produced in one direction by placing the head down, then the nystagmus reverses direction when the head is returned to the sitting position.
Repeated head positioning causes both the vertigo and accompanying nystagmus to fatigue and subside.
Abnormal horizontal head impulse test indicating abnormal vestibule-ocular reflex function.
HINTS testing not indicative of stroke.

Abbreviation: HINTS = horizontal head impulse test, nystagmus, and test of skew.

TABLE 170-7 Benign Paroxysmal Positional Vertigo (BPPV)

Canal Affected by BPPV	Frequency (%)	Diagnostic Maneuver	Nystagmus (direction named by fast component)
Posterior	85	Dix-Hallpike, affected ear down	Upbeat, affected ear down
Horizontal	10–17	Supine roll test (Pagnini-McClure test)	Horizontal, changes direction when head is turned to right or left while supine
Anterior	1	Dix-Hallpike, affected ear up	Downbeating, great concern for brainstem or cerebellar lesions

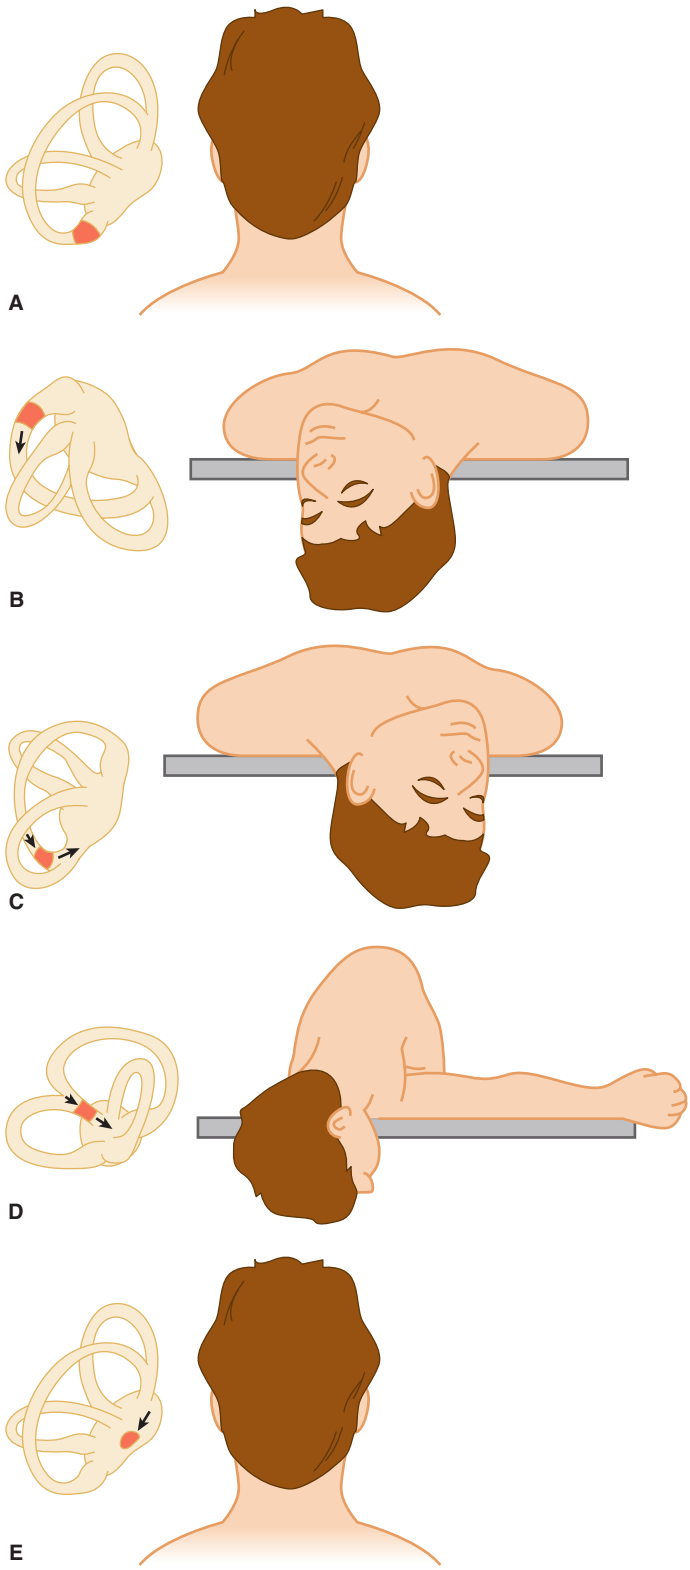

FIGURE 170-3. **A** through **C**. Dix-Hallpike position test; **D, E**. Epley Maneuver. Turn onto unaffected side. Hold position for 60 secs.

The affected ear is determined by the side of the positive Dix-Hallpike position test. Antihistamines or antiemetics administered before the maneuver may improve patient comfort. Seat the patient in the Dix-Hallpike position test, and turn the head 45 degrees toward the affected ear. Gently bring the patient to the recumbent position with the head hanging roughly 20 degrees below the examining table. Gently rotate the head 45 degrees to the midline. Then rotate the head a further 45 degrees to the unaffected side. The patient rolls onto the shoulder of the unaffected side, at the same time rotating the head a further 45 degrees. Return the patient to the sitting position and return the head to the midline. Wait 5 minutes after each portion of the maneuver to permit the particles to traverse their intended course. Observe for nystagmus in the same direction as during Dix-Hallpike testing. Nystagmus in the opposite direction suggests the particles have moved back toward the cupula; this portends an unsuccessful maneuver. Repeat the maneuver until both the vertigo and the accompanying nystagmus have disappeared. A home treatment device has been found to enable patients with an established diagnosis of BPPV to perform the maneuver themselves safely and effectively.[24]

While the Epley maneuver is safe and effective for posterior canal BPPV, relapses are common. Adverse effects include light-headedness and exacerbation of vertigo.

Most episodes of BPPV resolve spontaneously after a few days. Refer patients with persistent symptoms to an otolaryngologist.

MÉNIÈRE'S SYNDROME

Ménière's syndrome is a disorder associated with an increased endolymph within the cochlea and labyrinth. It tends to occur in older men and women with equal prevalence. The disease is usually unilateral but may become bilateral over time. The precise pathogenesis is unknown, but evidence suggests that patients have difficulty regulating the volume, flow, and composition of endolymph. The onset is usually sudden, with associated nausea, vomiting, and diaphoresis, with attacks lasting from 20 minutes to 12 hours. The frequency of attacks varies from several times per week to several times per month. Other associated symptoms include tinnitus, diminished hearing, and fullness in one ear. Between attacks, the patient is usually well, although decreased hearing may persist.

Ménière's syndrome is managed symptomatically with antihistamines and betahistine; combination therapy with triamterene and hydrochlorothiazide is also recommended in confirmed cases. Ménière's syndrome is the only condition for which betahistine has proven efficacy. A high-dose regimen of at least 48 milligrams three times daily has been shown to provide long-term prophylaxis.[25] Calcium channel blockers may also be used (Table 170-5). None of these drug treatments improves hearing. Intratympanic gentamicin administration may provide significant immediate and long-term relief.[26] Refer patients for treatment to an otolaryngologist. Attacks of vertigo are generally controllable, but tinnitus and hearing loss tend to be unresponsive to therapy.[27]

PERILYMPH FISTULA

A perilymph fistula is an opening in the round or oval window that permits pneumatic changes in the middle ear to be transmitted to the vestibular apparatus. Trauma, infection, or a sudden change in the pressure inside the ventricular system may cause the tear. The diagnosis is suggested by the sudden onset of vertigo associated with flying, scuba diving, severe straining, heavy lifting, coughing, or sneezing. Associated symptoms may include hearing loss. **The diagnosis is confirmed by nystagmus elicited by pneumatic otoscopy (Hennebert sign).**

Perilymph fistula is managed with symptomatic treatment and bed rest and referral to an ear, nose, and throat specialist for surgical repair (emergent referral for patients with acute associated hearing loss).

VESTIBULAR NEURONITIS

Vestibular neuronitis, a disorder of suspected viral etiology, is the second most common cause of peripheral vertigo. Unlike BPPV and Ménière's syndrome, vestibular neuronitis typically lasts several days and does not recur. The onset is sudden, often with a current or recent viral illness. Intense vertigo may require bedrest for several days. Unilateral loss of hearing and tinnitus may occur. Positive findings on physical examination include positive head thrust and horizontal or mild torsional nystagmus. The Romberg test is negative; however, the gait tends to be slow, cautious, and widely based. The condition remits spontaneously with no recurrence. Treatment is symptomatic. Both methylprednisolone and valacyclovir have been recommended, but there is insufficient evidence that these agents enhance recovery.[28]

VESTIBULAR GANGLIONITIS

Vestibular ganglionitis is believed to be caused by a neurotrophic virus such as varicella zoster reactivated years following initial infection. Herpes zoster oticus, also known as the Ramsay Hunt syndrome, is a neuropathic disorder thought to be associated with vestibular ganglionitis. It is characterized by deafness, vertigo, and facial nerve palsy. **The diagnosis is confirmed by the presence of grouped vesicles on an erythematous base inside the external auditory canal.** Treat this disorder with antiviral therapy started within 72 hours of the appearance of vesicles along with symptomatic treatments.

LABYRINTHITIS

Labyrinthitis, an infection of the labyrinth, causes peripheral vertigo associated with hearing loss. Viral labyrinthitis (associated with measles and mumps) has a course that is similar to vestibular neuronitis. Serous labyrinthitis occasionally causes vertigo.

Bacterial labyrinthitis may be a sequela of otitis media, in which bacteria and toxins diffuse across the membrane of the round window. Possible antecedents for bacterial labyrinthitis include otitis media with fistula, meningitis, mastoiditis, cholesteatoma, and dermoid tumor. **The hallmarks of this disease include sudden onset of vertigo with associated hearing loss and middle ear findings.**

Patients with bacterial labyrinthitis are at risk for meningitis and require antibiotics and referral to an ear, nose, and throat specialist for admission and possible surgical drainage.

OTOTOXICITY

Various drugs have been found to be ototoxic (**Table 170-8**).[29] Aminoglycoside antibiotics produce hearing loss and peripheral vestibular dysfunction by accumulating inside the endolymph, causing the death of cochlear and vestibular hair cells. However, because both inner ears are affected, vertigo is uncommon. Clinical manifestations include ataxia and oscillopsia (defined as the inability to maintain visual fixation while moving). The damage is usually irreversible but is dose- and duration-dependent. Loop diuretics (furosemide and ethacrynic acid) also cause irreversible vestibular toxicity and ototoxicity. *N*-Acetylcysteine administered orally may help prevent aminoglycoside-induced ototoxicity in hemodialysis patients.[30] Cytotoxic agents such as vinblastine and cisplatin cause vestibular damage; however, newer platinums, such as carboplatin, are less likely to do so. The antiarrhythmic drug quinidine and antimalarial drugs derived from quinine, such as chloroquine and mefloquine, also can cause vestibular symptoms that may be irreversible.

Reversible causes of vestibular damage and ototoxicity include nonsteroidal anti-inflammatory drugs, salicylates, minocycline, erythromycin, and some fluoroquinolones. Isolated cases of unsteady gait have been observed with antiviral drugs such as abacavir as well as antiparasitic agents. Solvents and other chemicals such as propylene glycol, toluene, mercury, and hydrocarbons can cause both peripheral and central vestibular symptoms.

TABLE 170-8 Ototoxic and Vestibulotoxic Agents

Agent	Dose Dependent	Reversible
Aminoglycosides	Yes	Usually not; possible improvement with *N*-acetylcysteine
Erythromycin	No	Yes
Minocycline	No	Yes
Fluoroquinolones	No	Yes
Nonsteroidal anti-inflammatory drugs; salicylates	Yes	Yes
Loop diuretics	No	Can be irreversible
Cytostatic drugs	Yes	No
Antimalarials	No	Yes
Anticonvulsants	Yes	Yes

Drugs that sometimes induce a central vestibular syndrome include tricyclic antidepressants, neuroleptics, opiates, and alcohol. Anticonvulsants cause dizziness and ataxia, especially in older patients. Lamotrigine may cause less dizziness.[31] Phenytoin, toluene, and cancer chemotherapy agents can cause irreversible cerebellar toxicity. Phencyclidine is a recreational drug that causes central vestibular symptoms, including nystagmus and ataxia.

In general, most patients adapt to chronic vertigo by relying on intact proprioception and vision. However, **benzodiazepines and neuroleptics that are often used as antivertigo therapy may exacerbate symptoms by delaying or inhibiting such compensation.** Thus, avoid using this therapy on a long-term basis. Refer patients with suspected ototoxicity to an otolaryngologist.

EIGHTH NERVE LESIONS AND CEREBELLOPONTINE ANGLE TUMORS

Lesions of the eighth cranial nerve such as meningiomas and acoustic schwannomas may produce mild vertigo. The onset is usually gradual and remains constant until central compensation takes place. Hearing loss usually precedes the vertigo. Tumors of the cerebellopontine angle such as acoustic neuromas, meningiomas, and dermoids may also cause vertigo. **These usually present with deafness and ataxia, as well as ipsilateral facial weakness, loss of the corneal reflex, and cerebellar signs.** All such patients require urgent diagnostic imaging as well as referral to a neurosurgeon.

POSTTRAUMATIC VERTIGO

Acute posttraumatic vertigo and unsteady gait are caused by a direct injury to the labyrinthine membranes. The onset of vertigo is immediate and is accompanied by nausea and vomiting. There may be a concomitant fracture of the temporal bone. Vertigo associated with a closed head injury warrants CT or MRI to exclude an intracranial hemorrhage. Vertigo due to direct labyrinthine trauma tends to resolve within several weeks. Closed head trauma also can displace otoconia from the utricular maculae, precipitating an attack of BPPV. Postconcussive syndrome can be associated with unsteadiness of gait and a vague sense of dizziness. These patients may be treated symptomatically, with referral to a specialist if symptoms fail to resolve.

VERTIGO AFTER COCHLEAR IMPLANTATION

Vertigo is a well-known complication of cochlear implantation. The etiology is likely multifactorial and includes the dislodging of otoconia and the introduction of bone dust into the labyrinth.[32]

DISORDERS CAUSING CENTRAL VERTIGO

Central vertigo is caused by disorders affecting the cerebellum and the brainstem. These include cerebrovascular disease, hemorrhage, migraine, demyelination, and neoplasms. Central vertigo is unlikely to be associated with tinnitus and hearing impairment. Nystagmus is more likely to be vertical than horizontal or rotatory and may be present in the absence of vertigo.

CEREBELLAR HEMORRHAGE AND INFARCTION

Cerebellar hemorrhage typically causes acute vertigo and ataxia along with headache, nausea, and vomiting. Instead of intense vertigo, patients tend to complain of a sense of side-to-side or front-to-back motion. Patients may have truncal ataxia and may not be able to sit without support. Romberg testing and tandem gait will be abnormal. Occasionally, there may be a sixth cranial nerve palsy or conjugate eye deviation away from the side with the hemorrhage. Cerebellar infarction has a similar clinical presentation. Such patients require emergent MRI, and those with cerebellar hemorrhage require emergent neurosurgical consultation.

WALLENBERG'S SYNDROME

A lateral medullary infarction (Wallenberg's syndrome) of the brainstem can cause vertigo as part of its clinical presentation. **Classic ipsilateral findings include facial numbness, loss of corneal reflex, Horner's syndrome, and paralysis or paresis of the soft palate, pharynx, and larynx (causing dysphagia and dysphonia).** Contralateral findings include loss of pain and temperature sensation in the trunk and limbs. Occasionally, lesions of the sixth, seventh, and eighth cranial nerves can occur, causing vertigo, nausea, vomiting, and nystagmus. These patients require emergent MRI and neurologic consultation.

VERTEBROBASILAR INSUFFICIENCY

Transient ischemic attack of the brainstem due to vertebrobasilar insufficiency can produce vertigo that may closely mimic peripheral vestibular disorders. Focal neurologic signs may be absent in more than half of patients.[3] Patients have typical risk factors for cerebrovascular disease. As with transient ischemic attacks in general, the vertigo may be of sudden onset and typically lasts from minutes to hours and should resolve completely within 24 hours. Vertebrobasilar insufficiency–induced vertigo may be accompanied by diplopia, dysphagia, dysarthria, bilateral long-tract signs, and bilateral loss of vision. Unlike other causes of central vertigo, vertebrobasilar insufficiency may be provoked by position. Turning the head partially occludes the ipsilateral vertebral artery. **If the contralateral artery is stenotic, head turning could cause transient ischemia to the brainstem, resulting in vertebrobasilar insufficiency.** Order a brain MRI and consult a neurologist in patients suspected of having vertebrobasilar insufficiency.

VERTEBRAL ARTERY DISSECTION

Vertebral artery dissection can lead to a stroke involving the posterior circulation. **The most common symptoms of vertebral artery dissection are dizziness, headache, and neck pain.** However, one in four patients with dissection present without headache.[3] Unlike vestibular migraine, the onset of headache is often sudden and severe. Recent head or neck trauma is a known risk factor. A history of trauma (e.g., motor vehicle crash, diving injury, or even coughing or sneezing) along with headache and dizziness should spark concern for underlying dissection. It is a rare but recognized complication of chiropractic neck manipulation.[33] The age of presentation is usually less than 50 years. Patients with suspected dissection require emergent diagnostic imaging and referral.

MULTIPLE SCLEROSIS

Demyelinating disease can present with vertigo that lasts several hours to several weeks and is usually nonrecurrent. The vertigo is mild, with nystagmus the most prominent finding on physical examination. Such patients require confirmatory testing with MRI as well as vestibular evoked myogenic potentials plus urgent referral to a neurologist.

NEOPLASMS

Neoplasms of the fourth ventricle can cause brainstem signs and symptoms, including vertigo. Such tumors include ependymomas in younger patients and metastases in older patients. These patients require diagnostic imaging while in the ED and should be referred to a neurosurgeon.

VESTIBULAR MIGRAINE

There is an epidemiologic link between vertigo and migraine. A disproportionate number of patients presenting to a dizziness clinic have a history of migraine, and the prevalence of vertigo is increased in patients with migraine. Vertigo can be a symptom of an aura, an analog or equivalent of the headache phase itself, or an associated symptom with the migraine prodrome. Basilar migraine is a migraine variant in which the aura has clinical manifestations similar to those of vertebrobasilar insufficiency. Vestibular migraine is the most common cause of recurrent spontaneous vertigo and should be considered in almost any patient with dizziness and headache.

The diagnostic criteria for migraine-related vertigo include a history of vertigo not attributable to other known conditions and a present or past history of migraine or a strong family history. In a first episode, cerebrovascular disease may have to be excluded.

Acute episodes are treated with acetaminophen and antiemetics. Frequent attacks may be managed with prophylactic agents such as metoprolol, topiramate, or valproic acid. **Avoid using ergotamine preparations or sumatriptan in patients with basilar migraine.**

Patients with Ménière's syndrome also have an increased prevalence of migraine. Therefore, patients who fail to respond to therapy specific for Ménière's syndrome may benefit from therapy for vertigo associated with migraine headaches.

SPECIAL CONSIDERATIONS

DISEQUILIBRIUM OF AGING

Disequilibrium of aging (sometimes referred to as "psychomotor disadaptation syndrome") manifests as ill-defined dizziness and gait unsteadiness. It is associated with age-related loss of hearing, balance, proprioceptive input, and vision, resulting in an alteration of postural reactions, reactional hypertonia, gait modifications, and fear of falling.[34] Other factors include a decline in central integration and processing, as well as a decrease in motor responses. Symptoms may be precipitated or exacerbated by diminished ambient light (with worsening of symptoms at night), unfamiliar surroundings, and the use of benzodiazepines and drugs with anticholinergic effects such as tricyclic antidepressants and neuroleptic agents. Refer these patients to an internist or gerontologist.

CONVULSIVE DISORDERS

Nonconvulsive status epilepticus, which is characterized by altered mental status without loss of consciousness or tonic-clonic phenomena yet associated with electroencephalographic evidence of seizure activity, may also produce nonvertiginous dizziness. Symptoms may last for hours to days. Refer patients with suspected convulsive disorders to a neurologist.

HYPERVENTILATION SYNDROME

Patients with primary hyperventilation may experience nonvertiginous dizziness or near-syncope during an episode. Diagnostic clues include paresthesias and carpopedal spasm.

PSYCHIATRIC DIZZINESS

Psychiatric dizziness presents as part of a recognized psychiatric disorder or symptom complex that is not related to known vestibular disorders. Dizziness, which can be chronic, is often reported by patients with primary and secondary anxiety disorders, especially panic disorder.[35] The diagnosis is made by exclusion of other more serious causes of dizziness.

DISPOSITION AND FOLLOW-UP

Discharge patients with peripheral vertigo from the ED once symptoms are controlled. Patients can be referred for vestibular rehabilitation therapy, an exercise-based program that promotes CNS compensation for peripheral vertigo. **Vestibular exercises are indicated for patients with BPPV, chronic vertigo, and psychiatric dizziness.** A Cochrane systematic review concluded that vestibular rehabilitation is safe and effective for unilateral peripheral vestibular vertigo.[33]

Refer all patients with a first episode of peripheral vertigo to their primary care physician or an otolaryngologist for further testing. Refer patients with BPPV who have had a particle-repositioning maneuver to an otolaryngologist for follow-up.

All patients with central vertigo require neuroimaging and other diagnostic testing to establish the diagnosis; life-threatening central causes of vertigo (e.g., stroke, cerebellar hemorrhage) require emergent diagnostic

imaging and neurologic or neurosurgical consultation while in the ED. Outpatient psychiatric consultation may be considered for patients with psychiatric dizziness.

CHAPTER 171

Seizures

Joshua G. Kornegay

INTRODUCTION AND PATHOPHYSIOLOGY

A seizure is an episode of abnormal neurologic function caused by inappropriate electrical discharge of brain neurons. Neuronal electrical discharge, in its most simple form, can be thought of as the homeostasis of glutaminergic (excitatory) and γ-aminobutyric acid (inhibitory) activity. The seizure is the clinical attack experienced by the patient in the setting of inappropriate excitatory activity. Some patients with "epileptic" electroencephalographic (EEG) discharges may not experience any overt clinical symptoms. Some seizure-like episodes may be due to causes other than abnormal brain electrical activity, but such attacks are not true seizures.

Epilepsy is a clinical condition in which an individual is subject to recurrent seizures. It implies a fixed, more excitatory condition of the brain with a lower seizure threshold. The term *epileptic* does not refer to an individual with recurrent seizures caused by reversible conditions such as alcohol withdrawal, toxins, hypoglycemia, or other metabolic derangements.

Primary, or *idiopathic*, seizures are those in which no evident cause can be identified. *Secondary*, or *symptomatic*, seizures are a consequence of an identifiable neurologic condition, such as a mass lesion, previous head injury, or stroke. Electrical stimulation of the brain, convulsant potentiating drugs, profound metabolic disturbances, or a sharp blow to the head all may cause *reactive seizures* in otherwise normal individuals. Reactive seizures are generally self-limited, and a reactive seizure is not considered to be a seizure disorder or epilepsy.

There are further definitions of seizures based on clinical factors: a **provoked seizure** has an acute precipitating event within 7 days of the insult; an **unprovoked seizure** has no acute precipitating factor or may result from a very remote incident; **status epilepticus** is seizure activity for ≥5 minutes or two or more seizures without regaining consciousness between seizures[1]; and **refractory status epilepticus** is persistent seizure activity despite the IV administration of adequate amounts of two antiepileptic agents.

SEIZURE CLASSIFICATION

The International League Against Epilepsy recommends dividing seizures into two major groups: *generalized seizures* and *partial seizures* (**Table 171-1**). When there are inadequate data to categorize the seizure, the seizure is considered *unclassified.*

TABLE 171-1 Classification of Seizures

Generalized seizures (consciousness always lost)
Tonic-clonic seizures (grand mal)
Absence seizures (petit mal)
Others (myoclonic, tonic, clonic, or atonic seizures)
Partial (focal) seizures
Simple partial (no alteration of consciousness)
Complex partial (consciousness impaired)
Partial seizures with secondary generalization (Jacksonian march)
Unclassified (inadequate information)

GENERALIZED SEIZURES

Generalized seizures are thought to be caused by a nearly simultaneous activation of the entire cerebral cortex, perhaps caused by an electrical discharge originating deep in the brain and spreading outward. The attacks begin with abrupt loss of consciousness. Loss of consciousness may be the only clinical manifestation of the seizure (as in absence attacks), or there may be a variety of motor manifestations (e.g., tonic posturing, clonic jerking of the body and extremities).

Generalized tonic-clonic seizures (grand mal) are the most familiar and dramatic of the generalized seizures. **In a typical attack, the patient suddenly becomes rigid (tonic phase), trunk and extremities are extended, and the patient falls to the ground.** As the tonic phase subsides, there is increasing coarse trembling that evolves into a symmetric, rhythmic (clonic) jerking of the trunk and extremities. Patients are often apneic during this period and may be cyanotic. They often urinate and may vomit. As the attack ends, the patient is left flaccid and unconscious, often with deep, rapid breathing. Typical attacks last from 60 to 90 seconds; bystanders generally overestimate the duration of the seizure. Consciousness returns gradually, and postictal confusion, myalgias, and fatigue may persist for several hours or more.

Absence seizures (petit mal) are very brief, generally lasting only a few seconds. **Patients suddenly develop altered consciousness but no change in postural tone. They appear confused, detached, or withdrawn, and current activity ceases.** They may stare or have twitching of the eyelids. They may not respond to voice or to other stimulation and may exhibit involuntary movements or lose continence. The attack ceases abruptly, and the patients typically resume previous activity without postictal symptoms. Patients and witnesses may be unaware that anything has happened. Classic absence seizures occur in school-age children and are often attributed by parents or teachers to daydreaming or inattention. The attacks can occur as frequently as 100 or more times daily and may result in poor school performance. They usually resolve as the child matures. Similar attacks in adults are more likely to be minor complex partial seizures and should not be termed absence. The distinction is important because the causes and treatment of the two seizures are different.

PARTIAL (FOCAL) SEIZURES

Partial seizures are due to electrical discharges beginning in a localized region of the cerebral cortex. The discharge may remain localized or may spread to involve nearby cortical regions or the entire cortex. Focal seizures are more likely to be secondary to a localized structural lesion of the brain.

In simple partial focal seizures, the seizure remains localized, and consciousness and mentation are not affected. It is possible to deduce the likely location of the initial cortical discharge from the clinical features at the onset of the attack. For example, unilateral tonic or clonic movements limited to one extremity suggest a focus in the motor cortex, whereas visual symptoms suggest an occipital focus. Bizarre olfactory or gustatory hallucinations suggest a focus in the medial temporal lobe. Such sensory phenomena, known as *auras,* are often the initial symptoms of attacks that then become more widespread, termed *secondary generalization.*

Complex partial seizures are focal seizures in which consciousness or mentation is affected. They are often caused by a focal discharge originating in the temporal lobe and are sometimes referred to as *temporal lobe seizures*. Complex partial seizures are commonly misdiagnosed as psychiatric problems because symptoms can be so bizarre. **Symptoms may include automatisms, visceral symptoms, hallucinations, memory disturbances, distorted perception, and affective disorders.** Common automatisms include lip smacking, fiddling with clothing or buttons, or repeating short phrases. Visceral symptoms often consist of a sensation of "butterflies" rising up from the epigastrium. Hallucinations may be olfactory, gustatory, visual, or auditory. There may be

complex distortions of visual perception, time, and memory. Affective symptoms may include intense sensations of fear, paranoia, depression, elation, or ecstasy. Because such seizures result in alterations of thinking and behavior, they were previously referred to as *psychomotor seizures,* but to avoid any confusion with psychiatric illness, the term *complex partial seizure* is preferred.

As noted, a focal seizure may spread to involve both hemispheres, mimicking a typical generalized seizure. For the purpose of classification, diagnosis, and treatment, such attacks are still regarded as focal seizures. In some patients, the discharge may spread so rapidly that no focal symptoms are evident, and the correct diagnosis may depend entirely on demonstration of the focal discharge on an EEG recording.

CLINICAL FEATURES

HISTORY

When a patient presents after the event, the first step is to determine whether the episode was truly a seizure. Obtain a careful history of the details of the attack from the patient and any bystanders who witnessed the attack. Inquire about the physical description of the attack, because witnesses may mislabel the activity and mistake nonseizure activity as a seizure.

Important avenues of inquiry include the presence of a preceding aura, abrupt or gradual onset, progression of motor activity, loss of bowel or bladder control, presence of oral injury, and whether the activity was localized or generalized and symmetric or unilateral. Ask about the duration of the episode and determine the presence of postictal confusion or lethargy.

Next, determine the clinical context of the episode. If the patient is a known epileptic, clarify the baseline seizure pattern. If the attack is consistent with the previous seizure pattern, identify precipitating factors of the current seizure. **Common precipitating factors include missed doses of antiepileptic medications; recent alterations in medication, including dosage change or conversion from brand name; sleep deprivation; increased strenuous activity; infection; electrolyte disturbances; and alcohol or substance use or withdrawal.**

If there is no previous history of seizures, a more detailed inquiry is needed. Symptoms such as unexplained injuries, nocturnal tongue biting, or enuresis suggest previous unwitnessed or unrecognized seizures. Ask about a history of recent or remote head injury. Ask about any previous similar episodes that may be suspect as seizures. Persistent, severe, or sudden headache suggests intracranial pathology. Pregnancy or recent delivery raises the possibility of eclampsia. A history of metabolic or electrolyte abnormalities, hypoxia, systemic illness (especially cancer), coagulopathy or anticoagulation, exposure to industrial or environmental toxins, drug ingestion or withdrawal, and alcohol use may point to predisposing factors (**Table 171-2**).

PHYSICAL EXAMINATION

Immediately obtain a complete set of vital signs and a point-of-care glucose determination. In the post-seizure setting, focus the initial exam on checking for injuries, especially to the head or spine, as a result of the seizure itself. A posterior shoulder dislocation is an injury that is easy to overlook. Lacerations of the tongue and mouth, dental fracture, and pulmonary aspiration are also frequent sequelae.

Perform a directed, complete neurologic examination and subsequent serial examinations. Follow the patient's level of consciousness and mentation closely to avoid missing nonconvulsant status epilepticus (see below). **A transient focal deficit (usually unilateral) following a simple or complex focal seizure is referred to as *Todd's paralysis* and should resolve within 48 hours.**

DIAGNOSIS

Clinical features that help to distinguish seizures from other, nonseizure attacks include:

- Abrupt onset and termination. Some focal seizures are preceded by auras that can last 20 to 30 seconds, but most attacks begin abruptly. Attacks reported to develop over several minutes or longer should be regarded with suspicion. Most seizures last only 1 or 2 minutes, unless the patient is in status epilepticus.
- Lack of recall. Except for simple partial seizures, patients usually cannot recall the details of an attack.
- Purposeless movements or behavior during the attack.
- Most seizures, except for simple absence attacks or simple partial seizures, are followed by a period of postictal confusion and lethargy.

TABLE 171-2 Common Causes of Provoked (Secondary) Seizures

Trauma (recent or remote)
Intracranial hemorrhage (subdural, epidural, subarachnoid, intraparenchymal)
Structural CNS abnormalities
Vascular lesion (aneurysm, arteriovenous malformation)
Mass lesions (primary or metastatic neoplasms)
Degenerative neurologic diseases
Congenital brain abnormalities
Infection (meningitis, encephalitis, abscess)
Metabolic disturbances
Hypo- or hyperglycemia
Hypo- or hypernatremia
Hyperosmolar states
Uremia
Hepatic failure
Hypocalcemia, hypomagnesemia (rare)
Toxins and drugs (many)
Cocaine, lidocaine, antidepressants, theophylline, isoniazid
Mushroom toxicity (*Gyromitra* spp.)
Hydrazine (rocket fuels)
Alcohol or drug withdrawal
Eclampsia of pregnancy (may occur up to 8 weeks postpartum)
Hypertensive encephalopathy
Anoxic-ischemic injury (cardiac arrest, severe hypoxemia)

DIFFERENTIAL DIAGNOSIS

Many episodic disturbances of neurologic function may be mistaken for seizures (seizure mimics). A complete review of these conditions is too lengthy for inclusion here, but several important entities are mentioned (**Table 171-3**).

Syncope usually presents with prodromal symptoms, such as lightheadedness, diaphoresis, nausea, and "tunnel vision." However, cardiac syncope may occur suddenly without any prodromal warning. Syncope may be associated with injury, incontinence, or even brief tonic-clonic activity. Recovery is usually rapid, with no postictal-like symptoms. For further discussion see chapter 52, "Syncope."

Pseudoseizures can be extremely difficult to distinguish from true seizures and may occur in a patient who also has a documented seizure disorder. Pseudoseizures are psychogenic in origin and are often associated with a conversion disorder, panic disorder, psychosis, impulse control disorder, Munchausen syndrome, or malingering. Suspect the

Hyperventilation syndrome
Migraine headache
Movement disorders

diagnosis of pseudoseizures when seizures occur in response to emotional upset or only occur with witnesses present. These attacks are often bizarre and highly variable. Patients often are able to protect themselves from noxious stimuli during the attack. Characteristic movements include side-to-side head thrashing, rhythmic pelvic thrusting, and clonic extremity motions that are alternating rather than symmetric. Incontinence and injury are uncommon, and there is usually no postictal confusion. Patients will often stop the seizure-like activity on command. Accurate diagnosis of pseudoseizures may require prolonged EEG or video monitoring to demonstrate normal EEG activity during an attack. The lack of a lactic acidosis or elevated prolactin level drawn within 10 to 15 minutes of the cessation of seizure-like activity makes true seizures much less likely.

Hyperventilation syndrome can be misdiagnosed as a seizure disorder. A careful history will reveal the gradual onset of the attacks with shortness of breath, anxiety, and perioral numbness. Such attacks may progress to involuntary spasm (especially carpopedal) of the extremities and even loss of consciousness, although postictal symptoms are rare. Asking the patient to hyperventilate often reproduces the episodes.

Movement disorders, such as dystonia, chorea, myoclonic jerks, tremors, or tics, may occur in a variety of neurologic conditions. Consciousness is always preserved during these movements, and the patient can often temporarily suppress the movements.

Migraine headaches may be preceded by an aura similar to that seen in some partial seizures. The most common migraine aura is the scintillating scotoma. Migraine headaches may also be accompanied by focal neurologic symptoms, such as homonymous hemianopsia or hemiparesis. However, active movement disorders are inconsistent with migraine.

LABORATORY TESTING

Individualize the use of laboratory studies. **In a patient with a well-documented seizure disorder who has had a single unprovoked seizure, the only tests that may be needed are a glucose level and pertinent anticonvulsant medication levels.**

In the case of an adult with a first seizure or unclear seizure history, more extensive studies are usually needed and depend on the clinical context. Obtain serum glucose, basic metabolic panel, lactate, calcium, magnesium, a pregnancy test, and toxicology studies. Consider assays for anticonvulsant drug levels. A seizure may result in a lactate-driven, wide anion gap metabolic acidosis.[2] Most lactate abnormalities will clear within 30 minutes. The prolactin level may also be elevated for a brief period (15 to 60 minutes) immediately after a seizure.[3] These tests can prove helpful in distinguishing true seizures from a pseudoseizure.

Interpret the results of anticonvulsant levels with caution. If the patient history is limited, a positive serum assay for anticonvulsant drugs suggests (but does not prove) the presence of a chronic seizure disorder. The usual therapeutic and toxic levels indicated in laboratory reports are helpful only as rough guides. **The therapeutic level of a drug is the level that provides adequate seizure control without unacceptable side effects.** A marked change in previously stable drug levels may indicate noncompliance, a change in medication, malabsorption of a drug, or ingestion of a potentiating or competing drug. A very low serum anticonvulsant drug level suggests noncompliance with medication and is the most common cause of a breakthrough seizure.

IMAGING

Obtain a CT scan of the head in the ED for patients with a first-ever seizure or a change in established seizure patterns to evaluate for a structural lesion. A noncontrast CT is an appropriate screening tool.[4,5] Obtain a CT scan if there is any concern for an acute intracranial process based on history, comorbidities, or findings on physical examination. **Concern for an acute intracranial process is an important indication for obtaining CT imaging, even if there is a coexistent metabolic process.**

Because many important processes, such as tumors or vascular anomalies, may not be evident on noncontrast studies, a follow-up contrast-enhanced CT or MRI is often needed. Almost one-quarter of adults with new-onset seizure will have visualized pathology on follow-up MRI, with rates increasing to as high as 53% in those with onset of a focal seizure.[6] The timing of further imaging studies can be discussed with the consulting neurologist.

Obtain other radiographic studies as indicated by the clinical presentation to avoid missing injuries acquired as a result of the seizure. Obtain radiographs of the cervical spine if there is suspicion of head or neck trauma. Chest radiographs may reveal primary or metastatic tumors or aspiration. Shoulder radiographs may help rule out posterior dislocations. Special examinations, such as cerebral angiography, are rarely part of the ED evaluation.

LUMBAR PUNCTURE

Lumbar puncture in the setting of an acute seizure is indicated if the patient is febrile or immunocompromised or if subarachnoid hemorrhage is suspected and the noncontrast head CT is normal. For further discussion, see chapters 166, "Spontaneous Subarachnoid and Intracerebral Hemorrhage" and 174, "Central Nervous System and Spinal Infections."

ELECTROENCEPHALOGRAPHY

Although EEG is very helpful, it is often not readily available in most EDs. Emergent EEG can be considered in the evaluation of a patient with persistent, unexplained altered mental status to evaluate for nonconvulsive status epilepticus, subtle status epilepticus, paroxysmal attack when a seizure is suspected, or ongoing status epilepticus after chemical paralysis for intubation. Patients in whom an emergent EEG is warranted typically require neurologic consultation and admission to a critical care setting.

TREATMENT OF UNCOMPLICATED SEIZURES

PATIENTS WITH ACTIVE SEIZURES

Typically, little is required during the course of an active seizure other than supportive and patient protective measures. If possible, turn the patient to the side to reduce the risk of aspiration. It is usually not necessary or even possible to ventilate a patient effectively during a seizure, but once the attack subsides, clear the airway. Suction and airway adjuncts should be readily available. **It is not necessary or recommended to give IV anticonvulsant medications during the course of an uncomplicated seizure.** Most seizures will self-resolve within 5 minutes. Any unnecessary sedation at this point will complicate the evaluation and result in a prolonged decrease in level of consciousness.[7] Seizures that fail to abate after 5 minutes are considered status epilepticus and require more aggressive medical interventions (see "Status Epilepticus" section, below).

PATIENTS WITH A HISTORY OF SEIZURES

Proper management of a patient with a well-documented seizure disorder who presents after one or more seizures depends on the particular circumstances of the case. Identify and correct potential precipitants that may lower the seizure threshold. Many seizures occur because of failure to take anticonvulsant medication as prescribed. Some anticonvulsants have very short serum half-lives, and missing even a single dose may result in a sharp drop in serum levels. If anticonvulsant levels are very low, supplemental doses are appropriate, and the regular regimen can be restarted or adjusted. A loading dose is also frequently provided. Without a loading dose, the patient may not achieve anticonvulsant effects for days to weeks and is at risk for subsequent seizures. Because there are no data comparing parenteral versus oral replacement, this issue is left to the discretion of the medical provider[8] and should be based on knowledge of pharmacology. For example, the oral loading dose of phenytoin is 20 milligrams/kg given in three divided doses every 2 to 4 hours, a time frame not acceptable for a typical ED stay, so the IV route is needed to achieve the proper loading dose.

In the known or suspected noncompliant patient, obtain a serum anticonvulsant level before administering a supplemental or loading dose to avoid drug toxicity. **If anticonvulsant levels are adequate and the patient has had a single attack, specific treatment may not be needed if the seizure pattern and frequency fall within the expected range for the patient.** If anticonvulsant levels are not locally available (e.g., levetiracetam or lacosamide), and there is a missed dose or noncompliance, give the usual dose in the ED before discharge.

Even well-controlled patients may have occasional breakthrough seizures. Attempt to identify any precipitants or conditions that have lowered the seizure threshold. If none is found, a change or adjustment of medication may be needed and should be made in consultation with the patient's primary care physician or neurologist. If the maintenance dose is increased, ensure follow-up within 1 to 3 days. There are no specific guidelines for the duration of ED observation in the situation of an individual with a prior history of seizures. Some clinicians discharge patients with seizures resulting from nontherapeutic anticonvulsant levels after administration of a loading dose of an anticonvulsant if vital signs are normal and the mental status has returned to baseline. Ideally, discharge patients with a reliable family member or friend and with medical follow-up arranged, as above.

PATIENTS WITH A FIRST UNPROVOKED SEIZURE

Guidelines do not recommend hospital admission or initiation of anticonvulsant therapy in the patient with a first unprovoked seizure, as long as the patient has returned to neurologic baseline.[1,8] The most important predictors of seizure recurrence are the underlying cause of the seizure and the results of the EEG. The decision to begin outpatient treatment with antiepileptics depends on the risk of recurrent seizures weighed against the risk–benefit ratio of anticonvulsant therapy. In general, patients with a first unprovoked seizure who have a normal neurologic examination, no acute or chronic medical comorbidities, normal diagnostic testing including noncontrast head CT, and normal mental status can safely be discharged from the ED. Initiation of antiepileptic medication may be deferred to the outpatient setting where further studies, including an EEG and MRI, can be performed.[1,4,8] Consider consultation and/or admission for patients who do not meet the above criteria.

Patients with provoked (secondary) seizures due to an identifiable underlying condition (Table 171-2) often require admission and should generally be treated to minimize seizure recurrence.

The ideal initial antiepileptic regimen is a single-drug therapy that controls seizures with minimum toxicity. If treatment is initiated, drug selection is based on the type of seizure and should be done in consultation with a neurologist. Antiepileptic agents, such as valproate, lamotrigine, topiramate, levetiracetam, and oxcarbazepine, are options for adults with new-onset seizures.[5,9] Consider developing common protocols between emergency medicine and neurology when treatment of new-onset seizures is initiated from the ED.

Instruct discharged patients to take precautions to minimize the risks for injury from further seizures. Swimming, working with hazardous tools or machines, and working at heights should be prohibited. Driving is prohibited until cleared by the neurologist or primary care physician. Driving privileges should conform to state law, and it may be up to the emergency physician to document seizure activity with the Department of Motor Vehicles.

SPECIAL POPULATIONS

HUMAN IMMUNODEFICIENCY VIRUS

Mass lesions, encephalopathy, herpes zoster, toxoplasmosis, *Cryptococcus*, neurosyphilis, and meningitis are all seen more frequently in this population and can all provoke seizure activity.[10,11]

Perform an extensive investigation for the cause of the seizure. If no space-occupying lesion is identified on noncontrast head CT scan and there is no evidence of increased intracranial pressure, perform a lumbar puncture to exclude CNS infection. If no explanation for seizures is found, then obtain a contrast-enhanced head CT or MRI.

NEUROCYSTICERCOSIS

Neurocysticercosis is caused by a CNS infection with the larval stage of the tapeworm *Taenia solium* and is the most common cause of provoked (secondary) seizures in the developing world.[12] The most common form of disease is parasitic invasion of brain parenchyma and cyst formation. Over 1 to 2 years, the cyst degenerates and becomes fibrotic, leaving a focal area of scar and calcification. Seizures are the most common clinical manifestation of neurocysticercosis and most frequently occur as the parasite is degenerating. In 80% to 90% of cases, the lesions resolve within 3 to 6 months, leaving the patient free of seizures. Up to 20% of patients will continue to have seizures and require ongoing therapy with antiepileptic medications.[12]

In most cases, neuroimaging in neurocysticercosis is nondiagnostic. CT or MRI may demonstrate a 1- to 2-cm cystic lesion with thin walls and a 1- to 3-mm mural nodule (the parasite), a localized area of ring-like enhancement with surrounding edema, a calcified lesion, or hydrocephalus. Definitive diagnosis relies on a combination of the patient's clinical picture, exposure history, serologic testing, and neuroimaging.

Seizures in neurocysticercosis are typically controlled by antiepileptic monotherapy. Definitive treatment of neurocysticercosis is controversial and highly variable, depending on the number, location, and viability of the parasites within the CNS.[13,14] Antiparasitics (praziquantel and albendazole) and steroids are best initiated in consultation with an infectious disease specialist or neurologist.

PREGNANCY

The management of seizures (or control of epilepsy) during pregnancy requires a multidisciplinary approach. Most seizures in pregnancy are not first-time seizures, and initial evaluation is generally as discussed earlier, with the addition of an obstetric evaluation to determine gestational age and fetal well-being.

When a woman beyond 20 weeks of gestation develops seizures in the setting of hypertension, edema, and proteinuria, the condition is defined as *eclampsia*. Magnesium sulfate has long been used to treat eclampsia with good results. In eclamptic women, magnesium sulfate infusion compared to diazepam and phenytoin resulted in a >50% reduction in recurrence of seizures and a lower incidence of pneumonia, intensive care unit admission, and assisted ventilation.[15-17] Detailed discussion of seizures in pregnancy is discussed in chapter 100, "Maternal Emergencies after 20 Weeks of Pregnancy and in the Postpartum Period."

ALCOHOL ABUSE

Seizures and alcohol use are associated through missed doses of medication, sleep deprivation as an epileptogenic trigger, increased propensity for head injury, toxic co-ingestions, electrolyte abnormalities, and withdrawal seizures. Benzodiazepines in doses sufficient to manage withdrawal symptoms will usually afford adequate protection from acute seizures. These doses are often very large and need to be given in an escalating fashion.[18] Evaluate and treat the alcohol-abusing patient with a first seizure as any other patient with a first-time seizure. Detailed discussion of alcohol withdrawal seizures is provided in chapter 292, "Substance Use Disorders."

STATUS EPILEPTICUS

Status epilepticus can occur in patients with a history of seizures or can be a first epileptic event. The most common causes of status epilepticus include subtherapeutic antiepileptic levels; preexisting neurologic conditions, such as prior CNS infection, trauma, hemorrhage, or stroke; acute stroke; anoxia or hypoxia; metabolic abnormalities; and alcohol or drug intoxication or withdrawal.[19]

Status epilepticus is a single seizure ≥5 minutes in length or two or more seizures without recovery of consciousness between seizures.[1,20,21] After 5 minutes, seizures are less likely to spontaneously terminate, less likely to be controlled with antiepileptic drugs, and more likely to cause neuronal damage. **Status epilepticus is a neurologic**

emergency, and treatment should be initiated in all patients with continuous seizure activity lasting more than 5 minutes.

As seizures surpass the 5-minute mark, dramatic changes occur at the cellular level. Decreased expression and internalization of γ-aminobutyric acid receptors, coupled with increased expression of both glutamine and *N*-methyl-D-aspartate receptors, lead to a greatly diminished seizure threshold.[22,23] The blood–brain barrier is also compromised, leading to CNS penetration of potassium and albumin, both of which are hyperexcitatory CNS chemicals.[24] After 20 minutes, hypotension, hypoxia, metabolic acidosis, hyperthermia, and hypoglycemia are present. Additionally, cardiac dysrhythmias, rhabdomyolysis, and pulmonary edema can develop.[25] After 2 hours of seizure activity, neurotoxic amino acids and calcium are released into cells, leading to permanent neuronal necrosis and apoptosis.[22] The hyperexcitatory milieu makes standard antiseizure therapies much less effective in seizure termination.

In **nonconvulsive status epilepticus**, the patient is comatose or has fluctuating abnormal mental status or confusion, but no overt seizure activity is present. The diagnosis is challenging and is typically made by EEG. Findings suggestive of nonconvulsive status epilepticus include a prolonged postictal period after a generalized seizure; subtle motor signs such as twitching, blinking, and eye deviation; fluctuating alterations in mental status; or unexplained stupor and confusion in the elderly.[25]

Epilepsia partialis continua is focal tonic-clonic seizure activity with normal alertness that most commonly affects the distal leg or arm.

TREATMENT OF STATUS EPILEPTICUS

The goal of treatment is seizure control as soon as possible and within 30 minutes of presentation (**Figure 171-1**). Examination; identification of potential causes; checking the airway, breathing, and circulation; and treatment all begin simultaneously. Direct a focused history and physical examination toward possible causes and subsequent injuries.

Establish large-bore IV access and determine a bedside glucose. Administer normal saline, avoiding IV fluids containing glucose because phenytoin is not compatible with glucose-containing solutions. Place the patient on oxygen, a cardiac monitor, a pulse oximeter, and end-tidal capnography.

In established status epilepticus, consider endotracheal intubation for airway protection, oxygenation, and ventilation. If a paralytic agent is used for intubation, use a short-acting agent so as not to mask ongoing seizure activity. Arrange for continuous EEG monitoring as soon as possible after paralytic agents have been used.

Initial laboratory evaluation includes blood glucose, a metabolic panel including calcium and magnesium, lactate, and if appropriate, a pregnancy test, a toxicology screen, and anticonvulsant levels.

Administer glucose IV if hypoglycemia is suspected or confirmed. Monitor temperature continuously, and treat hyperthermia with passive cooling. Place a urinary catheter to monitor urine output, and insert a nasogastric tube to help prevent aspiration.

If toxic ingestion is suspected as the cause of seizures, proceed with GI decontamination (as appropriate). Do not attempt lumbar puncture during status epilepticus. **If bacterial meningitis or encephalitis is suspected, start empiric antibiotic or antiviral therapy.** Status epilepticus can induce a brief peripheral leukocytosis as well as a mild cerebrospinal fluid pleocytosis. Radiographic studies, such as a CT scan, will usually need to be delayed until seizures are controlled.

ANTICONVULSANT DRUGS IN STATUS EPILEPTICUS

The drugs most often used in the therapy of status epilepticus are the benzodiazepines (lorazepam or, if not available, diazepam) and phenytoin or fosphenytoin (Figure 171-1). Benzodiazepines are used in patients with continuous or very frequent seizures to temporarily control the seizures until more specific agents can be given. IV lorazepam (2 to 4 milligrams) and IV diazepam (5 to 10 milligrams) have equal efficacy in controlling status epilepticus.[8] Compared to diazepam, lorazepam has a slightly slower onset (3 vs 2 minutes) but a significantly longer duration of action (12 to 24 hours vs 15 to 60 minutes) and is associated with fewer seizure

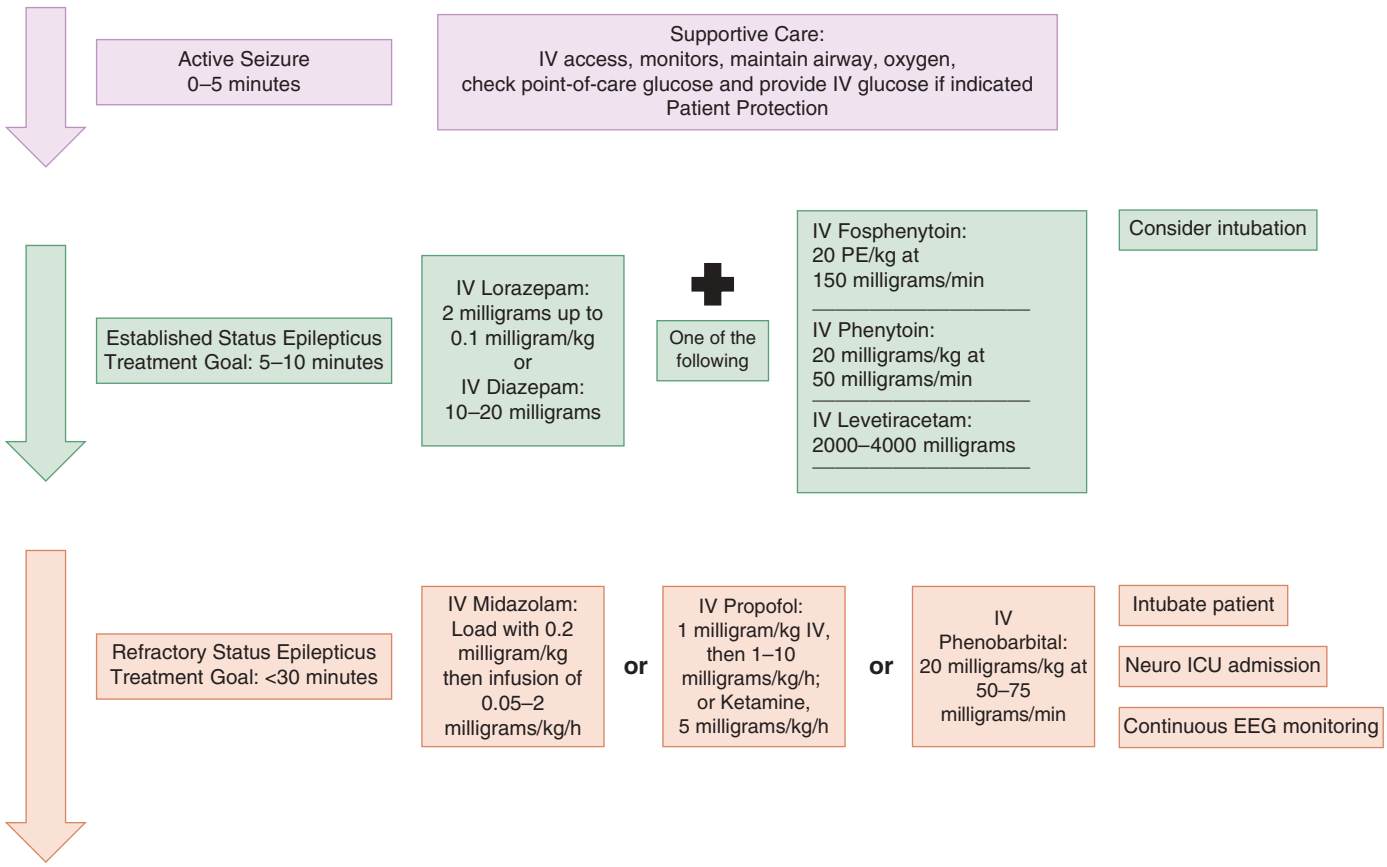

FIGURE 171-1. Guidelines for management of active seizures and status epilepticus. ICU = intensive care unit; PE = phenytoin equivalents.

recurrences. In one prehospital study, IM midazolam demonstrated decreased seizure time and fewer intensive care unit admissions when compared to lorazepam if no IV access was available[26]; however, **IV lorazepam is still considered the initial agent of choice.** Lorazepam is also more effective than phenytoin or phenobarbital as the initial drug.[27] Respiratory depression and hypotension may occur, especially in young children and in patients taking alcohol, barbiturates, narcotics, or other sedatives. In patients with difficult IV access and emergent need for seizure control, there may be a role for rectal diazepam gel or buccal midazolam. Although there have been no trials in adults, rectal diazepam has been used by EMS providers in children with good success for years, and recent trials of buccal midazolam (0.5 milligram/kg, up to 10 milligrams) show more efficacy than rectal diazepam in the pediatric population.[28,29]

In established status epilepticus, follow benzodiazepines with a longer-acting antiepileptic agent: fosphenytoin or phenytoin, levetiracetam, valproate, or lacosamide. One of these antiepileptic agents should be started within 20 minutes of diagnosis.[1]

Fosphenytoin is a water-soluble prodrug of phenytoin that is converted to phenytoin in the plasma. Fosphenytoin has similar time of onset, effectiveness, and cardiac effects as phenytoin. It has much fewer infusion-site reactions due to the lack of propylene glycol and ethanol as the diluents. Fosphenytoin may be infused quickly, and for that reason, it is preferred over phenytoin. Fosphenytoin dosing is expressed as phenytoin equivalents (PE) to prevent confusion. The loading dose is 20 PE/kg, which can be infused at 150 PE/minute over 10 to 15 minutes.[9] Fosphenytoin can also be given IM, which may be useful if the patient does not have IV access.

The loading dose for **phenytoin** is 20 milligrams/kg IV. Doses in excess of the usual 1000 milligrams are often required. Due to myocardial depression from its propylene glycol diluent, phenytoin is typically infused no faster than a rate of 25 milligrams per minute (taking about 1 hour to administer). The rate may be increased to 50 milligrams per minute during status epilepticus as long as hypotension does not develop. Place patients on a cardiac monitor, with blood pressure assessments every 5 to 15 minutes during the infusion and every 15 minutes for 1 hour after infusion.[30] Phenytoin should not be mixed with any glucose-containing IV fluid and should not be given IM due to erratic absorption. The drug is contraindicated in patients with second- or third-degree atrioventricular block. Other adverse effects include infusion site reactions, hypotension, and cardiac dysrhythmias. If side effects develop, stop the infusion and restart at a lower rate after side effects have resolved.

Valproic acid is effective but has serious side effects compared to the agents listed above. The U.S. Food and Drug Administration has issued a black box warning for hepatic failure and pancreatitis, and valproic acid should not be administered along with phenytoin. The dose is 20 milligrams/kg IV.[1,9,22,31,32]

Levetiracetam is very effective, is quick to administer, and has few interactions and side effects. The precise mechanism of action is unknown, but it may inhibit voltage-dependent calcium channels and facilitate γ-aminobutyric acid inhibitory transmission. The dose is 20 milligrams/kg IV. Although it is not yet approved by the Food and Drug Administration for status epilepticus, it is rapidly gaining favor as a first-line drug for established status epilepticus.[1,9,33-35]

Lacosamide is a potential alternative for status epilepticus with limited availability and limited data on its use. The dose is 200 milligrams IV given over 15 minutes.[1,36]

REFRACTORY STATUS EPILEPTICUS

Refractory status epilepticus is defined as persistent seizure activity despite the IV administration of adequate amounts of two antiepileptic agents and usually exceeds 60 minutes.[1] One study found that up to 31% of patients with status epilepticus went on to develop refractory status epilepticus.[37]

Various approaches to refractory status epilepticus have been suggested (Figure 171-1).[1,7,9,22,32-43] Overall, there are few controlled trials that strongly support a single agent or combination of agents. Current recommendations include propofol, midazolam, and barbiturates such as phenobarbital or pentobarbital given as infusions.[1] All of these agents can lead to hypotension, sometimes requiring concomitant vasopressor use, and require intubation. Ideally, treatment is in consultation with a neurologist and in an intensive care setting, because advanced respiratory support, cardiovascular support, and EEG monitoring are all needed.

Propofol is a widely used, lipophilic, general anesthetic that has come into favor for refractory status epilepticus. It can be started as an infusion at typical rates of 2 to 10 milligrams/kg/h and titrated up to effect seizure cessation. Propofol has the added benefit of a short half-life, allowing for quicker neurologic recovery after seizure control is achieved. At higher doses (>40 milligrams/kg/h), patients are at increased risk for hemodynamic instability, including hypotension, as well as propofol infusion syndrome.[1,7,9,22,39]

Midazolam is an easily titrated, infusible benzodiazepine that can also be used in the ongoing treatment of refractory status epilepticus. Midazolam can be started at 0.05 to 0.4 milligram/kg/h and is titrated up to seizure cessation.[1,9,40] Midazolam can accumulate in peripheral soft tissues, particularly with renal insufficiency, leading to a prolonged recovery period.

Barbiturates, such as **phenobarbital** (up to 20 milligrams/kg IV) or **pentobarbital**, may be considered as third-line drugs in patients whose seizures are not controlled despite full loading doses of benzodiazepines and other agents. However, **patients in refractory status may not respond to barbiturates.** One study found no added seizure control with phenobarbital.[32] A subsequent meta-analysis showed improved seizure control with pentobarbital compared to propofol or midazolam but no differences in mortality.[38] Respiratory depression and hypotension are more common when using barbiturates, especially at higher doses or when diazepam or lorazepam is also given.[1,9,22] Additionally, midazolam and propofol have the advantage over barbiturates of having a shorter half-life and rapid clearance, allowing for earlier extubation and clinical assessment.[1] For these reasons, current recommendations are to use propofol and midazolam infusions as first- and second-line agents, respectively, in refractory status epilepticus with barbiturates as third-line agents.[1,9,22,39,40]

Finally, **ketamine** may also be considered as a third-line agent in refractory status epilepticus. Ketamine is an *N*-methyl-D-aspartate receptor antagonist and helps block the hyperexcitatory pathway, which is thought to be a greater culprit in refractory status epilepticus. Ketamine can be administered as a bolus dose of 0.5 to 4.5 milligrams/kg or as an infusion up to 5 milligrams/kg/h. Multiple case reports and one retrospective study have demonstrated its safe use and likely benefit in terminating refractory status epilepticus.[22,41-43]

CHAPTER 172

Acute Peripheral Neurologic Disorders

Phillip Andrus
J. Michael Guthrie

INTRODUCTION

Acute peripheral neurologic lesions are a diverse group of disorders. By definition, they involve injury or disease in sensory and motor fibers outside of the central nervous system (CNS) extending to the neuromuscular junction. The peripheral nervous system (PNS) serves sensory, motor, and autonomic functions. Thus, the patient with a peripheral nerve lesion may have deficits in any combination of these functions. **Exclude central processes, such as stroke or spinal cord injury, before considering an acute peripheral lesion.**

DISTINGUISHING CENTRAL AND PERIPHERAL LESIONS

Use CNS and PNS neuroanatomy principles to distinguish lesions. Peripheral nerves contain varying amounts of motor, sensory, and autonomic fibers and follow well-described paths that make them prone to typical injuries. Thus, peripheral nerve lesions are more likely to be confined to one limb and to present with the involvement of multiple sensory modalities and motor symptoms. A typical example would be a nerve compression syndrome presenting with weakness, numbness, and tingling that developed after the arm was held in an unusual position for a prolonged period. However, weakness and numbness can be seen in both peripheral and central disorders. Hyporeflexia sometimes occurs with acute central lesions, but hyperreflexia and spasticity invariably develop with time. PNS disorders, like CNS diseases, can affect bulbar structures, resulting in diplopia, dysarthria, or dysphagia. Despite the overlap, CNS disorders have other features not seen in peripheral disease. For example, aphasia, apraxia, and vision loss are hallmarks of cortical disease. Most CNS lesions will result in upper motor neuron signs: hyperreflexia, hypertonia (spasticity), and extensor plantar (Babinski) reflexes. Perhaps the most important distinguishing component is the examination of deep tendon reflexes. Dorsiflexion of the great toe with fanning of remaining toes and flexion of the leg is a pathologic Babinski's sign, indicating a central disruption of the pyramidal tract. Although there can be many similarities between patients with CNS and PNS lesions, the distinctions are clear (**Table 172-1**). Lateralization of weakness, hyperreflexia, positive Babinski's sign, or any other CNS finding requires further investigation for a central rather than peripheral disorder.

LOCALIZING PERIPHERAL NERVE LESIONS

Patients with peripheral nerve disorders frequently require diagnostic evaluation unavailable during the initial ED encounter. A careful history and physical examination will exclude critical diagnoses and point toward the appropriate management.

TABLE 172-1 Differentiating Central Nervous System from Peripheral Nervous System Disorders

	Central	Peripheral
History	Cognitive changes Sudden weakness Nausea, vomiting Headache	Weakness confined to one limb Weakness with associated pain Posture- or movement-dependent pain Weakness after prolonged period in one position
Physical Examination		
Reflexes	Brisk reflexes (hyperreflexia) Babinski's sign Hoffman's sign	Hypoactive reflexes Areflexia
Motor	Asymmetric weakness of ipsilateral upper and lower extremity Facial droop Slurred speech	Symmetric proximal weakness
Sensory	Asymmetric sensory loss in ipsilateral upper and lower extremity	Reproduction of symptoms with movement (compressive neuropathy) All sensory modalities involved
Coordination	Discoordination without weakness	Loss of proprioception

HISTORY

The elements required to localize the process will usually include the following: symmetry; proximal versus distal symptoms; sensory, motor, or autonomic involvement; and mono- versus polyneuropathy. Sensory symptoms may include numbness, tingling, dysesthesias, pain, or ataxia. Motor symptoms manifest as weakness. Autonomic disability may present as orthostasis, bowel or bladder dysfunction, gastroparesis, or sexual dysfunction. Associated findings will frequently narrow the differential diagnosis or suggest a specific diagnosis. For example, in the setting of a recent viral infection or vaccination, consider Guillain-Barré syndrome. Is there a history of diabetes or subacute trauma? Does the patient with thrush or wasting and undiagnosed immunodeficiency have a human immunodeficiency virus (HIV)-associated neuropathy? Patients with an attached tick may have tick paralysis.

PHYSICAL EXAMINATION

Perform a comprehensive neurologic examination on patients with peripheral nerve disorders, paying particular attention to the specific area and distribution involved. Evaluate for hypotonia, muscle wasting, fasciculations, and hyporeflexia. Is there focal weakness? What is the perception of light touch, vibration, and position sense? If there are sensory deficits, what spinal nerve levels do they involve?

DIAGNOSIS

Many patients with peripheral nerve disorders will require electromyography and nerve conduction velocity studies. Electromyography is used to differentiate primary muscular or neuromuscular junction problems from peripheral nerve disorders. Nerve conduction velocity studies, which measure the speed of conduction by observing the response to nerve stimulation by distally placed electrodes, can differentiate between axonal loss and demyelination. Combined with the history and physical examination, these tests allow the consultant to better localize the lesion and make a firm diagnosis. Lumbar puncture and cerebrospinal fluid (CSF) analysis are frequently required to confirm the diagnosis in acute or subacute inflammatory and infectious processes. In certain cases, nerve biopsy may be required. In cases where biopsy is considered, MRI can direct the biopsy site to the area of greatest utility.

TREATMENT

Management of PNS disorders depends on the specific diagnosis. However, a few general principles apply. Initiate supportive care for severe, life-threatening neuromuscular diseases in the ED. Monitor patients with the potential for respiratory failure, aspiration, and cardiac dysrhythmias. **For patients at risk for diaphragmatic failure, measure baseline forced vital capacity or negative inspiratory pressure in the ED to assess whether there is an immediate need for respiratory support or admission to an intensive care unit.** Admit patients with acute peripheral neurologic conditions if there is potential respiratory or autonomic compromise, or with severe or rapidly progressing weakness. If a peripheral disorder is suspected and the patient does not require admission, arrange for neurologic follow-up within 7 to 10 days.

ACUTE PERIPHERAL NEUROPATHIES

GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome is an acute polyneuropathy characterized by immune-mediated peripheral nerve myelin sheath or axon destruction. The prevailing theory is that antibodies directed against myelin sheath and axons of peripheral nerves are formed in response to a preceding viral or bacterial illness. Symptoms are at their worst in 2 to 4 weeks, and recovery can vary from weeks to a year.

Clinical Features Classically, Guillain-Barré syndrome is preceded by a viral illness, followed by **ascending symmetric weakness or paralysis and areflexia or hyporeflexia**. Paralysis may ascend to the diaphragm, compromising respiratory function and requiring mechanical ventilation in one third of patients. Autonomic dysfunction may be present as well.

TABLE 172-2 Diagnostic Criteria for Classic Guillain-Barré Syndrome

Required
Progressive weakness of more than one limb
Areflexia
Suggestive
Progression over days to weeks
Recovery beginning 2–4 weeks after cessation of progression
Relative symmetry of symptoms
Mild sensory signs and symptoms
Cranial nerve involvement (Bell's palsy, dysphagia, dysarthria, ophthalmoplegia)
Autonomic dysfunction (tachycardia, bradycardia, dysrhythmias, wide variations in blood pressure, postural hypotension, urinary retention, constipation, facial flushing, anhydrosis, hypersalivation)
Absence of fever at onset
Cytoalbuminologic dissociation of cerebrospinal fluid (high protein and low white cell count)
Typical findings on electromyogram and nerve conduction studies

TABLE 172-3 Managing Respiratory Failure in Guillain-Barré Syndrome

Indications for intubation
Vital capacity <15 mL/kg
Declining one breath count
Pao_2 <70 mm Hg on room air
Bulbar dysfunction (difficulty with breathing, swallowing, or speech)
Aspiration
Indications for admission to intensive care unit
Patients with 4 or more of the following findings: inability to stand, inability to lift the head, inability to lift the elbows, insufficient cough, time from symptom onset to hospital admission <7 days or elevated liver enzymes
Autonomic dysfunction
Bulbar dysfunction
Initial vital capacity <20 mL /kg
Initial negative inspiratory force less than −30 cm of water
Decrease of >30% of vital capacity or negative inspiratory force
Inability to ambulate
Treatment with plasmapheresis

Abbreviation: Pao_2 = partial pressure of arterial oxygen.

There are several variants of Guillain-Barré syndrome. The **Miller-Fisher syndrome** variant is associated with ***Clostridium jejuni* infection**. It is preceded by diarrhea and is characterized by ophthalmoplegia, ataxia, and decreased or absent reflexes. Weakness is less severe and the disease course is milder than Guillain-Barré syndrome. Antibody testing for *C. jejuni* can confirm the diagnosis. Acute motor axonal neuropathy is a pure motor variant, also associated with *C. jejuni* infection, and is seen in Japan and China. Another variant is acute motor and sensory axonal neuropathy, with loss of both motor and sensory function. This variant begins abruptly, progresses rapidly, and has a prolonged course and poor prognosis.

Diagnosis The diagnosis is mostly historical, but lumbar puncture and electrodiagnostic information can improve confidence in the diagnosis. **Table 172-2** lists the specific diagnostic criteria.

CSF analysis shows high protein levels (>45 milligrams/dL) and WBC counts typically <10 cells/mm^3, with predominantly mononuclear cells. When there are >100 cells/mm^3, other considerations include HIV, Lyme disease, syphilis, sarcoidosis, tuberculous or bacterial meningitis, leukemic infiltration, or CNS vasculitis. Electrodiagnostic testing demonstrates demyelination. Nerve biopsy reveals a mononuclear inflammatory infiltrate. If MRI is performed to rule out alternative diagnoses, it will show enhancement of affected nerves.

Treatment The first step in management is assessment of respiratory function. Airway protection in advance of respiratory compromise decreases the incidence of aspiration and other complications. A well-established monitoring parameter is vital capacity, with normal values ranging from 60 to 70 mL/kg. A simple bedside assessment of respiratory status is obtained by trending values reached when the patient counts from 1 to 25 with a single breath. **Avoid depolarizing neuromuscular blockers like succinylcholine for intubation in Guillain-Barré syndrome due to the risk of a hyperkalemic response.**

Both IV immunoglobulin and plasmapheresis shorten the time to recovery. Neither has been shown to be superior to the other, nor are they more efficacious when used together. There are adverse effects seen with both modalities of treatment. IV immunoglobulin has been associated with thromboembolism and aseptic meningitis; plasmapheresis is associated with hemodynamic instability, but a lower rate of relapse. In general, IV immunoglobulin is more widely available and less cumbersome to administer. Corticosteroids are of no benefit and may be harmful.[1]

Disposition Admit patients with acute Guillain-Barré syndrome to a unit where cardiac, respiratory, and neurologic functions can be monitored. Even if a patient does not initially meet the criteria for intubation, intensive care unit admission may still be indicated in order to avoid sudden, unmonitored respiratory failure (**Table 172-3**).[2]

BELL'S PALSY AND UNILATERAL FACIAL PARALYSIS

Bell's palsy or idiopathic facial nerve palsy is the most common cause of unilateral facial paralysis. There are 23 to 25 cases per 100,000 annually, affecting men and women equally. Cranial nerve VII, the facial nerve, supplies motor innervation to the muscles of expression of the face and scalp, the stapedius muscle, and taste to the anterior two thirds of the tongue. The cause of Bell's palsy is not clear. Herpes simplex virus DNA and antigens have been discovered around the facial nerve of affected patients. However, antiviral medications are ineffective, casting doubt on the once predominant theory that herpes simplex virus is responsible for the disease.

Clinical Features **Idiopathic Bell's palsy may be preceded by pain around or behind the ear.** Onset of facial paralysis is acute, with maximal symptoms in 2 to 3 days. Facial numbness or hyperesthesia can accompany paralysis. Subtle dysfunction of cranial nerves V, VIII, IX, and X may be associated; for example, patients may also complain of decreased taste or hyperacusis due to paralysis of the stapedius muscle. On exam, patients will have facial droop, effacement of wrinkles and forehead burrows, and inability to completely close the eye. Recurrent idiopathic Bell's palsy occurs in a small number of patients.

Diagnosis Diagnosis of idiopathic Bell's palsy is based on the history and physical exam and is a diagnosis of exclusion of other conditions that can cause facial palsy. **The most important alternative diagnoses to exclude are ear infections and stroke.** Always perform an ear examination to identify otitis media and malignant otitis, and palpate the mastoids for tenderness, because infections of the ear and mastoids can affect the mastoid, tympanic, labyrinthine, or meatal segments of the cranial nerve VII (**Figure 172-1**).

When a central process causes facial paralysis, the forehead will be spared, as the forehead is supplied by cranial nerve VII arising near the pontomedullary junction, with crossed innervation. Peripheral facial nerve palsies will manifest as weakness throughout the facial nerve distribution, including the forehead. **Middle cerebral artery ischemia or stroke** consists of hemiparesis, facial plegia sparing the forehead, and sensory loss all contralateral to the affected cortex. **Rarely, a brainstem stroke may mimic Bell's palsy if the stroke affects the area where the facial nerve wraps around the abducens (cranial nerve VI) nucleus.** Brainstem stroke findings include peripheral facial nerve palsy and ipsilateral gaze palsy due to ischemia of the abducens nucleus. So, **test extraocular muscle function for all patients suspected of having Bell's palsy. Any patient with facial paralysis sparing the forehead or inability to abduct an eye should undergo neuroimaging to assess for stroke.** No imaging or laboratory testing is needed in patients with high suspicion of Bell's palsy unless further studies are required to exclude alternative diagnoses.

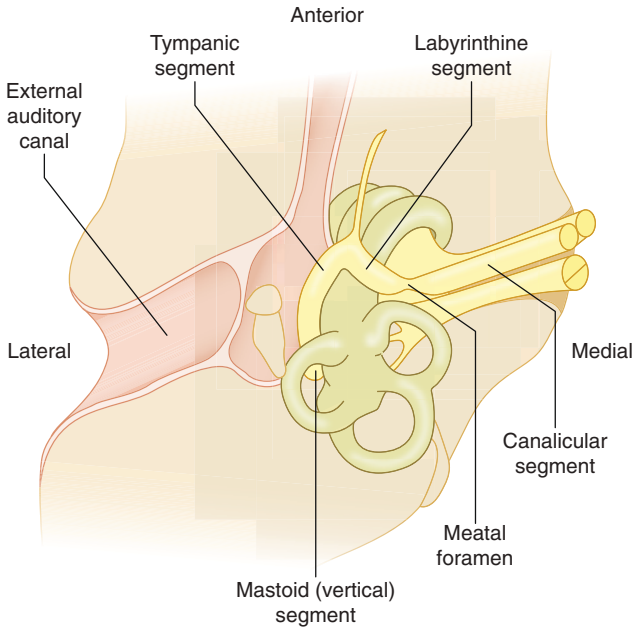

FIGURE 172-1. Relationships of cranial nerve VII to the inner and middle ear. [Adapted with permission from Lalwani AK (ed): *Current Diagnosis & Treatment in Otolaryngology-Head & Neck Surgery*, 3rd ed. McGraw-Hill, Inc., 2012. Sect XVI Facial Nerve Chapter 70. Figure 70-3, Part A.]

A number of viral infections and other disorders have been associated with Bell's palsy (e.g., mumps, Epstein-Barr virus, rubella, Lyme disease; see later discussion) but are suspected by associated signs and symptoms.

Treatment and Disposition Treatment with corticosteroids increases the frequency of complete recovery.[3] The dose of prednisone is 1 milligram/kg per day PO for 7 days. There is no benefit from antiviral medications, either alone or in addition to steroid therapy.[4] There is insufficient evidence to support acute surgical decompression. The greatest risk to patients with facial paralysis is corneal abrasions and keratitis due to eyelid weakness and incomplete eye closure. Patch the affected eye if there is incomplete closure, and provide instructions for ophthalmology follow-up to determine when the patch can be removed. Make sure there is no lid movement under the eye patch. Provide patients with ocular lubricants, including a tear replacement for daytime and a more viscous topical lubricant for sleep.

Most patients begin to recover within 3 weeks, but about 15% will have permanent paralysis. Ensure follow-up within 7 days with a primary care physician or ear, nose, and throat specialist.

RAMSEY HUNT SYNDROME (HERPES ZOSTER OTICUS)

Ramsey Hunt syndrome is a herpes zoster infection of the geniculate ganglion. Signs and symptoms include unilateral facial nerve palsy, severe pain, and a vesicular eruption on the face. Ramsey Hunt syndrome may be indistinguishable from Bell's palsy if paralysis precedes the vesicular eruption. Cranial nerve VIII may also be involved with associated vertigo, nausea, and hearing loss. As opposed to classic Bell's palsy, when active herpes zoster is suspected, treatment is with both steroids (prednisone 1 milligram/kg per day PO for 7 days) and antivirals (famciclovir 500 mg PO three times a day for 7 days or valacyclovir 1 gram PO three times a day for 7 days).[5]

ACUTE NEUROPATHIES OF LYME DISEASE

Lyme disease may cause a broad range of nervous system disease, both peripheral and central, acute and chronic. Consider Lyme disease as the causative agent in patients who have facial palsy with erythema migrans, tick bite, or arthritis. Some patients will have bilateral facial palsy. Multifocal Lyme polyradiculopathy may occur in the acute phase of Lyme infection. Signs and symptoms include burning and painful neuropathy, plexopathy, and other mononeuropathies.

Diagnosis is based on history of tick bite and a physical examination that uncovers an attached tick or erythema chronicum migrans rash (see Figure 251-18). If CSF is obtained, it will show the mononuclear pleocytosis typical of Lyme infection. Treatment is with doxycycline 100 milligrams twice daily for 14 to 21 days. Facial nerve palsies in Lyme disease represent the secondary stage of illness and require 1 month of treatment with doxycycline (100 milligrams PO twice a day) or amoxicillin, cefuroxime, ceftriaxone, or azithromycin.

FOCAL MONONEUROPATHIES

Focal mononeuropathies are most likely due to focal nerve compression, although systemic processes may also lead to mononeuropathy. Diabetes is the most common systemic cause of noncompressive focal neuropathy. Focal mononeuropathy can occur at any point of compression along the course of a peripheral nerve, but most commonly occurs along the ulnar, median, radial, lateral femoral cutaneous, and peroneal nerves.

MEDIAN MONONEUROPATHY (CARPAL TUNNEL SYNDROME)

The most common form of any focal mononeuropathy is median mononeuropathy, or carpal tunnel syndrome. Carpal tunnel syndrome results from compression of the median nerve at the wrist where it traverses the carpal tunnel. The boundaries of the carpal tunnel are the carpal bones and the flexor retinaculum. The most common etiology is injury due to repetitive use, but other causes include diabetes mellitus, pregnancy, amyloidosis, obesity, renal failure, rheumatoid arthritis, hypothyroidism, trauma, and edema.

Clinical Features The classic signs of carpal tunnel syndrome are pain, paresthesias, and numbness in the distribution of the median nerve—the palmar aspect of the thumb, index, middle, and radial aspect of the fourth finger. Patients may report symptoms in the entire hand, but careful examination will reveal preserved sensation in the fifth and ulnar fourth digits. Symptoms are worsened by extension and flexion of the wrist and are worse at night. Weakness and wasting of the muscles of the thenar eminence may be noted on exam.

Diagnosis Provocative testing, such as Tinel's sign and Phalen's maneuvers, can confirm the diagnosis of carpal tunnel syndrome (**Figure 172-2**). **Tinel's sign** detects irritated nerves by percussing over the nerve and eliciting tingling. Tapping on the palmar aspect of the wrist will result in an electric shock sensation shooting into the hand when there is compression of the median nerve. **Phalen's maneuver** is positive for carpal tunnel syndrome when holding the wrists in flexion for 60 seconds evokes or worsens symptoms. Electrodiagnostic testing demonstrates slowing of nerve conduction across the carpal tunnel. Testing is typically performed on an outpatient basis to confirm the diagnosis or to aid in the decision for operative repair.

Treatment and Disposition The initial treatment of carpal tunnel syndrome is conservative. Encourage evaluation of workplace ergonomics. Provide a wrist splint, with the wrist in neutral position (**Figure 172-3**). Nonsteroidal anti-inflammatory drugs are often given. Refer to a hand surgeon if splinting is not effective, for steroid injection and consideration for surgical repair.

ULNAR MONONEUROPATHY (CUBITAL TUNNEL SYNDROME AND GUYON'S CANAL SYNDROME)

The ulnar nerve extends from the medial cord of the brachial plexus and courses through the cubital tunnel behind the medial epicondyle at the elbow before entering the forearm. At the wrist, it passes through Guyon's canal, bounded by the hamate and pisiform bones and the ligament connecting them. It supplies cutaneous innervation to the medial palm via the superficial terminal branch and to the fifth and medial fourth

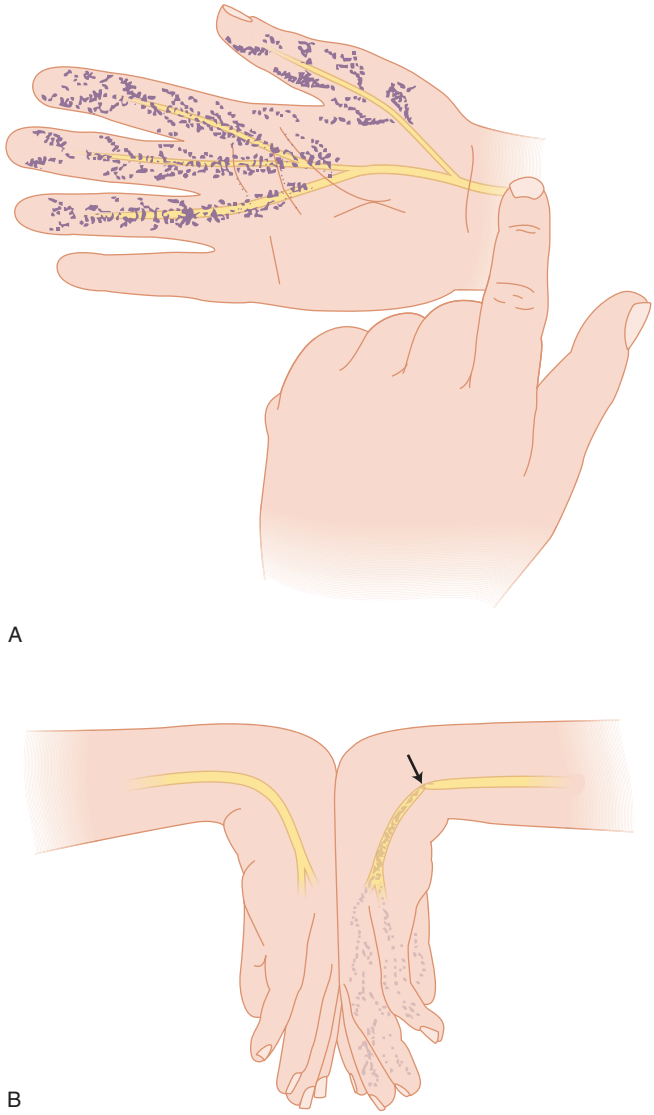

FIGURE 172-2. **A.** Tinel's sign for median nerve compression. The Tinel test is performed by tapping the volar surface of the wrist over the median nerve. **B.** Phalen's maneuver. Phalen's maneuver is performed by compressing the opposing dorsal surfaces of the hands with the wrists flexed together as shown. This causes tingling over the median nerve distribution. [Reproduced with permission from Simon RR, Sherman SC, Koenigsknecht SJ: Wrist. In: *Emergency Orthopedics: The Extremities, 5th ed.* © 2007, McGraw-Hill Inc., New York.)

fingers via the deep terminal branch and innervates the palmaris brevis muscle. The ulnar nerve is most vulnerable to repetitive stress, inflammation, and trauma in the cubital tunnel and at Guyon's canal.

Cubital tunnel syndrome is the most common ulnar mononeuropathy and the second most common compressive mononeuropathy. It results from pressure on the ulnar nerve at the medial epicondyle.

Guyon's canal syndrome is caused by entrapment of the ulnar nerve in Guyon's canal of the wrist. It is also called **"handlebar palsy,"** because it occurs in cyclists from prolonged compression of the wrist against the handlebars.

Clinical Features The classic symptoms of ulnar mononeuropathy include tingling in the fifth and lateral fourth fingers. With time, numbness and weakness of the intrinsic muscles of the hand develop. In severe cases, paralysis and wasting of the intrinsic muscles of the hand may occur.

Diagnosis Provocative testing is useful. Ulnar compression is possible if tapping on the cubital tunnel at the elbow provokes symptoms. A positive elbow flexion sign is seen when symptoms recur within 3 minutes of the elbow being held in flexion with the wrist in extension. **Froment's sign** is an inability of the thumb to oppose or put pressure against the index finger. To perform this test, ask the patient to hold a piece of paper between thumb and index finger. If you can pull the paper away or the thumb flexes at the interphalangeal joint to compensate for weakness of the adductor pollicis brevis, the test is positive. In the patient with suspected **cubital tunnel syndrome**, consider C8 entrapment and thoracic outlet syndrome. C8 entrapment can be differentiated by the presence of neck pain and worsening symptoms with neck flexion. Thoracic outlet syndrome worsens with shoulder abduction. Electrodiagnostic testing serves to precisely localize the lesion. In Guyon's canal syndrome, or handlebar palsy, compression of the ulnar nerve is more likely to spare sensory fibers that branch off before the canal. It presents as intrinsic weakness without sensory symptoms. Diagnosis of Guyon's canal syndrome is difficult, and MRI can sometimes aid in diagnosis.

Treatment and Disposition In most cases of ulnar nerve mononeuropathy, the goal of treatment in the ED is to initiate conservative treatment and to ensure proper diagnosis and appropriate follow-up, usually with an orthopedist. Pain is not a common component of this syndrome, but anti-inflammatory medication may alleviate symptoms. Reduce repetitive use at work and home, and eliminate habits that cause pressure on the elbow or wrist.

DEEP PERONEAL NERVE ENTRAPMENT

The deep peroneal nerve may become entrapped at three locations along its course: the fibular head, anterior to the ankle joint as it passes beneath the extensor retinaculum (anterior tarsal tunnel syndrome), and distal to this point. Compression of the deep peroneal nerve may result from proximal fibular fracture or habitual crossing of the legs. Patients develop foot drop or numbness of the web between the great and second toes. Conservative treatment is recommended initially—provide a splint or brace to maintain the foot at a right angle with the leg. Prompt follow-up with a neurologist is important because nerve conduction studies should be performed to differentiate this syndrome from lumbar root or motor neuron disease.

MERALGIA PARESTHETICA

Meralgia paresthetica is entrapment of the lateral femoral cutaneous nerve in the inguinal canal. Entrapment causes numbness and pain of the anterolateral thigh. The cause can be pelvic (pregnancy, enlarging

mass, aneurysm), extrapelvic (trauma, tight garment or belt, obesity), or systemic (diabetes). On examination, the patient may complain of hyperesthesia in the area of pain, and Tinel's sign may be evident when percussing over the anterior superior iliac spine. The **pelvic compression test** also supports this diagnosis: turn the patient on his or her side, compress the pelvis, and if the patient's symptoms are relieved after 30 seconds of lateral compression of the pelvis, the diagnosis is confirmed.

Conservative management with nonsteroidal anti-inflammatory drugs, weight loss, relief from tight garments, and physiotherapy is usually successful. Local injection of lidocaine and corticosteroid near the insertion of the inguinal ligament into the anterior superior iliac spine provides relief. Surgical decompression or nerve resection may be required for relief of symptoms.

PLEXOPATHIES

The cervical, brachial, and lumbosacral plexuses are formed by the convergence of nerve roots, which then branch into peripheral nerves. In the case of the brachial plexus, the process of mixing and dividing is repeated in the stages of trunks and cords before peripheral nerves take off. Plexopathies share many of the same causes, the most common being trauma, surgery, neoplasm, and radiation therapy. Despite this similarity, plexopathies differ significantly in diagnosis and management.

BRACHIAL PLEXOPATHY

The brachial plexus, formed by the C5-T1 nerve roots, is the most common site of plexopathy. The brachial plexus is made complex by the nerve roots merging into upper middle and lower trunks, which split and merge into lateral posterior and medial cords that split again and form five peripheral nerves (see Figure 172-3). Injury at each of these anatomic locations will result in differing symptoms. Brachial plexopathies generally manifest as weakness first, but pain and paresthesias may also develop. On examination, the patient has weakness in various distributions of the brachial plexus. The upper trunk is the more common site of involvement, affecting strength of proximal arm and shoulder musculature. Infraclavicular plexopathy due to trauma is frequently associated with injury to the axillary vessels. Causes of brachial plexopathy include trauma (penetrating trauma, humeral neck fracture, severe traction injury, or dislocation), shoulder reduction, neoplasm (Pancoast tumor), radiation, or surgery. A **"burner"** is burning pain involving one upper extremity, sometimes with numbness, paresthesias, or weakness, occurring after trauma to the neck and shoulder. It can occur in football players and other athletes during sports. A burner can be a brachial plexopathy, caused by traction to the shoulder or an injury to the cervical nerve roots caused by neck flexion-hyperextension. Brachial plexopathies can also result from cervical rib compression, midshaft clavicular fracture, or penetrating trauma. Assessment consists of careful neurologic examination, spine imaging, and consultation with neurology, neurosurgery, or orthopedics, depending on the specific injury identified.

LUMBOSACRAL PLEXOPATHY

The L1-S4 nerve roots form the lumbosacral plexus. Causes of lumbosacral plexopathy are less likely traumatic and more likely to include radiation, diabetic amyotrophy, aortic aneurysm, retroperitoneal hemorrhage, or compression from arteriovenous malformations. The differential diagnosis also includes the **cauda equina and conus medullaris syndromes**. Lesions affecting the lumbar portion of the plexus result in weakness of hip adduction and flexion and knee extension, decreased sensation at the top and inner thigh, and decreased patellar reflexes. Lesions affecting the sacral portion of the plexus result in inability to abduct the thigh at the hip joint, weakness of hip extension and knee flexion, and decreased sensation of the back of the thigh and below the knee. Plain radiographs of the lumbar spine are useful to screen for spine compression from degenerative or neoplastic disease. Perform MRI when cord injury or compression is considered. See chapter 279, Neck and Back Pain, for detailed discussion of epidural compression syndromes, cauda equina syndrome, and conus medullaris syndrome. CT of the abdomen will exclude aortic aneurysm, psoas muscle masses, and retroperitoneal hemorrhage, which also present with asymmetric lower extremity weakness. Management of plexopathies is usually directed at the underlying cause.

CERVICAL PLEXOPATHY

The cervical plexus, formed by the C1-C4 nerve roots, is the least common plexopathy. Apart from trauma or neoplasm, the condition is occasionally seen postoperatively due to positioning during surgery. Patients may have few symptoms. Neoplastic lesions may cause a deep boring and constant pain. Due to anatomic parameters, electrodiagnostic assessment is difficult and unreliable. Order a CT or MRI scan if a neoplastic process is considered. The management of cervical plexopathy is usually nonoperative.

NEUROMUSCULAR JUNCTION DISORDERS

BOTULISM

Botulism is a toxin-mediated neuromuscular junction disorder that causes acute weakness leading to respiratory failure. In 2010, the Centers for Disease Control and Prevention reported 112 cases of botulism. Of these, 76% were infantile botulism, 15% were wound botulism, and 8% were food borne.[6] Botulism affects infants between the ages of 1 week and 11 months and has been implicated as a cause of sudden infant death syndrome. The causative organism, *Clostridium botulinum*, is an anaerobic spore-forming bacterium found in soil and honey. In suitable environments, these spores germinate and release toxin that irreversibly binds the presynaptic membrane of peripheral and cranial nerves, inhibiting the release of acetylcholine at the peripheral nerve synapse. Three of the eight known toxins, types A, B, and E, produced by *C. botulinum* cause human disease. The most commonly implicated is toxin A, which is also used cosmetically in injection form. Most cases of botulism are isolated events associated with improperly preserved canned foods. In adults, botulism results from ingestion of preformed toxin. Infantile botulism occurs due to ingestion of spores that germinate in the higher pH of the infant GI tract. Botulism can result from wound infections, mostly occurring in injection drug users. In 2010, every reported case of wound botulism but one was due to injection drug use.[7] Toxin type E is associated with preserved or fermented fish and marine mammals, and the latter are the most important sources of botulism in Alaska, Japan, Russia, and Scandinavia. *C. botulinum* is classified as a category A bioweapon by the Centers for Disease Control and Prevention, among the most lethal.[7]

Clinical Features Onset of symptoms occurs 6 to 48 hours after the poisoning with toxin. Patients experience nausea, vomiting, abdominal cramps, and diarrhea or constipation, which may easily be misdiagnosed as an acute gastroenteritis. **Classically, botulism produces a descending, symmetric paralysis.** Since the disorder is at the neuromuscular junction, there is no sensory deficit and no pain. The muscles first affected are the cranial nerves and bulbar muscles. The patient presents with diplopia, dysarthria, and dysphagia and may report blurred vision. Deep tendon reflexes are normal or diminished. Toxin-mediated decrease in cholinergic output causes anticholinergic symptoms, such as constipation, urinary retention, dry skin and eyes, and hyperthermia. **Pupils are often dilated and nonreactive to light.** Pupillary findings provide an important point of differentiation from myasthenia gravis, which does not affect the pupil. Infantile botulism presents as constipation, poor feeding, lethargy, and weak cry; consequently, this diagnosis must be in the differential of the "floppy" infant.

Diagnosis The diagnosis of botulism is made based on clinical findings and exclusion of other processes. The toxin can be identified in both serum and stool, but the assay is not commonly available. If the suspected food source is available, it should be tested for toxin.

Treatment and Disposition Initial treatment is supportive. Secure the airway if there is respiratory compromise. In several retrospective cohort studies, botulinum equine antitoxin was associated with decreased number of days on the ventilator and in the hospital, and it is most effective when used early.[7] The Centers for Disease Control and Prevention recommend giving one 10-mL vial of trivalent equine antitoxin as soon as the diagnosis is made. Human botulism immunoglobulin has been shown to decrease mechanical ventilation requirements and length of intensive care unit and hospital stays.[9]

Patients diagnosed with botulism require admission to the intensive care unit and intubation for respiratory failure. Report suspected cases to the local health department so that further exposures can be prevented.

TICK PARALYSIS

Tick paralysis, or tick toxicosis, is an uncommon disease caused by a poorly defined neurotoxin secreted in the saliva of several tick species. It is most common in spring and summer and in the Pacific Northwest, western, and southeastern states. Most cases are in children.

Clinical Features Initially, 4 to 7 days after tick attachment, patients experience nonspecific influenza-like symptoms including malaise and weakness. These symptoms progress to ataxia and then an **ascending weakness and paralysis** without sensory involvement. Infants and children may be listless or irritable. When the bulbar nerves and diaphragm become involved, respiratory failure ensues.

Diagnosis Tick paralysis is diagnosed based on typical symptoms and when the culprit tick is located. **Perform a complete body search for ticks before initiating treatment for other possible diagnoses.** The most common tick attachment site is the scalp. If no tick is found, the differential diagnosis of acute ataxia and ascending flaccid paralysis without sensory involvement includes Guillain-Barré syndrome, botulism, spinal cord tumor, and poliomyelitis.

Misdiagnosis of tick paralysis can lead to failure to find and remove the tick and unnecessary therapies such as central venous access, plasma exchange, and IV immunoglobulin. Tick paralysis and Guillain-Barré syndrome are indistinguishable even with nerve conduction studies.[10]

Treatment and Disposition Treatment involves complete removal of the attached tick. Remove ticks by taking hold of the very head of the tick with tweezers and applying gentle steady traction.

Admit patients with respiratory distress to the intensive care unit, and admit all patients to the hospital to ensure symptoms do not progress. Local wound care and supportive care (including intubation and mechanical ventilation if necessary) result in excellent recovery within hours to days.[10]

INFLAMMATORY MYOPATHIES

Although not acute peripheral neurologic lesions, polymyositis and dermatomyositis present with similar symptoms to many peripheral neuropathies. These diseases are rare inflammatory myopathies causing symmetric weakness that progresses over weeks to months.

Clinical Features Patients develop weakness of the proximal limbs, trunk, and neck. Some experience dysphagia, myalgias, and rarely dyspnea when the respiratory muscles become involved. Sensation and reflexes are normal, and the ocular muscles are usually spared. Occasionally cardiac muscle may be involved with cardiomyopathy, heart failure, and conduction disturbances. The findings of dermatomyositis are similar with the addition of a diffuse violaceous rash often on the face and trunk.

Diagnosis Diagnosis is mainly clinical, but certain laboratory findings are characteristic such as elevated erythrocyte sedimentation rate, elevated creatinine kinase, and leukocytosis. The differential diagnosis includes Lambert-Eaton syndrome, endocrinopathies, toxic myopathies, and infectious myopathies.

Treatment and Disposition To prevent irreversible muscle damage, both polymyositis and dermatomyositis require treatment with systemic corticosteroids or other immunosuppressants.

Admit patients with rhabdomyolysis, respiratory distress, or profound weakness. Otherwise, patients may be discharged with neurology or rheumatology follow-up within 7 days.

SUBACUTE AND ACUTE ON CHRONIC PERIPHERAL NERVE LESIONS

Neuropathies can also be associated with an underlying medical disorder, such as HIV and diabetes.

HUMAN IMMUNODEFICIENCY VIRUS–ASSOCIATED PERIPHERAL NEUROLOGIC DISEASE

HIV infection, its complications, and its pharmacologic treatments are associated with a number of peripheral neurologic disorders. The most common of these, HIV neuropathy and antiretroviral drug–induced neuropathy, are chronic processes that do not cause sudden disability or symptoms. HIV-infected patients have a high rate of mononeuritis multiplex and an inflammatory myopathy resembling polymyositis. In late-stage acquired immunodeficiency syndrome, almost all patients manifest neuropathy. Patients in the early stages of HIV infection have greater susceptibility to Guillain-Barré syndrome. The presentation is similar to that of the non–HIV-infected patient. Treatment is the same as in non-HIV Guillain-Barré syndrome, with an emphasis on identifying patients who are likely to need intubation and mechanical ventilation early in the ED stay followed by close monitoring of respiratory function.

CYTOMEGALOVIRUS RADICULITIS

In the latter stages of acquired immunodeficiency syndrome, cytomegalovirus may acutely infect the lumbosacral nerve roots, causing a polyradiculopathy or cauda equina syndrome. Evidence of systemic cytomegalovirus infection, including retinitis, is almost always present. As opposed to the more common chronic neuropathy of HIV, patients with cytomegalovirus radiculitis become acutely weak, with primarily lower extremity involvement, and may have variable degrees of bowel and bladder dysfunction. The examination shows primarily lower extremity weakness and hyporeflexia, with decreased sensation in the lower extremities and groin. Rectal tone may be impaired. Lumbar puncture reveals a pleocytosis with predominantly polymorphonuclear cells and modestly increased protein. Viral DNA is detected by polymerase chain reaction in most patients and is highly specific. MRI of the lumbosacral spine demonstrates swelling and clumping of the cauda equina. Imaging is recommended to exclude mass lesions of the lower spine or nerve roots. Early identification is important, as antiviral treatment is effective. The treatment of cytomegalovirus radiculitis is IV ganciclovir, started at 5 milligrams/kg every 12 hours for 3 to 6 weeks. Treatment can be initiated before definitive diagnosis.

DIABETIC PERIPHERAL NEUROPATHY

Diabetes mellitus remains the most common cause of noncompressive focal neuropathy. A variety of mechanisms contribute to the pathophysiology of diabetic neuropathy. Chronic hyperglycemia and glycemic variability lead to oxidative stress and neuroinflammatory processes that result in a variety of neuropathic syndromes.

Diabetic peripheral neuropathy is the term used for any neuropathy in a type 1 or type 2 diabetic patient. The most common manifestation of diabetic peripheral neuropathy is a distal symmetric polyneuropathy, but it may also lead to focal neuropathies and mononeuropathy multiplex. Diabetic peripheral neuropathy is an example of a distal axonopathy resulting in length-dependent, centripetal "dying back" of the affected nerves. This phenomenon produces the typical stocking and glove distribution of diabetic neuropathy.

Hyperglycemic neuropathy is seen in newly diagnosed diabetics and normally improves with glycemic control. Insulin neuritis is a reversible condition characterized by acute limb pain and paresthesias associated with rapid glycemic control with insulin. Painful diabetic neuropathy is usually intermittent and worse at night. It can be experienced variably as pins and needles, throbbing, burning, achy, or cramping. Duration is less than 6 months. After 6 months, the same process is termed chronic painful diabetic neuropathy. Diabetic neuropathic cachexia is a rare syndrome causing weight loss and painful dysesthesias of the limbs and trunk.

Diabetic amyotrophy is a lumbosacral plexopathy seen in patients with a long-standing history of diabetes and presents with back pain followed by weakness. Patients report the acute onset of ipsilateral back pain, followed within days by progressive leg weakness. Sensory findings are absent. The examination reveals decreased leg power in a variety of patterns reflecting impairment of plexus function with relatively

TABLE 172-4 Medications Used in the Treatment of Painful Diabetic Neuropathy

Class	Starting Dose	Notes
Anticonvulsants	Pregabalin, 50 milligrams three times daily Gabapentin, 300 milligrams at bedtime	May cause somnolence, dizziness, weight gain Similar adverse effects to pregabalin
Antidepressants	Duloxetine, 30 milligrams daily Desipramine, 10–25 milligrams before bedtime	Consider with concomitant depression Tricyclic antidepressant with fewest side effects
Topical therapy	Capsaicin, 0.075% up to four times daily Lidocaine, 5% two to four patches daily	Apply using gloved hand Cut in half to save cost
Opioids	Oxycodone CR®, 10 milligrams twice daily Tramadol, 50 milligrams twice daily	May cause constipation, somnolence Avoid in patients with seizure or on selective serotonin reuptake inhibitor

symmetric sensation. There may be muscle wasting in affected limbs in long-standing disease. Deep tendon reflexes may be diminished on the affected side. Bowel and bladder functions are not affected.

There is a clear relationship between glycemic control and neuropathy. The Diabetes Control and Complications Trial demonstrated a 60% reduction in risk of developing neuropathy with tight glycemic control, which persisted for 8 years.[11] Emphasize strict foot care to the diabetic who has already developed neuropathy. Neuropathy-associated anesthesia may result in inadvertent trauma and subsequent development of ulcers, cellulitis, fasciitis, osteomyelitis, and eventual amputation. Symptomatic management is an ED patient's most immediate concern. Nonsteroidal anti-inflammatory drugs are ineffective in treating neuropathic pain and are relatively contraindicated in the diabetic patient due to their renal and cardiac effects. Narcotics carry addictive potential. Tricyclic antidepressants, anticonvulsants, and topical capsaicin all have proven beneficial (**Table 172-4**). Best evidence supports the use of duloxetine, venlafaxine, amitriptyline pregabalin, gabapentin valproate, tramadol, or oxycodone.[12]

CHAPTER 173

Chronic Neurologic Disorders

Daniel A. Handel
Sarah Andrus Gaines

AMYOTROPHIC LATERAL SCLEROSIS

Amyotrophic lateral sclerosis (ALS), often called *Lou Gehrig's disease*, causes rapidly progressive muscle atrophy and weakness resulting from the degeneration of both upper and lower motor neurons. ALS leads to varying degrees of spasticity, hyperreflexia, and muscle paralysis, eventually resulting in pulmonary complications and the need for mechanical ventilatory support. Because there is no cure, clinicians attempt to slow disease progression and preserve function as much as possible. Medical management is directed at preventing pulmonary infections and forestalling terminal respiratory failure.

PATHOPHYSIOLOGY

Since 2009, 13 genes and loci have been identified that are associated with the disease.[1] Inclusions in the TAR DNA-binding protein-43 have been found in both ALS and frontotemporal dementia.[2] Environmental exposures are suspected to increase the risk of ALS, but no specific ones have been identified to date.[3]

Gross CNS pathology includes frontal cortical atrophy, degeneration of both the corticospinal and spinocerebellar tracts, a reduction in large cervical and lumbar motor neurons, and cranial nerve nuclei degeneration. Both motor and sensory peripheral nerves undergo axonal degeneration and segmental demyelination, including motor end plate and axon terminal involvement.

CLINICAL FEATURES

Upper motor neuron demyelination and dysfunction cause limb spasticity, hyperreflexia (including Babinski sign and a brisk jaw-jerk reflex), and emotional lability. Limb weakness, a lower motor neuron dysfunction, is the first symptom in 65% of patients.[4] Other associated lower motor neuron dysfunctions include atrophy, cramps, fasciculations, dysarthria, dysphagia, and difficulty in mastication. At the time of initial presentation, asymmetric extremity cramping, fatigue, weakness, muscle fasciculations, and atrophy can be seen, especially in the upper extremities.[5] Facial weakness, dysarthria, tongue weakness, atrophy, and fasciculations can be seen with bulbar lower motor neuron dysfunction. Despite these profound motor findings, sensory and cognitive function is usually spared. Regardless of the initial symptoms, widespread motor and respiratory dysfunction progresses within weeks to months. Significant extremity atrophy occurs, as well as fasciculations, hyperreflexia, foot drop, and claw deformity of the hand. Patients also may develop monotonous speech caused by tongue atrophy, despite the relative sparing of facial and eye movements. Some patients eventually diagnosed as having ALS present initially with cervical or back pain consistent with an acute compressive radiculopathy. Despite successful operative intervention, significant muscle wasting consistent with motor neuron dysfunction develops shortly after the procedure.[6] **Progressive respiratory muscle weakness initially causes exertional dyspnea and eventual dyspnea at rest.** Overt dementia and parkinsonism may occur in up to 15% of patients, especially those with ALS. Other cognitive problems, such as apathy, poor attention and motivation, and altered social skills, may be noted.

DIAGNOSIS

The clinical diagnosis of ALS is suggested when there are signs of both upper and lower motor neuron dysfunction, including weakness, muscle atrophy, fasciculations, and hyporeflexia without other CNS dysfunction.[7] Given the complexity of diagnosing ALS, the median time to diagnosis is 14 months.[1] ALS-like symptoms can be seen with other systemic illnesses, such as diabetes, dysproteinemia, thyroid and parathyroid dysfunction, vitamin B_{12} deficiency, heavy metal toxicity, and vasculitis, as well as CNS and spinal cord tumors. The diagnosis requires the exclusion of other inflammatory neuropathies, such as myasthenia gravis. Refer patients with signs suggesting ALS to a neurologist for definitive diagnosis. The Amyotrophic Lateral Sclerosis Functional Rating Scale (revised) is reliable for diagnosis of ALS.[8] Electromyography, nerve conduction velocity studies, spinal fluid analysis, and neuromuscular biopsies are useful diagnostic studies. MRI excludes other disease processes but does not confirm the diagnosis of ALS.[9]

TREATMENT

Therapy is designed to enhance muscle function, especially those that support breathing, swallowing, and speech, in order to avoid malnutrition, recurrent aspiration, or choking. Riluzole, which modulates the excitotoxin glutamate, may prolong survival.[10-13] It is most useful in patients with a clear diagnosis of ALS whose symptoms have been

present for <5 years, with a forced vital capacity >60% of predicted, who do not have a tracheostomy. Guidelines on care and treatment of ALS patients are available.[12,13]

Optimizing pulmonary function, including the eventual use of long-term assisted ventilation, is an important part of enhancing the quality of life as diaphragm weakness progresses.[12] Many ALS patients will find some benefit from regular progressive resistance exercise, which may provide an anti-inflammatory effect, a neuroendocrine effect, or beneficial effects on CNS plasticity and myofiber remodeling.[14]

DISPOSITION

Typically, patients with ALS will not present to the ED undiagnosed unless there is extremely rapid disease progression or a long period without medical care. **Emergency management usually is required for acute respiratory failure, aspiration pneumonia, choking episodes, or trauma related to extremity weakness. Blood gas determination does not reliably predict impending respiratory failure**, because mild hypoxia and hypercarbia may exist throughout the disease course. **A forced vital capacity <25 mL/kg, or a 50% decrease from predicted normal, increases the risk of aspiration pneumonia and respiratory failure.** Provide treatment to improve pulmonary function (e.g., nebulized medications, steroids, antibiotics, assisted ventilation, and intubation). Because the need for long-term ventilatory assistance rarely reverses, establish or confirm the patient's preference regarding intubation through patient and family conversation, a living will, or power of attorney for health care. Hospital admission is indicated with impending respiratory failure, pneumonia, the inability to control secretions, or a worsening overall status that requires social service intervention for long-term placement.

MYASTHENIA GRAVIS

Myasthenia gravis is an autoimmune disease characterized by muscle weakness and fatigue, which is seen especially with repetitive use of voluntary muscles. Acetylcholine receptor antibodies impair receptor function at the neuromuscular junction, causing muscle weakness, most often in proximal muscles. This weakness is generally relieved by rest and requires long-term immunotherapy. The diagnosis of cholinergic and myasthenic crises and the aggressive management of respiratory complications associated with a myasthenic crisis are the most important issues for the ED management of myasthenia gravis patients. Occasionally a first diagnosis of myasthenia gravis can be suspected in the ED if increasing muscle weakness is noted during the ED stay or is reported by the patient to occur over the day.

PATHOPHYSIOLOGY

In the normal neuromuscular junction, acetylcholine release by the nerve fiber causes a localized end plate potential that leads to muscle fiber contraction. In myasthenia gravis, there is a marked decrease in the number and function of the muscle fiber acetylcholine receptors, despite normal nerve anatomy and function. Failure to respond to acetylcholine stimulation causes decreased muscle fiber potential amplitudes, leading to decreased muscle strength. Acetylcholine receptor autoantibodies are seen in approximately 80% of patients.[15] These antibodies react with the acetylcholine receptor. Disease severity can be correlated with acetylcholine receptor autoantibody levels. The autoantibodies cause accelerated acetylcholine receptor degradation, dysfunction, and blockade.

Either dysfunction of the **thymus gland** or an immune response to exogenous infectious antigens causes the pathologic autoimmune response. The thymus is abnormal in most patients with myasthenia gravis, most often as thymic hyperplasia or a thymoma. Thymectomy resolves or improves the symptoms in most patients, especially those with a thymoma. It is likely that the acetylcholine receptor autoantibodies arise after exposure to similar antigens, such as those caused by herpes simplex virus or bacterial infection, causing a pathologic attack on the acetylcholine receptor proteins.

CLINICAL FEATURES

The symptoms of myasthenia gravis can mimic the symptoms seen in many other chronic neurologic disorders, and some call it "the great imitator." **Most myasthenia gravis patients have general weakness, especially of the proximal extremity muscle groups, neck extensors, and facial or bulbar muscles.** Although ptosis and diplopia are the most common presenting symptoms, limb weakness and oropharyngeal symptoms, such as dysphagia, dysarthria, dysphonia, and dyspnea, can also be seen initially or occur over time. Ocular signs can include Cogan lid twitch (in which the eyes are lowered for 10 to 20 seconds, then droop or twitch when the patient attempts to raise them); ptosis; cranial nerve III, IV, or VI weakness; gaze palsies; internuclear or complete ophthalmoplegia; and end-gaze nystagmus.[16] Symptoms can fluctuate throughout the day, usually worsening as the day progresses or with prolonged muscle group use, such as with prolonged reading or prolonged chewing during a meal. Despite the presence of profound muscle weakness, there usually is no deficit in sensory, reflex, or cerebellar functioning. **Myasthenia gravis in elderly patients can be misdiagnosed as ischemic stroke, especially when new-onset facial weakness is seen.**[17]

Although weakness is typically focal and mild to moderate in severity, rarely, undiagnosed patients with myasthenia gravis may present with extreme weakness in the muscles of respiration, resulting in respiratory failure. **This life-threatening situation, termed *myasthenic crisis*, can be seen before diagnosis or as a result of inadequate drug therapy or drug tolerance.**

DIAGNOSIS

Consider the diagnosis of myasthenia gravis in any patient who complains specifically of ocular disturbances or proximal limb muscle weakness not associated with systemic causes of generalized fatigue. Involvement of the facial muscles or muscles of mastication and swallowing may suggest myasthenia gravis, as well as the observations that the symptoms fluctuate, often worsening as the day progresses, and are alleviated by rest.[18] The differential diagnosis includes congenital myasthenia gravis, Lambert-Eaton syndrome (seen with small-cell lung tumors), drug-induced myasthenia (e.g., penicillamine, procainamide, quinines, aminoglycosides), botulism, thyroid disorders, and other causes of ocular disorders, such as intracranial mass lesions.

The diagnosis is established through the administration of edrophonium chloride (an acetylcholinesterase inhibitor); electromyography, which demonstrates a postsynaptic neuromuscular junctional dysfunction with repetitive nerve stimulation; and serologic testing for acetylcholine receptor antibodies. **In the presence of abnormal neuromuscular transmission, edrophonium or neostigmine is expected to improve muscle strength in objectively weak limb, ocular, and pharyngeal muscles.** Because these drugs can actually cause profound weakness in the presence of other disorders that impair neuromuscular transmission, be prepared to provide ventilatory support or perform endotracheal intubation as a complication of pharmacologic testing. Electromyographic testing with repetitive nerve stimulation demonstrates a rapid reduction in the size of the muscle action potential, a finding that correlates with the clinical observation of enhanced weakness with prolonged or repetitive muscle use.

TREATMENT

Treatment includes administration of the acetylcholinesterase inhibitors pyridostigmine or neostigmine, thymectomy, chronic immune suppression with corticosteroids or azathioprine, and acute immune modulation using plasma exchange or IV immunoglobulin when indicated.[19-21] A favorable response to thymectomy can occur in patients with a thymoma, a limited response to acetylcholinesterase inhibitor therapy, and a short time interval between diagnosis and operative intervention.[22,23] Most patients show improvement with oral corticosteroids in the short term, although high-dose steroids sometimes result first in more weakness before improvement. Azathioprine or mycophenolate[24] can supplement chronic oral steroid therapy and lowers the steroid dose.[24,25] Severe symptoms, such as those that would require hospital admission, might require the use of IV immunoglobulin[26,27] or a combination of high-dose steroids and plasma exchange.

TABLE 173-1 Drugs to Avoid in Myasthenia Gravis

Steroids	Adrenocorticotropic hormone,* methylprednisolone,* prednisone*
Anticonvulsants	Phenytoin, ethosuximide, trimethadione, paraldehyde, magnesium sulfate, barbiturates, lithium
Antimalarials	Chloroquine,* quinine*
IV fluids	Sodium lactate solution
Antibiotics	Aminoglycosides, fluoroquinolones,* neomycin,* streptomycin,* kanamycin,* gentamicin, tobramycin, dihydrostreptomycin,* amikacin, polymyxin A, polymyxin B, sulfonamides, viomycin, colistimethate,* lincomycin, clindamycin, tetracycline, oxytetracycline, rolitetracycline, macrolides, metronidazole
Psychotropics	Chlorpromazine,* lithium carbonate,* amitriptyline, droperidol, haloperidol, imipramine
Antirheumatics	D-Penicillamine, colchicine, chloroquine
Cardiovascular	Quinidine,* procainamide,* β-blockers (propranolol, oxprenolol, practolol, pindolol, sotalol), lidocaine, trimethaphan; magnesium; calcium channel blockers (verapamil)
Local anesthetics	Lidocaine,* procaine,*
Analgesics	Narcotics (morphine, hydromorphone, codeine, Pantopon, meperidine)
Endocrine	Thyroid replacement*
Eye drops	Timolol,* echothiophate
Others	Amantadine, diphenhydramine, emetine, diuretics, muscle relaxants, central nervous system depressants, respiratory depressants, sedatives, procaine,* phenothiazines
Neuromuscular blocking agents	Tubocurarine, pancuronium, rocuronium, gallamine, dimethyl tubocurarine, succinylcholine, decamethonium

*Case reports implicate drugs in exacerbations of myasthenia gravis

TABLE 173-2 Edrophonium Testing in Myasthenia Gravis

	Myasthenic Crisis	Cholinergic Crisis
Pathology	Undermedication, decrease in acetylcholine receptor causes decreased stimulation by ACh	Overmedication, excess anticholinesterase drugs, overstimulation by ACh
Finding after edrophonium administration	Visible improvement in muscle contractibility, fusion of diplopia, or resolution of ptosis	Worsening of symptoms, muscle weakness, and possible respiratory paralysis
Implication of edrophonium test finding	Patient positive for myasthenia gravis, undermedication of anticholinesterase drugs	Overmedication has occurred, possibly due to insufficient effect from anticholinesterase drugs
Clinical treatment required based on test results	Increase in anticholinesterase drugs, such as pyridostigmine and neostigmine	Treat with atropine; if respiratory paralysis occurs, assist with ventilation

Abbreviation: ACh = acetylcholine.

Muscle weakness usually does not return to normal even with the use of immunomodulators. Variability in the amount of muscle weakness occurs in response to asthma exacerbations, infections, menstruation, pregnancy, emotional stress, hot weather, and other disorders that alter the response to medication, such as pulmonary, renal, and GI disease.

Many drugs used in the ED affect neuromuscular function—especially common antibiotics (**Table 173-1**). Make sure that myasthenia gravis patients being treated for other conditions receive their usual dose of cholinergic inhibitors, such as pyridostigmine, while waiting in the ED. The suggested pyridostigmine dose is 60 to 90 milligrams PO every 4 hours. **If a dose is missed, the next dose is usually doubled. If the patient cannot take oral medications or is intubated, administer one-thirtieth of the PO dose (2 to 3 milligrams) of pyridostigmine by slow IV infusion. The usual IV dose for neostigmine is 0.5 milligram.** Consult a neurologist to determine the optimal IV dose, rate of infusion, and timing of repeat pyridostigmine or neostigmine dosing.

The most significant ED complication of myasthenia gravis is respiratory failure, which is usually precipitated by infection, surgery, or the rapid tapering of immunosuppressive drugs. Although intubation should be considered in patients with a low forced vital capacity or in the presence of abnormal blood gas analysis, this decision is made primarily on clinical grounds. Because of the increased sensitivity of myasthenia gravis patients to neuromuscular junction inhibitors and an unpredictable reaction to succinylcholine in particular,[28] **avoid the administration of depolarizing or nondepolarizing paralytic agents** in preparation for intubation. Patients with myasthenia are extremely sensitive to these agents, and the paralytic effects can be expected to persist at least two to three times longer than in normal patients. Consider using short-acting agents such as etomidate, fentanyl, or propofol in smaller doses.[29] Intubation using deep inhalational anesthetics, including halothane, isoflurane, or sevoflurane, is also a possible strategy. If paralytic agents are absolutely necessary, consider using one-half the dose of these agents, although there are no clinical studies supporting this recommendation.

Up to 15% to 20% of myasthenia gravis patients will undergo a myasthenic crisis requiring acute emergency intervention.[30] Myasthenic crisis, which occurs either because of disease exacerbation or inadequate drug therapy, must be distinguished from cholinergic crisis, which is caused by excessive cholinergic effects of the drugs used to treat the disease. This differentiation can be made in the ED by the use of edrophonium chloride testing (**Table 173-2 and Figure 173-1**).

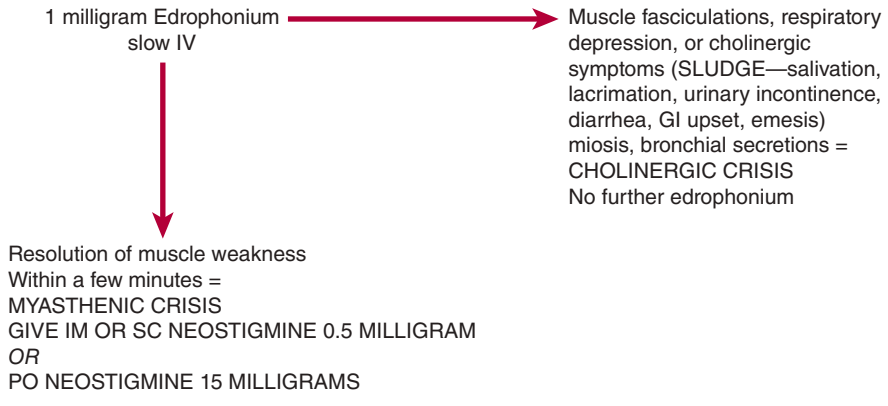

FIGURE 173-1. Edrophonium test for myasthenic versus cholinergic crisis.

Edrophonium is used for this purpose because of its rapid onset (30 seconds) and the short duration of effects (5 to 10 minutes). **A positive result, one that suggests that the symptoms are caused by a myasthenia exacerbation, is characterized by the resolution of muscle weakness within a few minutes.** To ensure that the patient does not react adversely to the edrophonium test (as a result of excessive baseline cholinergic effects), administer only 1 milligram by slow IV push initially. The development of muscle fasciculations, respiratory depression, or cholinergic symptoms within a few minutes of this test dose of edrophonium suggests that the baseline muscle weakness is related to a cholinergic crisis, rather than a myasthenic crisis, and further edrophonium administration is contraindicated. If there is no evidence of adverse cholinergic effects, up to 10 milligrams of edrophonium can then be given in order to demonstrate benefit in the face of a presumed myasthenic crisis. In other words, if the symptoms improve with the 1-milligram edrophonium test dose, then the testing is considered positive for myasthenic crisis, and additional anticholinergic therapy can be provided to reverse the effects of myasthenia gravis itself. Neostigmine can then be given IM or SC in 0.5- to 2.0-milligram doses, with clinical effectiveness by 30 minutes and lasting for up to 4 hours. Alternatively, 15-milligram neostigmine tablets can be given PO, each having a clinical effect comparable with that of a 0.5-milligram parenteral neostigmine injection.

In children, the total edrophonium IV dose is 0.15 milligram/kg, not to exceed 10 milligrams. To test adverse cholinergic effects with a test dose in children, give an initial IV edrophonium dose one tenth that of the total dose. For children weighing <75 lb (34 kg), a test dose of 1 milligram is appropriate, and a total dose of 5 milligrams can be used in 1-milligram increments. In infants, or when IV access is not available in children <75 lb (34 kg), the IM edrophonium test dose is 0.5 to 2.0 milligrams.

If giving edrophonium to patients with cardiac disease, place the patient on a cardiac monitor and pulse oximetry, have the crash cart with atropine available, and have intubation equipment prepared. Edrophonium may cause bradycardia, atrioventricular block, atrial fibrillation, and cardiac arrest. Although atropine will counteract the muscarinic effects (miosis, lacrimation, salivation, bradycardia) of edrophonium, it will not reverse the nicotinic effects (skeletal muscle paralysis) of a cholinergic crisis. Acute respiratory failure can result from either acute myasthenic crisis or acute cholinergic crisis. Patients with cholinergic crisis who worsen with edrophonium test dose administration may require immediate intubation and management of excessive secretions and acute bronchospasm.

DISPOSITION

When determining final disposition, consider other complications of muscle weakness in patients with myasthenia gravis, such as impaired swallowing, aspiration pneumonia, dehydration, and decubitus ulcers.

PRACTICE GUIDELINES

The American Academy of Neurology provides a guideline on medical treatment of the ocular symptoms involved in myasthenia gravis, as well as a summary of thymectomy indications.[31] Additionally, the European Federation of Neurological Societies has formulated a versatile therapeutic plan for treatment.[32] Cyclosporin and cyclophosphamide significantly improve myasthenia gravis, whereas azathioprine, mycophenolate, and tacrolimus have not been found to provide significant benefit.[33] Corticosteroids are stated to be useful short-term.[34]

MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is a neurologic disorder that causes variable motor, sensory, visual, and cerebellar dysfunction as a result of multifocal areas of CNS myelin destruction. Paresthesias, gait difficulty, extremity weakness, poor coordination, and vision disturbances occur most often with a relapsing and remitting clinical course. Despite the lack of a definitive cure, immunosuppression and immunomodulation provide adequate symptomatic relief in the majority of patients, such that most have only mild to moderate lifetime morbidity and a reduction in overall life expectancy of only 5 to 10 years.[35]

Three clinical courses are noted in patients with MS. Up to 90% have a relapsing and remitting course, with relapses lasting weeks to months. The remaining patients have either a relapsing and progressive course or a chronically progressive clinical course, the latter of which is more common with advanced age.

PATHOPHYSIOLOGY

The cause of MS is unknown. It is best described as an inflammatory disorder resulting in scattered neuron demyelination. The most frequently postulated theory is a genetic predisposition triggered by a virus (such as herpes or human T-cell leukemia virus type I), heavy metals, or other environmental toxins that induce an immune-mediated neuronal inflammation and demyelinization.[36] There is no risk of MS from vaccinations.[37] MS causes a dysfunction in oligodendrocytes such that the axonal myelin sheaths are damaged, slowing nerve impulse conduction. Scattered cerebral and spinal plaques cause gliosis primarily in the white matter, with relative axon sparing.

Plaques occur in multiple areas, including the cerebrum, brainstem, spinal cord, and cranial nerves. Lesions in the corticospinal tracts, posterior columns, and spinothalamic tracts will cause upper motor neuron, proprioception/vibration, and pain/temperature dysfunction, respectively. Cranial nerve lesions result in optic neuritis, as well as facial motor and sensory deficits.

CLINICAL FEATURES

MS is suggested when a young person presents multiple times with neurologic symptoms that suggest different areas of pathology, often with resolution of the earlier symptoms. For most patients, lower extremity symptoms are more severe than upper extremity symptoms. For example, a young person might complain of an inability to walk on a street without tripping over a curb or a sense of clumsiness with physical activity. **The physical examination may reveal decreased strength, increased tone, hyperreflexia, clonus, a positive Babinski reflex, a decrease in both vibration sense and joint proprioception, and a reduction in pain and temperature sensation.** Although sensory and motor deficits are present initially in only one third of patients, all patients will experience these findings at some point during the disease course. Patients describe these deficits as a heaviness, weakness, stiffness, or extremity numbness. **Lhermitte sign** is commonly experienced during the course of MS and is described as an electric shock sensation, a vibration, or a pain radiating down the back and often into the arms or legs resulting from the flexion of the neck. Rarely, patients with established MS may present with acute transverse myelitis, with complete or near-complete loss of motor function. Cerebellar lesions may cause a kinetic tremor, dysmetria, or truncal ataxia. Vertigo may develop as a result of brainstem lesions.

Optic neuritis, which usually causes acute or subacute central vision loss, may be the initial sign of MS in up to 30% of patients. Vision loss, which occurs over several days and is usually unilateral, often is preceded by retrobulbar pain or extraocular muscle pain that may be reproduced with periorbital palpation. Optic neuritis may cause an afferent pupillary defect, or **Marcus Gunn pupil**. This is found when a light directed into the affected eye causes pupil dilation instead of constriction (see chapter 241, "Eye Emergencies"). The optic disc may be pale. Although ocular pain most often resolves over several days, it may take months for the vision disturbances to resolve. Most patients at some time experience blurred vision, compromised color vision, and/or eye pain due to optic neuritis. Nystagmus, diplopia, and internuclear ophthalmoplegia are often seen. Internuclear ophthalmoplegia usually causes abnormal eye adduction bilaterally and horizontal nystagmus. When bilateral internuclear ophthalmoplegia is seen acutely in an otherwise healthy young person, it is highly suggestive of MS.

Dysautonomias can cause vesicourethral dysfunction, resulting in urinary retention, urgency, frequency, detrusor–external sphincter

dyssynergia, and stress or overflow incontinence. GI dysfunction can cause constipation and fecal incontinence. Sexual dysfunction, especially in males, may be a presenting symptom and correlates with other types of urologic dysfunction. Cognitive and emotional changes, including dementia, decreased motivation, depression, and bipolar mood disorders, occur in many patients. Cerebral MS, which affects only 5% of MS patients, can cause a severe, disabling decrease in intellect as well as seizures. Overall, the incidence of generalized seizures is the same in patients with MS as in the general population. Simple partial seizures are twice as common in patients with MS than in the general population. Treatment can cause seizures, and the treatment of seizures can worsen symptoms of MS.[38]

MS symptoms often worsen with increases in body temperature, as occurs with exercise, fever, or even hot baths. Visual acuity may worsen with increases in body temperature. Most initial attacks or exacerbations of MS will progress over several days, peak at about 1 week, and resolve over several weeks to months. Complete recovery from an acute exacerbation occurs more commonly early in the course of the disease than it does in later years.

DIAGNOSIS

The diagnosis of MS is suggested when a patient has either two or more prolonged or worsening episodes of neurologic dysfunction that suggest distinct white matter pathology or spinal cord dysfunction in two or more distinct locations.[39] Optic, cerebrospinal fluid, and neuroimaging findings, as well as typical features such as dysautonomias, all suggest the diagnosis. Symptoms that mimic MS are seen with systemic lupus erythematosus, Lyme disease, neurosyphilis, human immunodeficiency virus disease, and Guillain-Barré syndrome, which is associated with peripheral nervous system demyelination. MS progression is often monitored with the Expanded Disability Status Scale and the Multiple Sclerosis Functional Composite scores.[40]

Nearly all patients will demonstrate some nervous system pathology on MRI neuroimaging. T2-weighted scans demonstrate multiple discrete lesions in the supratentorial white matter, homogeneous borders surrounding the ventricles, or infratentorial or spinal cord lesions.[41] Although CT is not as sensitive as MRI, it may show cerebral atrophy, ventricular enlargement, and low-density focal lesions in the cerebrum, brainstem, or optic nerves. Cerebrospinal fluid protein and gammaglobulin concentrations can be elevated. A slight increase in cerebrospinal fluid WBCs (up to 25/mm^3) can also be seen, most of which are T lymphocytes.

TREATMENT

Consult a neurologist for diagnosis or treatment. Treatment modalities include mitoxantrone, glucocorticoids, natalizumab, interferon-β, and glatiramer.[42] Mitoxantrone has been associated with bone marrow and cardiac toxicity.[43] High-dose methylprednisolone therapy shortens the duration of exacerbations.[44,45] There is a 1:1000 incidence of progressive multifocal leukoencephalopathy with natalizumab treatment.[46] IV immunoglobulin is suggested for postpartum exacerbations and for patients with relapsing-remitting disease in whom other therapies such as interferon-β and glatiramer are not tolerated.[47]

DISPOSITION

Prioritize management at identifying the complications of acute exacerbations, such as respiratory distress, optic neuritis, pulmonary infections, severe constipation, and worsening muscle weakness. Use rapid sequence induction and the Sellick maneuver for endotracheal intubation because of an increased aspiration risk as a consequence of decreased gastric motility. Also, because many patients with MS have labile autonomic nervous system function, be prepared to treat hypotension in the setting of rapid sequence induction, emergency intubation, mechanical ventilation, and surgical anesthesia. Treat seizures with standard anticonvulsant medications and management protocols. Reduce fever to minimize the weakness associated with elevated temperature. **Test for urinary tract infections and pyelonephritis, especially in patients with residual urine volumes >100 mL.** Obtain a postvoid residual urine volume and a urine culture, and initiate antibiotic therapy whenever there is clinical evidence of a urinary tract infection or significant bacteriuria. When feasible, discharged patients should manage elevated residual urine volumes with intermittent sterile catheterization as opposed to chronic placement of a urinary drainage catheter. **Hospitalize for a disease exacerbation or for IV antibiotic or steroid therapy.** Admission is also indicated when depression or suicidal ideation require inpatient management.

PRACTICE GUIDELINES

The American Academy of Neurology has published guidelines describing the use of MRI in MS diagnosis, treatment with natalizumab and mitoxantrone, and the utility of the measurement of interferon-β antibody levels. These guidelines conclude the following: The use of natalizumab reduces clinical features such as relapse rate and disease severity but is associated with adverse effects.[48] Mitoxantrone has modest beneficial clinical effects that must be balanced against adverse effects.[49] The presence of MRI-identifiable lesions at the time of symptom onset is associated with later definitive MS diagnosis.[50] The European Federation of Neurological Societies also provides similar guidelines that address neuroimaging, MS treatment options, and the use of interferon-β antibody levels.[51-54] The Cochrane Collaboration has published reviews outlining the use of amantadine, azathioprine, corticosteroids, cyclophosphamide, mitoxantrone, and dietary interventions, as well as the treatment of ataxia. These reviews conclude the following:

1. The use of amantadine to reduce fatigue in MS patients is not substantiated.[55]
2. Azathioprine is a useful alternative to interferon-β in patients who frequently relapse and require steroid therapy.[56]
3. There is no clear benefit to the use of oral or IV steroids in the treatment of optic neuritis in MS patients, although quicker recovery of vision may occur with IV therapy.[57]
4. Cyclophosphamide does not prevent the progression of MS symptoms, and its use is associated with significant adverse effects.[58]
5. Mitoxantrone modestly reduces MS patient disease progression and relapse frequency and should be considered for patients with worsening disability caused by MS.[59]
6. Dietary regimens and vitamin supplementation have yet to demonstrate clinical benefit for MS patients.[60]
7. There are insufficient data to support any specific therapies for the treatment of ataxia and/or tremors that occur in MS patients.[61]

LAMBERT-EATON MYASTHENIC SYNDROME

Lambert-Eaton myasthenic syndrome is an autoimmune disorder that causes fluctuating weakness and fatigue, especially of the proximal limb muscles. Patients with Lambert-Eaton myasthenic syndrome may show some improvement in strength with sustained or repeated exercise. For example, when the patient is asked to grasp the examiner's hand, the squeeze becomes more forceful over several seconds—this is termed the **Lambert sign**. Lambert-Eaton myasthenic syndrome is sometimes associated with an antibody attack of P/Q-type voltage-gated calcium channels of axon nerve terminals.[62,63] These channels are integral to the release of acetylcholine during the action potential, and thus any calcium ion flow impairment results in muscle weakness. Lambert-Eaton myasthenic syndrome diagnosed in the absence of these anti-P/Q–type voltage-gated calcium channel antibodies is termed *seronegative*. It is hypothesized that seronegative Lambert-Eaton myasthenic syndrome is also incited by autoantibodies.[64] Patients often complain of myalgias, muscle stiffness (especially in the hip and shoulders), paresthesias, metallic tastes, and autonomic symptoms (e.g., dry mouth and impotence) caused by muscarinic cholinergic insufficiency. Although eye movements are unaffected, pupillary reflexes can be abnormal. Motor reflexes may be diminished. The sensory examination can be normal, but because the disease is associated with malignancy,

paraneoplastic or chemotherapy-induced neuropathy can lead to a superimposed sensory deficit.

Lambert-Eaton myasthenic syndrome is predominantly a disease associated with older men with a history of cigarette smoking and lung cancer. The syndrome can precede detection of malignancy by several years. Approximately half of patients have concurrent small-cell lung cancer. Diagnosis is confirmed by electromyography. Small-cell lung cancer in Lambert-Eaton myasthenic syndrome patients correlates strongly with more rapid disease progression.[65] Electromyography is abnormal as a result of diseased calcium channels at the cholinergic nerve terminals. Reduced compound muscle action potentials that increase by >100% following maximal voluntary action on electrophysiologic testing helps to confirm the diagnosis.[66]

TREATMENT

Treatment is mostly supportive. Progression to respiratory or bulbar failure is rare. Neuromuscular transmission can also be enhanced with 3,4-diaminopyridine, which is considered first-line treatment.[67,68] Immunosuppression with corticosteroids, IV immunoglobulin, guanidine, aminopyridines, and azathioprine also can be used to reduce symptom severity.[69,70] Hospital admission is indicated when infectious complications occur or when severe disability requires inpatient immunotherapy.

PRACTICE GUIDELINES

Guidelines suggest that treatment with either 3,4-diaminopyridine or IV immunoglobulin could provide some benefit by improving muscle strength and compound muscle action potential amplitudes.[71-73]

PARKINSON'S DISEASE

Parkinson's disease is an extrapyramidal movement disorder characterized by a resting tremor, cogwheel rigidity, bradykinesias or akinesias, and impaired postural reflexes. The disease is associated with a reduced number of functional dopaminergic receptors in the substantia nigra. Drug therapy is designed to enhance central dopaminergic activity, thus decreasing the relative excess in central cholinergic activity. Even though multiple drug and surgical therapies can be used to minimize symptoms, the disease still progresses without symptom remission in most patients.

PATHOPHYSIOLOGY

Parkinson's disease is characterized by the presence of cellular cytoplasmic inclusions, termed *Lewy bodies,* and extracellular pigment granules that stimulate macrophage activity. In the pigmented areas of the midbrain, especially the substantia nigra, there is depigmentation, dopaminergic neuron loss, and gliosis. These cellular changes result in the loss of functional dopaminergic receptors, causing a decrease in the overall level of striatal dopamine.

CLINICAL FEATURES

The clinical diagnosis of Parkinson's disease is based on the presence of one or more of four hallmark neurologic signs identified in the mnemonic ***TRAP:*** **resting *tremor*, cogwheel *rigidity*, bradykinesia or *akinesia*, and impairment in *posture* and equilibrium**. Besides these signs, there also may be facial and postural changes, voice and speech abnormalities, depression, and muscle fatigue. Before diagnosis, most patients will have symptoms for months to years, including a general feeling of slowness or stiffness and/or difficulties with handwriting and other skills that require manual dexterity. The first stage of the disease is the premotor phase that includes reduced olfaction and constipation. This is followed by the motor phase, which responds to L-dopa in the honeymoon phase of the disease. When patients start to see motor complications, they experience fluctuations and dyskinesia. In late-stage disease, patients experience motor disabilities, freezing of their gait, falls, incontinence, orthostatic hypotension, and dementia.[74]

Patients typically will complain initially of a unilateral resting tremor of the upper extremity. The tremor is a repetitive low-amplitude movement usually involving the fingers and thumb, but also of the legs or face, that occurs five or more times per minute, described as **"pill rolling."** Tremors can dissipate when intentional movement is performed, which differentiates it from the kinetic tremor of other neurologic disorders. For example, on physical examination, the resting tremor of Parkinson's disease will become less prominent as the patient performs the finger-to-nose test, and tremor resumes once this purposeful movement is ended and the limb is supported and at rest. Cogwheel rigidity is elicited by causing passive movement of the limb through a full range of motion. As the limb is moved, its muscles develop an increased tone, and a ratchet-like movement is noted. Bradykinesia, the general sense of slowness of voluntary movement, is often felt to be the most debilitating symptom. The most severely affected patients can develop akinesia, the inability to perform the movements necessary for daily living, such as turning over in bed, rising from a seated position, or walking. When the disorder impairs postural reflexes, patients may have an impaired ability to turn or change direction while walking or may lose their balance and fall. Patients are also commonly affected by impulse control disorders.[75]

DIAGNOSIS

The clinical diagnosis of Parkinson's disease is straightforward, if all of the TRAP symptoms are present. The symptoms of Parkinson's disease also can be seen in postencephalitis patients and those with other infections such as neurosyphilis, subacute spongiform encephalopathy, and acquired immunodeficiency syndrome. Parkinsonism can occur as a result of street drugs, toxins, neuroleptic drugs, hydrocephalus, head trauma, and more rare and complex neurologic disorders.

In **drug-induced Parkinson's disease**, akinesia is the most common sign, with resting tremor less commonly observed. Other characteristics of drug-induced parkinsonism include a history of drug ingestion known to interfere with central dopamine activity, short interval between symptom onset and maximal disability, bilateral presentation of motor dysfunction, and the presence of other drug-related motor abnormalities.

There is no definitive laboratory or neuroimaging study that is pathognomonic for diagnosis. CT and MRI most often only show CNS atrophy.

TREATMENT

Currently available therapies do not change the underlying pathology but can reduce symptoms. Therapies include anticholinergics, such as trihexyphenidyl and benztropine; drugs that increase central dopamine levels, such as amantadine, levodopa, and carbidopa; and dopamine receptor agonists, such as bromocriptine and pergolide. Ergot agonists are no longer recommended, as newer agents have replaced them.[76] When symptoms cause severe motor dysfunction, the monoamine oxidase inhibitor selegiline and the catechol methyltransferase inhibitors entacapone and tolcapone may be effective.

Levodopa, which is converted into dopamine by decarboxylases that are present peripherally, can cause symptoms such as anorexia, nausea, and vomiting due to increases in peripheral dopamine levels. When levodopa is combined with carbidopa, a peripheral decarboxylase inhibitor, smaller doses of levodopa are required for effectiveness, reducing side effects. Over time, the effectiveness of levodopa will diminish, requiring the additional use of dopamine receptor agonist therapy. Individuals who are fully mobile, in the "on" state, can suddenly convert to the "off" state and become akinetic, especially in the morning shortly after rising and before taking the initial daily dose. This "on-off" phenomenon is treated by the use of controlled-release preparations of the combined carbidopa-levodopa therapy. Human aromatic L-amino acid decarboxylase allows for more effective levodopa conversion to dopamine without the adverse effects of high doses of levodopa.[77] Other dopamine agonists that have been found to be effective as monotherapy included piribedil, pramipexole, ropinirole, rotigotine, and cabergoline.[78]

When drug effectiveness diminishes over time or when significant motor or psychiatric complications occur, a "drug holiday" lasting approximately 1 week is often attempted. Despite the fact that withdrawal

of dopaminergic therapy can worsen symptoms, functioning actually can improve once therapy is resumed, with improvement lasting weeks to months. Deep brain stimulation can treat advanced disease with motor disabilities and can improve quality of life.[79]

The treatment for drug-induced parkinsonism is termination of the causative agents. Patients who are refractory to optimal drug therapy for all types of Parkinson's disease may benefit from pallidotomy, a stereotactic neurosurgical procedure that enhances medical therapy effectiveness and reduces dyskinesia severity.[80,81] Thalamic stimulation or thalamotomy is useful for patients with severe tremor.

SPECIAL CONSIDERATIONS

Although most patients with Parkinson's disease present to the ED already diagnosed, some might present undiagnosed with motor or sensory symptoms that may not be attributed immediately to the disorder. Patients may experience motor symptoms such as freezing episodes, dysphagia, or abnormalities of whole-body movement. Sensory complaints may include akathisias, paresthesias, muscles aches, or extremity pain. Although severe pain is usually related to the loss of medication efficacy, it can be a prominent symptom of undiagnosed Parkinson's disease. Complications related to motor, gait, and truncal disabilities include deep venous thrombosis, pulmonary embolism, aspiration pneumonia, compressive neuropathies, and trauma from frequent falls. Autonomic disturbances, such as orthostatic hypotension, intestinal motility disorders, and bladder dysfunction, can occur, as well as facial seborrhea. Behavior abnormalities caused by frontal lobe dysfunction and dementia also are seen.

Dyspnea, respiratory distress, and pneumonia are more likely during the "off" periods, when drug efficacy is reduced. The most common cause of death in severe Parkinson's disease is respiratory failure.

Dopaminergic therapy toxicities can include cardiac dysrhythmias, orthostatic hypotension, dyskinesias, and dystonias. Psychiatric and sleep disturbances, including nightmares, auditory and visual hallucinations, paranoia, and psychosis, are related to the treatment dose and duration and can be improved by a reduction in dosage or a drug holiday. Depression and panic attacks are common and can occur in patients independent of dopaminergic therapy. Psychotropics (such as haloperidol) that can cause tardive dyskinesia must be used carefully, if at all, in patients with Parkinson's disease.

Adjustment of chronic therapies should be done in consultation with the patient's primary care physician or neurologist, who can often help to determine which symptoms reflect dopaminergic excess and whether prior drug holidays have improved the patient's symptoms.

POLIOMYELITIS AND POSTPOLIO SYNDROME

Poliomyelitis is a neurotropic enterovirus that causes paralysis through motor neuron destruction, muscle denervation, and atrophy. Indigenously acquired wild poliovirus was eradicated from the United States in 1979 and from the Western Hemisphere in 1991. However, the disease is still endemic in India, Pakistan, Afghanistan, and Nigeria.[82] Postpolio syndrome, also called *postpoliomyelitis progressive muscular atrophy*, is an important sequela of acute poliomyelitis. This disorder is characterized by the recurrence of motor symptoms, following a latent period of several decades, after the resolution of the motor symptoms caused by the initial infection.

Mass immunization with the inactivated poliovirus vaccine or attenuated oral poliovirus vaccine has dramatically reduced the incidence of polio, but polio outbreaks still occur in populations that are not consistently or adequately immunized. Immunocompromised patients are at greater risk for contracting polio after exposure to children who were vaccinated with the attenuated oral poliovirus vaccine. With the use of attenuated oral poliovirus vaccine, some immunized children will develop polio, as will some young adults who are exposed to children who have been vaccinated with the attenuated oral poliovirus vaccine; immunocompromised patients are at greater risk for this. In developing countries, recent intramuscular injections, tonsillectomy, and strenuous exercise all are associated with increased polio infection severity.

Postpolio syndrome is expected to affect up to 100,000 of the 250,000 U.S. adults with a history of polio. Because most cases of polio occurred before mass immunization, patients diagnosed now with postpolio syndrome most likely will be >50 years old. Disease onset is 20 to 35 years after the initial infection. Although postpolio syndrome most often occurs after a stable, disease-free period of 20 to 30 years, current retrospective reviews claim 35 years.[83] There are risk factors that predict an earlier onset of postpolio syndrome. These include advanced age at the time of initial polio infection, greater residual motor disability, residual bulbar or respiratory signs, and the occurrence of recent injuries that require limb immobilization. Postpolio syndrome is a diagnosis of exclusion.[84]

PATHOPHYSIOLOGY

In developed countries, the viral transmission of polio is oral to oral, whereas in developing countries, where the sanitation is poor, the transmission is fecal to oral. Acutely, the polio enterovirus enters the body through the GI tract and reproduces in the GI lymphoid tissue, termed *gut-associated lymphoid tissue*. Oral secretion of the virus takes place for several days, whereas stool excretion can last for several weeks.

At a critical concentration, the virus spreads to the large motor nuclei of the spinal cord, the brainstem, and the reticular formation. The vestibular and brainstem motor nuclei, hypothalamus, thalamus, cerebellum, and precentral motor cerebral cortex also can be infected by the poliovirus. There is loss of infected neurons. Neuron loss then causes a cycle of muscle denervation and reinnervation, resulting in loss of muscle function.

The cause of the postpolio syndrome is unknown. The motor neuron degeneration is thought to be a result of dysfunction in the individual nerve axons in surviving motor neurons.

CLINICAL FEATURES

Acute Poliomyelitis Polio infection is asymptomatic in >90% of cases. The majority of **symptomatic polio infections** involve only a minor viral illness that causes no paralysis, termed *abortive polio.* After an incubation period of a few days, symptoms may include fever, malaise, headache, sore throat, and GI symptoms. Some of the patients who experience the minor viral illness, especially young children, may develop aseptic meningitis as the infection resolves. Only 1% to 2% of all poliovirus infections result in the major illness associated with neurologic involvement. Often there is resolution of the minor viral illness symptoms before development of neurologic symptoms, so that it is difficult to identify the preceding minor viral illness. Muscle pain, stiffness, and weakness during the early viral syndrome may be premonitory of later paralysis.

When the major illness occurs, most commonly the spinal cord anterior horn cells are affected, causing asymmetric proximal limb weakness, especially in the lower extremities. **Flaccid and weak muscles, absent tendon reflexes, and fasciculations characterize spinal polio.** Although polio patients note pain, paresthesias, and transient sensory abnormalities, sensory deficits are usually not found on clinical examination. Maximal paralysis usually occurs within 5 days, and muscle wasting then occurs over several weeks. Autonomic dysfunction, including sweating disturbances, urine retention, delayed gastric emptying, and constipation, is commonly found. Most spinal polio patients will demonstrate improved motor function, with resolution of the paralysis occurring within the first year after the acute infection.

Up to 20% of polio patients with paralysis will develop bulbar polio, which can cause speech, swallowing, facial muscle, and extraocular muscle dysfunction. Acute polio infection also can cause encephalitis and can disturb the reticular formation, resulting in cardiac dysrhythmias, blood pressure alterations, hypoxia, and hypercarbia. Patients who survive the acute episode of encephalitis normally recover without residual effects.

Consider **acute paralytic poliomyelitis** whenever an at-risk patient develops an acute febrile illness, aseptic meningitis, and asymmetric flaccid paralysis associated with the loss of deep tendon reflexes and normal sensation. As with other causes of aseptic meningitis, the cerebrospinal fluid reveals pleocytosis during the first

week after paralysis onset. The cerebrospinal fluid white cell count can elevate into the hundreds, with a predominance of neutrophils early in the disease course. Although the poliovirus can be cultured from the cerebrospinal fluid early in the disease course, throat and rectal swabs provide a greater yield. When a particular viral serotype is identified, serial serum antibody titers can be used to verify the cultures.

The most important cause of paralysis on the differential diagnosis that must be considered and excluded is Guillain-Barré syndrome, which, unlike the acute polio infection, causes more symmetric muscle weakness. Acute paralysis can result from peripheral neuropathies caused by infectious mononucleosis, Lyme disease, or porphyria. Paralysis also can result from inflammatory myopathies, electrolyte abnormalities, toxins, or other viruses, such as coxsackieviruses, mumps, echoviruses, and nonpolio enteroviruses. Paralysis also can result from acute spinal cord compression, vascular lesions, and transverse myelitis, all of which should produce a sensory level and sphincter disturbances. In children, it is necessary to exclude spinal muscular atrophy, which can be undiagnosed until it is manifested by dramatic limb weakness caused by an acute febrile illness.

Postpolio Syndrome Patients with **postpolio syndrome** complain of muscle fatigue, joint pain, worsening of skeletal deformities, or weakness in muscles that were spared during the initial viral infection.[85] When muscle weakness is observed, atrophy, pain, and fasciculations may be noted both in previously unaffected muscle groups and in those previously involved. Patients may also develop new bulbar, respiratory, or sleep difficulties. For example, laryngeal muscle weakness can cause progressive dyspnea, dysphagia, and/or hoarseness. Some patients complain of abnormal movements in sleep that disturb normal sleep, requiring therapy with benzodiazepines or dopaminergic drugs.[86] These symptoms occur independently of any concurrent neurologic, orthopedic, psychiatric, or systemic medical illness.

To diagnose postpolio syndrome, the patient should have a history of acute paralytic poliomyelitis with stable recovery of motor function associated with residual muscle atrophy, weakness, and areflexia with normal sensation in at least one limb. Additionally, there should be new muscle symptoms or weakness not attributable to an acute injury, neuropathy, radiculopathy, or systemic, neurologic, or psychiatric illness.

Treatment of the new muscle weakness seen with postpolio patients is primarily symptomatic, with the use of analgesic and anti-inflammatory medications. Most patients with postpolio syndrome benefit from muscle training[87] and daily exercise.[88] An additional therapeutic option is lamotrigine (Lamictal). When used in conjunction with an exercise routine, lamotrigine may improve the quality of life in postpolio patients.[89]

CHAPTER 174

Central Nervous System and Spinal Infections

Mary E. Tanski
O. John Ma

BACTERIAL MENINGITIS

INTRODUCTION AND EPIDEMIOLOGY

Bacterial meningitis is a life-threatening emergency that affects 1.38 out of 100,000 people, with a case fatality rate of 14.3%.[1] Although the incidence of bacterial meningitis has declined significantly since the initiation of vaccination programs, the disease is still prevalent and associated with significant morbidity and mortality.[2-4] In the United States, the most common causes of bacterial meningitis are *Streptococcus pneumoniae* (58.0%), group B *Streptococcus* (18.1%), *Neisseria meningitidis* (13.9%), *Haemophilus influenzae* (6.7%), and *Listeria monocytogenes* (3.4%).[1] *Escherichia coli* in the neonatal population and *Mycobacterium tuberculosis* in immunocompromised hosts are also important considerations.[5]

PATHOPHYSIOLOGY

Organisms enter the cerebrospinal fluid either through hematogenous or direct contiguous spread. In hematogenous spread, bacteria colonize the upper airway and invade the bloodstream, gradually making their way to the subarachnoid space. The subcapsular components of *S. pneumoniae*, *H. influenzae* type b, and *N. meningitides* induce an inflammatory cascade, and leukocyte toxins cause cellular swelling and inflammation of the brain and meninges.[6] Blood–brain barrier permeability increases, allowing protein and water to enter and leading to vasogenic edema. Cerebrospinal fluid drainage is inhibited by reduced absorption of the arachnoid granules with resultant obstruction and hydrocephalus, and cerebrospinal fluid is forced into the periventricular parenchyma causing interstitial edema. Disruption of cell membrane homeostasis causes cytotoxic edema. As the brain and meninges rest in a fixed-volume skull, this leads to an elevation in intracranial pressure. Vasculitis decreases cerebral blood flow and can cause ischemia and thrombosis. Additionally, neurons are directly injured by free radicals from granulocytes and endothelial cells.[7]

In direct contiguous spread, organisms gain entry into the cerebrospinal fluid from adjacent infections such as sinusitis, brain abscess, or otitis media. Organisms can also enter directly with penetrating traumatic injury, through congenital defects, or during neurosurgical procedures. In these cases, the organisms and their pathophysiologic effects vary.

Important risk factors for bacterial meningitis are listed in **Table 174-1**.

CLINICAL FEATURES

The presentation of fever, headache, stiff neck, and altered mental status is commonly seen in patients with bacterial meningitis. Although most patients have at least two of four of these symptoms, their absence does not exclude meningitis. Headache is the most common symptom and is seen in more than 85% of patients. Fever is the second most common symptom.[7] Seizures and focal neurologic deficits are seen in 25% to 30% of patients.

History Assess historical data in order to elicit risk factors suggestive of certain pathogens. *N. meningitidis* is associated with close living

quarters, such as in military barracks and college dormitories. Unvaccinated patients are at risk for *H. influenzae*. Consider *L. monocytogenes* in older adults and alcoholics.[8] Penetrating head trauma makes *S. pneumoniae* more likely. *Staphylococcus aureus*, coagulase-negative staphylococci, and streptococci are the most commonly implicated organisms after craniotomy, whereas coagulase-negative staphylococci are commonly seen after ventriculoperitoneal shunt and spinal surgery.[4] Immunocompromised patients, such as those with human immunodeficiency virus, on chronic steroids, or with a history of splenectomy, are susceptible to meningitis with encapsulated organisms.

Physical Examination Evaluate for focal neurologic dysfunction such as hemiparesis, facial asymmetry, visual field deficits, or disordered eye movements. Increased intracranial pressure can cause papilledema, decreased venous pulsations, or cranial nerve palsy especially involving cranial nerves 3, 4, 6, and 7. Assess for meningeal irritation with Brudzinski sign (flexion of hips and knees in response to passive neck flexion) and Kernig sign (contraction of the hamstrings in response to knee extension while the hip is flexed). Examine the skin for cutaneous stigmata such as petechiae, splinter hemorrhages, and pustules, and consider aspirating to send for culture.[9] Percuss the sinuses and examine the ears for signs of primary infection.

DIAGNOSIS

Lumbar Puncture The diagnosis of meningitis is based on cerebrospinal fluid results obtained by lumbar puncture (LP). Withhold LP if there is coagulopathy, as evidenced by thrombocytopenia or anticoagulant or antithrombotic use, until coagulopathy is corrected. As a general rule, a platelet count ≤20,000/μL (and some prefer ≤50,000/μL) or INR ≥1.5 is a contraindication to performing an LP on an emergent basis.[10] The risk of bleeding complications such as epidural hematoma resulting from LP in the presence of aspirin, antiplatelet agents, and nonsteroidal anti-inflammatory drugs is not known, and risks and benefits of LP must be considered in such circumstances.[11,12] Send cerebrospinal fluid for studies including Gram stain and culture, cell count with differential, glucose, and protein.[7] Typical cerebrospinal fluid findings for bacterial, viral, fungal, and neoplastic meningitides are listed in **Table 174-2**,[13-16] but there is considerable overlap in findings.

Laboratory Testing Bacterial meningitis is associated with an elevated opening pressure >170 mm H_2O, and WBCs are elevated greater than 1000/mm^3 with a neutrophilic predominance. Gram stain is positive in 60% to 80% of patients before antibiotics are initiated, with a significant decline once antibiotics have been started. Cerebrospinal fluid protein is often elevated above 200 milligrams/dL, and glucose is often decreased below 40 milligrams/dL or the glucose serum–to–cerebrospinal fluid ratio is <0.4.[13-15] Although it is not specific for bacterial meningitis, cerebrospinal fluid lactate is a promising indicator to assist with differentiation between aseptic and bacterial meningitis.[16]

Sterilization of the cerebrospinal fluid is possible within 2 hours of initiating parenteral antibiotics in meningococcal and 6 hours in pneumococcal meningitis, highlighting the importance of timely LP.[17] Without antibiotics, Gram stain is positive in 60% to 80% of cases, but in patients treated with antibiotics, the Gram stain is positive in 7% to 41%.[15] Cerebrospinal fluid culture is positive in 80% to 90% of cases if cerebrospinal fluid analysis is preformed before antibiotics are initiated, although results are not available during the course of the ED stay. **However, when bacterial meningitis is considered, never withhold empiric antibiotic therapy in order to collect the cerebrospinal fluid sample.**[18]

Rapid latex agglutination tests can be used to detect bacterial antigens and improve bacterial identification. These tests are available for *S. pneumoniae, group* B streptococci, *H. influenzae, E. coli*, and *N. meningitides*, but are associated with false-positive and false-negative results and limited sensitivity and specificity. Polymerase chain reaction testing is highly sensitive for organisms such as *S. pneumoniae, N. meningitides*, group B streptococci, *H. influenzae, L. monocytogenes*, and *M. tuberculosis* but does not provide information on antimicrobial susceptibility.[7] Serum procalcitonin, C-reactive protein, and cerebrospinal fluid lactate concentrations have been studied as adjuncts to diagnosis of bacterial meningitis with negative cerebrospinal fluid examinations, but are not a substitute for decision making in the treatment of an individual patient.[19] If suspicion is great despite negative initial cerebrospinal fluid results, admit for empiric antibiotic treatment and consider repeat LP.[13]

CT Scan before Lumbar Puncture Perform the LP as soon as possible to secure the diagnosis of meningitis. Concern about the complication of cerebral herniation from LP has led to controversy regarding whether patients require a CT scan of the brain prior to the procedure.[15]

Risk factors for brain herniation are listed in **Table 174-3**. Order a head CT prior to LP in patients exhibiting any of these high-risk criteria. Although a CT scan can help identify contraindications for an LP, a normal CT scan does imply that there is no risk of herniation with LP if a patient exhibits clinical predictors of impending herniation such as deteriorating mental status, posturing, irregular respirations and pupillary changes, or seizures.[20]

TREATMENT

After addressing airway, breathing, and circulation status, immediately initiate empiric antibiotic therapy if bacterial meningitis is clinically suspected. **Never delay administration of empiric antibiotic therapy for neuroimaging or to perform LP, because antibiotic treatment takes precedence over definitive diagnosis.**[6] Obtain blood cultures to assist in identification of the organism and to help guide inpatient therapy if it will not delay time to antibiotics. Base antibiotic selection on the clinical scenario including age, immunization status, living conditions, and past medical history.

Empiric Treatment for Presumptive Bacterial Meningitis The empiric antibiotic regimen for adults between 18 and 49 years of age is a third-generation cephalosporin, such as ceftriaxone, 2 grams IV, plus vancomycin, 15 milligrams/kg IV, to cover the common pathogens *S. pneumoniae* and *N. meningitides*. For adults over the age of 50 years who

TABLE 174-2 Cerebrospinal Fluid (CSF) Diagnostic Evaluation

	Opening Pressure (<170 mm H_2O)*	Color (clear)	Gram Stain (negative)	Cell Count (<5 WBC, 0 PMN)	Glucose (>40 mg/dL)	Protein (<50 mg/dL)	Cytology (negative)
Bacterial	Elevated	Cloudy, turbid	Positive (60%–80% before antibiotic, 7%–41% after antibiotic)	>1000–2000/mm^3 WBC, neutrophilic predominance, >80% PMN	<40 mg/dL, CSF/blood glucose ratio <0.3–0.4	>200 mg/dL	Negative
Viral	Normal	Clear or bloody	Negative	<300/mm^3 WBC, lymphocytic predominance, <20% PMN	Normal	<200 mg/dL	Negative
Fungal	Normal to elevated	Clear or cloudy	Negative	<500/mm^3	Normal to slightly low	>200 mg/dL	Negative
Neoplastic	Normal	Clear or cloudy	Negative	<300/mm^3	Normal to slightly low	>200 mg/dL	Positive

*Normal values and findings are in parentheses.

Abbreviation: PMN, polymorphonuclear lymphocyte.

TABLE 174-3 Criteria for Obtaining Head CT before Lumbar Puncture[6,15,20]

Altered mental status or deteriorating level of consciousness
Focal neurologic deficit
New-onset seizure
Papilledema
Immunocompromised state
Malignancy
History of focal CNS disease (stroke, focal infection, tumor)
Concern for mass CNS lesion
Age >60 y

are immunocompromised, add ampicillin, 2 grams IV, to cover *L. monocytogenes*.[6] If patients have a severe allergy to penicillin, options include replacing ceftriaxone with chloramphenicol and substituting ampicillin with trimethoprim-sulfamethoxazole. Consider adding acyclovir if herpes simplex virus (HSV) encephalitis is suspected.[13] Use a fourth-generation cephalosporin, such as cefepime, plus vancomycin for patients who have recently undergone neurosurgery.[14] Initiate antibiotics as soon as possible in order to increase survival and reduce morbidity.[3,7]

The second priority is administration of steroids to patients with presumptive pneumococcal meningitis. Administration of dexamethasone before or with the first dose of antibiotics has been shown to reduce cerebrospinal fluid inflammation, reduce the risk of morbidity and mortality in adults, and reduce hearing loss and other neurologic sequelae in children, especially with *S. pneumoniae* infection.[8,21] The recommended dosage of dexamethasone is 10 milligrams IV for adults.[21]

Current guidelines provide no recommendation for the most common ED situation, in which the first dose of empiric antibiotics is given before LP is performed or before results of LP are received. Common sense suggests that dexamethasone could be administered just before, or concurrently with, empiric antibiotics to patients with strong suspicion for bacterial meningitis or to patients in whom grossly purulent cerebrospinal fluid is obtained at the time of LP. Infectious Disease Society of America guidelines state that dexamethasone should not be given to adults who have already received antibiotics.

SPECIAL SITUATIONS

Bacterial Meningitis Resulting from Sinusitis or Otitis The prevalent use of antibiotics has decreased the frequency of suppurative intracranial complications from sinusitis and otitis, but bacterial meningitis resulting from these diseases still occurs. The virulence of the affecting organism and host factors, such as immunocompromised state, influence spread to the CNS. In the ear, bacteria can spread through endolymphatic channels, bony erosions, or osteothrombophlebitis of small vessels. Thrombophlebitis of veins is a common mechanism by which bacteria disseminate from the sinuses; this may result in cavernous sinus thrombosis or empyema.[22] CT imaging is very sensitive for sinusitis and permits earlier diagnosis with demonstration of air-fluid levels in the involved sinuses. CT is nonspecific, however, and should be interpreted with the clinical background in mind (**Figure 174-1**). Infections are often polymicrobial. Initiate empiric antibiotic therapy with fluoroquinolones, such as levofloxacin or moxifloxacin, or with a third-generation cephalosporin, such as ceftriaxone, plus metronidazole.[23] Invasive infections and those with intracranial spread require emergency consultation for surgical drainage.

Additional Adjunctive Treatment for Bacterial Meningitis Monitor patients with meningitis closely for complications or signs of clinical deterioration, especially evaluating their respiratory and neurologic status.[8] Treat hyperpyrexia and manage seizures with anticonvulsants. Avoid hypotonic fluids, and monitor serum sodium level serially to detect syndrome of inappropriate antidiuretic hormone or cerebral salt wasting.[7,21] Closely evaluate for signs of increased intracranial pressure and vasculopathy that may lead to brain ischemia. If signs of elevated intracranial pressure are detected, elevate the bed to 30 degrees, use 25% mannitol or hypertonic 3% saline for diuresis, and consider a trial of mild hyperventilation.[7] Measurement of intracranial and systemic arterial pressure may be useful in severe cases to monitor cerebral perfusion pressure. Consider admission to the intensive care unit to ensure proper level of care.[8]

Chemoprophylaxis for Those Exposed to Bacterial Meningitis

Bacterial meningitis is spread by droplets, and risk for developing bacterial meningitis after exposure is estimated to be 500 to 800 times higher than the general population.[14] Chemoprophylaxis has been shown to decrease transmission of *N. meningitidis* by 89% in close contacts. Chemoprophylaxis is recommended for individuals who have been exposed to patients diagnosed with *N. meningitidis* and *H. influenzae*.[9] It is not recommended for patients diagnosed with pneumococcal meningitis.[14] Close contacts include housemates, individuals exposed to secretions (shared utensils or toothbrushes, kissing, mouth-to-mouth resuscitation), and individuals who intubated the patient without a facemask. To be most effective, initiate chemoprophylaxis within 24 hours of contact. Risk of infection after a period of 2 weeks from exposure is considered rare, and prophylaxis is not recommended after this time period. Treatment options for high-risk contacts include rifampin 10 milligrams/kg to a maximum of 600 milligrams per dose every 12 hours for four doses, ciprofloxacin 500 milligrams orally once, or ceftriaxone 250 milligrams IM once.[9] Instruct all patients who receive chemoprophylaxis to seek medical attention immediately if they develop any symptoms of illness or meningitis.

DISPOSITION AND FOLLOW-UP

Admit all patients diagnosed with bacterial meningitis and those highly suspected of having meningitis to the hospital on droplet isolation.

VIRAL MENINGITIS

INTRODUCTION

Viral meningitis typically presents with subacute headache and fever and findings of meningeal irritation, such as nuchal rigidity. Several viruses can cause viral meningitis, including nonpolio enteroviruses, HSV, varicella-zoster virus, cytomegalovirus, adenovirus, and human immunodeficiency virus. Specific diagnosis depends on isolation of the virus or positive results on immunoassay of the cerebrospinal fluid. Nonpolio enteroviruses (echovirus, coxsackievirus, and enterovirus) typically are seen in summer through fall and account for more than 90% of all cases of viral meningitis.[4]

LABORATORY TESTING

Viral meningitis is associated with normal opening pressures and a negative Gram stain. WBCs are <300/mm^3 with a lymphocytic predominance, and usually less than 20% polymorphonuclear lymphocytes.[20] Protein is often slightly elevated, but not typically above 200 milligrams/dL, and cerebrospinal fluid glucose is normal. The percentage of polymorphonuclear cells may be higher in early viral meningitis, and in some cases, glucose levels may be decreased.[13] Consider partially treated bacterial meningitis if a patient with symptoms consistent with meningitis had previously been treated with antibiotics and the LP suggests aseptic meningitis. Viral culture is insensitive, so if a viral etiology is suspected, send for molecular testing by polymerase chain reaction from the cerebrospinal fluid.[4] Polymerase chain reaction testing is available for HSV, enterovirus, and other viral organisms.

DISPOSITION AND FOLLOW-UP

There can be overlap of cerebrospinal fluid findings with early bacterial meningitis and partially treated bacterial meningitis, making specific diagnosis for some cases of viral meningitis difficult in the ED. Although supportive care is the mainstay of treatment for viral meningitis, it is appropriate to admit the toxic-appearing patient to the hospital for empiric antibiotic therapy until culture results return in situations of diagnostic uncertainty. HSV-2 meningitis can cause necrotizing encephalitis and neurologic deficits.[4] Admit patients with diagnosed or suspected HSV-2 meningitis after beginning treatment with acyclovir 10 milligrams/kg IV every 8 hours.[8]

FUNGAL CNS INFECTIONS

Over the past 30 years, the incidence of fungal CNS infections has been increasing, likely due to acquired immunodeficiency syndrome as well as an increase in patients on immunosuppressants due to stem cell and organ transplants.[24] The most common cause of fungal meningitis is *Cryptococcus neoformans*, followed by *Coccidioides immitis*, which can be seen in immunocompetent hosts as well as the immunocompromised.[4,24] *Aspergillus* and *Candida* are most often discovered in immunocompromised hosts. Mucormycoses can be seen especially in diabetics from direct extension of sinus infection.

LABORATORY TESTING

The cerebrospinal fluid analysis of fungal meningitis shows lymphocytic predominance, an elevated opening pressure, low glucose, and slightly increased protein.[5,25] Significant elevations in opening pressure are often seen in cryptococcal meningitis. Gram stain is negative, and WBC is usually <500/mm^3. Consider fungal testing especially for immunocompromised patients where fungal etiologies are suspected, including India ink staining and serum cryptococcal antigen testing, cytology, and histopathology.[5] Send cerebrospinal fluid for *Borrelia* antibodies in patients with suspected Lyme disease and for acid-fast stain and culture for suspected mycobacteria in tuberculous meningitis.

Patients often have a prolonged symptom course. Use fungal stain and culture for diagnosis if a fungal etiology is suspected, and look for elevated opening pressure during LP. Consider CT or MRI to search for intracranial complications such as granulomas or abscesses.

TREATMENT

Treatment for fungal infections is dependent on diagnosis through LP. Amphotericin is the agent of choice in cryptococcal meningitis. Use fluconazole or itraconazole for *C. immitis*. Treat *Candida* meningitis with amphotericin B and flucytosine.[5]

VIRAL ENCEPHALITIS

Viral CNS infections can also cause viral encephalitis, which is an infection and inflammation of the brain parenchyma.[4] Viral encephalitis is clinically distinguished from viral meningitis with presence of neurologic findings such as altered level of consciousness, focal weakness, or seizures, although the two often coexist.

The causes of viral encephalitis vary year to year and across geographical locations, with an incidence of 3.5 to 7.5 per 100,000 people.[26] Immune status, exposure to insects or animals, and travel history play a key role in determining the etiology. An underlying cause, however, is found in only about a third of cases.[25] HSV accounts for 40% to 50% of cases where a cause is determined. HSV-1 is responsible for most cases of HSV encephalitis; HSV-2 frequently causes aseptic meningitis but is not usually associated with development of encephalitis.[26] Other viral pathologic agents in North America include Epstein-Barr virus, cytomegalovirus, and rabies. Common arboviral encephalitides include La Crosse encephalitis, St. Louis equine encephalitis, Western equine encephalitis, and West Nile virus.

PATHOPHYSIOLOGY

Immunocompromised patients such as those with organ or stem cell transplants are susceptible to new or reactivated infections with HSV and varicella-zoster virus. Impaired immune status also plays a role in cytomegalovirus encephalitis. The arboviruses are transmitted by mosquitoes and ticks. Rabies is transferred by the bite of an infected animal and leads to severe encephalitis and a very high mortality rate.[4] Common to all is preliminary viral invasion of the host at a site where replication takes place that is outside the CNS. Most viruses then reach the nervous system hematogenously during viremia. However, at least three important viruses—rabies, HSV, and herpes zoster virus—reach the spinal cord and

eventually the brain by traveling backward within axons from a distal site, where they gain access to nerve endings. Once in the brain, disruption of neural cell functions by the virus and by the effects of the host's inflammatory responses ensue. Gray matter is predominantly affected, resulting in cognitive and psychiatric signs, lethargy, and seizures.

CLINICAL FEATURES

Consider encephalitis in patients exhibiting behavioral changes, new psychiatric symptoms, cognitive deficits, or seizures.[25] Although the triad of headache, fever, and altered mental status may be seen, it is not invariably present. Assess for signs of clinical syndromes outside the CNS. Rash or skin vesicles suggest herpes zoster, and skin vesicle culture may be useful for diagnosis. Lymphadenopathy or splenomegaly points to Epstein-Barr virus, which can be picked up on serologic testing. New onset of psychiatric symptoms and behavioral changes may be attributable to HSV. MRI, electroencephalogram, and polymerase chain reaction of the CSR could assist in making the diagnosis.

Physical Examination Examine for signs of meningeal irritation and increased intracranial pressure and for neurologic findings that reflect the areas of involvement. Carefully assess mental status and cognition. Encephalitis may show regional tropism. HSV involves limbic structures of the temporal and frontal lobes with prominent psychiatric features, memory disturbance, and aphasia. Some arboviruses predominantly affect the basal ganglia, causing choreoathetosis and parkinsonian movements. Involvement of the brainstem nuclei that control swallowing leads to the hydrophobic choking response characteristic of rabies encephalitis.[27]

DIAGNOSIS

Neuroimaging studies such as MRI or CT, electroencephalography, and LP are important in ruling out mass occupying lesions and making the diagnosis of encephalitis. MRI is more sensitive than CT. Obtain an MRI to help exclude lesions such as brain abscesses, and examine for findings suggestive of HSV encephalitis, such as involvement of the gray matter in the medial temporal and inferior frontal lobes (**Figure 174-2**). Electroencephalogram findings are generally nonspecific but can be useful in cases such as HSV encephalitis where an almost pathognomonic picture of periodic, asymmetric sharp waves is seen in the setting of acute febrile encephalopathy.[25] LP is the most useful diagnostic procedure in the ED once imaging studies exclude the increased intracranial pressure and the risk of uncal herniation.

Consider bacterial meningitis in the differential diagnosis when fever and meningeal symptoms predominate. A late-summer encephalopathy suggests the possibility of arbovirus encephalitis, and an animal bite for which no antirabies treatment was administered has relevance for rabies. Suspect subarachnoid hemorrhage with acute onset of severe headache as the presenting sign. Lyme disease, tuberculosis, and fungal and neoplastic meningitis are in the differential diagnosis in less fulminant cases. If focal neurologic signs are present, consider brain abscess, empyema, or cavernous sinus thrombosis as possible causes.

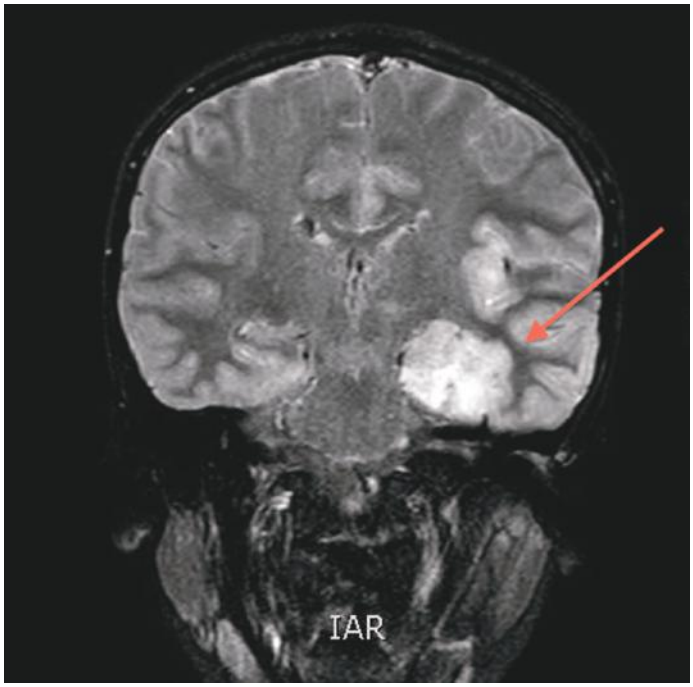

FIGURE 174-2. Fluid-attenuated inversion recovery hyperintensity in the left temporal lobe and left insula (arrow) suggests the diagnosis of herpes encephalitis. [Photo contributed by Elizabeth Yutan, Department of Radiology, Oregon Health & Science University.]

TREATMENT

The antiviral of choice for HSV encephalitis is high-dose acyclovir at 10 milligrams/kg IV.[8,26] Initiate treatment as soon as possible because the prognosis of HSV encephalitis is correlated with neurologic condition at the time antivirals are initiated. Treat varicella-zoster virus with acyclovir, 10 to 15 milligrams/kg IV. Patients with herpes zoster virus encephalitis may also benefit from acyclovir therapy. Treat patients with cytomegalovirus encephalitis with ganciclovir, 5 milligrams/kg IV.[27] There are no known treatments for arbovirus encephalitis; consider initiating treatment with acyclovir empirically until a cerebrospinal fluid diagnosis is made.[8] Rabies encephalitis is rare but neurologically devastating, and once symptomatic, it is usually fatal.

DISPOSITION AND FOLLOW-UP

Prognosis of viral encephalitides depends on the causative virus and host factors. Older adults and those who are immunocompromised are more likely to have an adverse outcome. Admit patients with encephalitis to the hospital. Patients may require intensive care unit care if they have signs of altered mental status or coma.

BRAIN ABSCESS

INTRODUCTION

A brain abscess begins as a focal area of cerebritis, which develops into a central pus-filled cavity ringed by a layer of granulation tissue and an outer fibrous capsule in a period of about 14 days.[28] It is surrounded by edematous brain tissue infiltrated with inflammatory cells. A brain abscess is a pathologic response typical of a relatively competent immune system against a bacterial invader. Focal brain infections from other organisms, such as granulomas due to tuberculosis, necrotic lesions of toxoplasmosis in immunocompromised patients, or cystic lesions of cysticercosis, are not abscesses in the pathologic sense.

PATHOPHYSIOLOGY

Organisms reach the brain hematogenously, from direct contiguous infection, or by direct seeding by neurosurgery or penetrating trauma. Hematogenous spread accounts for 15% to 30% of cases, direct spread from infection accounts for 25% to 50%, and trauma or surgery for 8% to 20%. The route is unknown in 15% to 20% of cases.[28,29] Direct spread usually results in an isolated brain abscess, whereas hematogenous seeding results in multiple abscesses.

Investigate for the source of the brain abscess in order to determine the likely bacterial etiology and to treat the source itself. Otogenic brain abscesses are often caused by gram-negative rods and are located adjacent to the temporal lobe or cerebellum. Sinogenic or odontogenic abscesses are often caused by anaerobic and microaerophilic streptococci and are commonly located in the frontal lobes. Abscesses formed from hematogenous spread are usually polymicrobial, with anaerobic and microaerophilic streptococci commonly represented. Direct implantation or traumatic injuries yield staphylococci, with Gram-negative rods also seen in cases related to neurologic surgery.[25]

CLINICAL FEATURES

History Presenting features of brain abscess are nonspecific, and patients are generally appear nontoxic. Headache is the most common feature, with fever as a close second. Although most patients present with one or more findings of headache, fever, altered mental status, focal neurologic symptoms, seizures, or balance changes, the classic triad of headache, fever, and focal neurologic deficit is present in <25% of all patients.[28,29] The nonspecific presentation contributes to both severity and outcome of brain abscesses because diagnosis and treatment are often delayed.[30] Symptoms reflect the infectious and neurologic (focal and mass-effect producing) aspects of the disease and are often present for 1 to 8 weeks.[28] The presentation may be dominated by the origin of the infection (e.g., ear or sinus pain). Seizure occurs in 25% to 34% of patients.[31]

Physical Examination Examine for focal neurologic signs that demonstrate the site of the lesion; for example, a frontal lobe lesion presenting with hemiparesis, a temporal lobe lesion presenting with homonymous superior quadrant visual field deficits or aphasia, or a cerebellar lesion presenting with limb incoordination or nystagmus. Focal signs are present in approximately 60% of patients. Assess for potential sites of origin, which may raise suspicion of brain abscess when the presentation is otherwise nonspecific (e.g., otitis media, sinus tenderness, evidence of pulmonary suppuration, or right-to-left shunting) in a patient with subacute headache and lethargy.

DIAGNOSIS

Neuroimaging is essential to the diagnosis of brain abscess and is one instance where a contrast-enhanced head CT scan is preferred over a noncontrast study in the ED. A noncontrast CT scan may only show a hypodense low-attenuation abnormality with mass effect, but later in the course, CT may show a peripheral ring.[28] A head CT with IV contrast shows one or several thin, smooth rings of enhancement surrounding a low-density central area and surrounded by edema (**Figure 174-3**). MRI usually demonstrates a ring whether or not gadolinium enhancement is used. Both CT and MRI are highly sensitive; CT is often more readily available in the ED. Avoid LP if clinical suspicion is high or focal neurologic deficits are present to prevent potential herniation in the case of increased intracranial pressure. If possible, obtain cultures of blood and other sites of infection to guide future management.

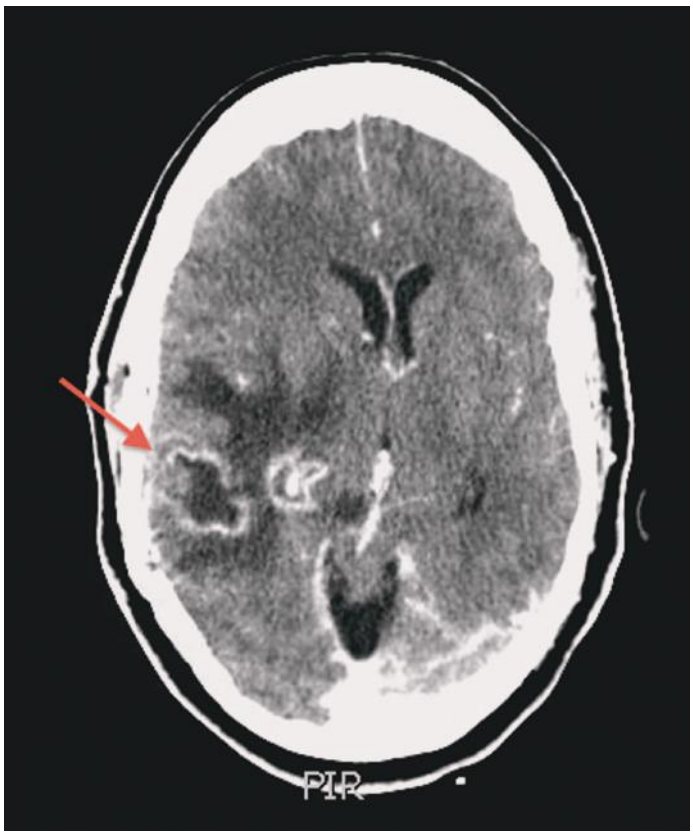

FIGURE 174-3. Ring-enhancing brain abscess with surrounding edema (arrow). [Photo contributed by David Peterson, Department of Radiology, Oregon Health & Science University.]

The differential diagnosis is broad because of the nonspecific symptoms of brain abscess. A sudden onset with focal features may suggest cerebrovascular disease. Prominent fever, stiff neck, and altered mental status may suggest meningitis or encephalitis. A protracted course with features of increased intracranial pressure may suggest neoplasm. Brain neoplasm, subacute brain hemorrhage, and other focal brain infections, such as toxoplasmosis, may mimic the imaging findings of brain abscess.

TREATMENT

Early combination empiric antibiotic therapy is important (**Table 174-4**). A multidisciplinary approach with neurosurgery and infectious disease consultations will help guide treatment selection. Aminoglycosides, macrolides, and first-generation cephalosporins are not effective treatment for brain abscess. Treatment with steroids is controversial.

DISPOSITION AND FOLLOW-UP

Neurosurgery involvement is paramount in the treatment and management decisions. Patients with small abscesses <2.5 cm, with good clinical condition with a Glasgow coma score >12, and who have an etiology that is known may be treated with IV antibiotics alone.[32] Aspiration may be done by the neurosurgical team to elucidate the causative organism. Total excision is less necessary with improved imaging, although it is preformed in the setting of increased intracranial pressure or after failed medical management or aspiration.[5]

EPIDURAL ABSCESS

INTRODUCTION AND EPIDEMIOLOGY

Spinal epidural abscess is a collection of pyogenic material that accumulates in the epidural space between the dura and vertebral periosteum and often leads to devastating neurologic outcomes.[33,34] Spinal epidural abscess is a rare diagnosis and accounts for 0.2 to 1.2 cases per 10,000 hospital admissions. The incidence has doubled in the past two decades, largely attributed to factors such as an increasing proportion of immunocompromised patients, more prevalent IV drug use, a larger number of spinal procedures being preformed, and improved imaging modalities for detection.[35,36] Despite improvement in diagnosis and treatment, mortality remains high at 2% to 20%.[33] *S. aureus* is the most commonly involved bacteria and is responsible for 70% of cases with a higher proportion of methicillin-resistant *S. aureus* seen in patients with implantable devices.[33,36] Other pathogens include *Staphylococcus epidermidis*, streptococcal species, and gram-negative bacilli, which is especially prevalent in IV drug users. Mycobacteria and fungi causing spinal epidural abscess are rare.

PATHOPHYSIOLOGY

Spinal epidural abscess arises from hematogenous spread through blood circulation 25% to 50% of the time, with soft tissue, urine, and respiratory infections contributing in the majority of cases. In general, hematogenously spread epidural abscesses are more likely to be found in the posterior epidural space. Ten to 30% of spinal epidural abscesses are caused by direct extension from infected adjacent tissue, such as psoas abscess, vertebral diskitis, or vertebral osteomyelitis. Direct extension often infects the anterior portion of the spinal column.[33,37] Fifteen to 22% of spinal epidural abscesses are caused iatrogenically from neurosurgical procedures, including percutaneous diagnostic and therapeutic techniques. Trauma contributes to a small proportion of spinal epidural abscesses, with the remainder of cases without an identifiable source.[35,36]

Most spinal epidural abscesses affect the thoracic and lumbar spine, where the epidural space is wider with a larger venous plexus.

TABLE 174-4 Guidelines for Empiric Treatment of Brain Abscess Based on Presumed Source

Presumed Source	Primary Empiric Therapy	Alternative Therapy
Otogenic	Cefotaxime 2 grams IV every 4–6 h or ceftriaxone 2 grams IV every 12 h PLUS metronidazole 500 milligrams IV every 8 h	Piperacillin/tazobactam 4.5 grams IV every 6 h
Odontogenic	Penicillin G 4 million units IV every 4 h	Ceftriaxone 2 grams IV every 12 h PLUS metronidazole 500 milligrams IV every 6 h
Sinogenic	Cefotaxime 2 grams IV every 6 h or ceftriaxone 2 grams IV every 12 h PLUS metronidazole 500 milligrams IV every 8 h	No recommendation
Penetrating trauma	Cefotaxime 2 grams IV every 6 h or ceftriaxone 2 grams IV every 12 h PLUS metronidazole 500 milligrams IV every 8 h ± rifampin 10 milligrams/kg every 24 h	No recommendation
After neurosurgical procedure	Vancomycin loading dose 25–30 milligrams/kg IV loading dose or linezolid 600 milligrams IV every 12 h PLUS ceftazidime 2 grams IV every 8 h ± rifampin 10 milligrams/kg every 24 h	Can substitute linezolid 600 milligrams IV every 12 h instead of vancomycin. Can substitute meropenem 2 grams IV every 8 h OR piperacillin/tazobactam 4.5 grams IV every 6 h OR cefepime 2 grams IV every 8 h for ceftazidime.
Unknown source	Cefotaxime 2 grams IV every 6 h PLUS metronidazole 500 milligrams IV every 6 h	No recommendation

Note: See also http://www.hopkins-abxguide.org; accessed June 18, 2014.

The cervical spine is affected only 5% to 20% of the time, although morbidity and neurologic devastation are much greater in these cases.[38]

Mechanisms for spinal cord neurologic sequelae are uncertain and are thought to be from a combination of direct compression from the abscess itself, ischemia due to compression of spinal veins and arteries, and septic thrombophlebitis.[33]

CLINICAL FEATURES

Back pain is the most common presenting complaint and is seen in 70% to 90% of cases. Fever is another common symptom, followed by the presence of a neurologic deficit. However, the classic triad of back pain, fever, and neurologic symptoms is seen in a minority of patients (8% to 37%) on initial presentation.[33,36] Typically, patients with spinal epidural abscess progress through four stages in a period ranging from hours to days. Stage 1 consists of back pain, fever, and localized spinal tenderness. Stage 2 is composed of spinal irritation, including radicular pain, hyperreflexia, and nuchal rigidity. Stage 3 involves the bowel and bladder, with symptoms of fecal or urinary incontinence, as well as focal neurologic deficits such as motor weakness. Finally, in stage 4, paralysis ensues.[33,36]

HISTORY

Screen any patient presenting with back pain, fever, or neurologic complaint for spinal epidural abscess. Patients may have a history of chronic back pain or may offer a mechanism of mild trauma as an explanation for their symptoms, which can distract from a diagnosis of spinal epidural abscess. Similarly, neck pain or stiffness is often thought to be meningitis or encephalitis, causing cervical spinal epidural abscess to be overlooked.

Carefully search for back pain red flags in the patient's history, including immunocompromised states, such as human immunodeficiency virus or diabetes, and immunosuppressant medications, such as steroids or chemotherapy. Elicit a history of recent systemic illness or infection. Inquire about any current or former IV drug use, which can make patients higher risk for spinal epidural abscess development from *Pseudomonas* species. Solicit information about prior spinal surgeries or procedures, including LPs, epidurals, spinal injections, or anesthesia. Ask about any changes in bowel or bladder habits, specifically episodes of bladder fullness or urinary or fecal incontinence.[36,39]

PHYSICAL EXAMINATION

Perform a thorough physical examination starting with a general assessment of sources of infection, including observation of the skin and palpation of soft tissues for signs of infection. Palpate the spine searching for tenderness to palpation, especially in the midline, which may suggest spinal epidural abscess. Complete a full neurologic examination, including sensory dermatome testing and motor evaluation including ambulation. Check reflexes for hyper- or areflexia. Evaluate for symptoms of cauda equine syndrome. Perform a rectal examination looking for decreased rectal tone, which has a sensitivity of 60% to 80%, and an evaluation of perianal sensation for saddle anesthesia, which has a sensitivity of 75%.[40]

DIAGNOSIS

Diagnosis is delayed in many patients with spinal epidural abscess due to nonspecific presenting symptoms and the rarity of diagnosis. Send blood for laboratory studies including blood culture, CBC, erythrocyte sedimentation rate, and C-reactive protein. Leukocytosis is seen in only 60% to 75% of patients and is not sensitive or specific enough for a diagnosis of spinal epidural abscess. Erythrocyte sedimentation rate is much more sensitive and, in one study, was elevated in 110 of 117 patients diagnosed with spinal epidural abscess.[41] C-reactive protein has the advantage of rising faster than erythrocyte sedimentation rate and returns to normal sooner as well, but some labs have a delay in resulting C-reactive protein. Do not withhold further diagnostics and treatment pending C-reactive protein.[36] Blood cultures are positive in 40% of cases and may be helpful for inpatient teams. Do not perform LP if there is suspicion for spinal abscess. Cerebrospinal fluid culture is positive less than a quarter of the time, and LP poses the risk of traversing an abscess and causing meningitis or a subdural infection.[36]

MRI with gadolinium is the gold standard imaging study for the diagnosis of spinal epidural abscess and has a sensitivity and specificity greater than 90%.[37] If MRI is not available, consider emergent transfer to an appropriate referral center. In patients with contraindications to MRI, CT with myelography can be useful to localize epidural compression but is limited in its ability to distinguish abscess from other compressive lesions.[36] Plain radiographs are not sensitive or specific for diagnosis of spinal epidural abscess.[37]

TREATMENT

Once diagnosis has been established, prompt treatment is essential to reduce morbidity and enhance survival. Immediate consultation and evaluation with a spine surgeon are paramount, and if a spine surgeon is not available, emergent transfer to a referral center is appropriate.[36] Neurologic outcome is correlated with degree of neurologic deficit prior to treatment, so time is of the essence.

There are no conclusive data regarding surgery versus conservative antibiotic therapy, and practices vary considerably from immediate operative therapy to conservative IV antibiotic therapy.[37] Patients with

neurologic deficits usually require evacuation of the abscess with decompressive laminectomy, debridement, and long-term IV antibiotics, and some studies have shown improved outcomes with emergent surgery.[35] Patients who are neurologically intact or who have had neurologic deficits for >72 hours may be candidates for conservative treatment or CT-guided aspiration depending on the spinal surgeon's practice, with the understanding that if they develop neurologic deficits or decompensate immediate surgical therapy is likely required.[35]

Start empiric antibiotic therapy if there will be an unavoidable delay for surgery or if the patient exhibits neurologic dysfunction or signs of sepsis. Appropriate empiric antibiotics can include a combination of vancomycin, 25 to 30 milligrams/kg loading dose and then 15 milligrams/kg every 12 hours, to cover methicillin-resistant *S. aureus* along with ceftazidime, 2 grams IV every 8 hours, or cefepime, 2 grams IV every 12 hours.[33,42] Consider adding gentamicin, 5 milligrams/kg IV every 24 hours, if the spinal epidural abscess occurred after a neurosurgical procedure.[42] Once cultures return, an infectious disease consult may be helpful to determine long-term antibiotic choice and duration.

DISPOSITION AND FOLLOW-UP

Admit patients diagnosed with spinal epidural abscess directly to the operating room for spinal surgery. If the patient will receive conservative therapy, then admit to the intensive care unit for close monitoring, neurologic checks, and further management in conjunction with the spinal surgery team.

Lumbar Puncture Checklist

1. Assess patient for risk factors or clinical signs of increased intracranial pressure, as in Table 174-3. If signs or risk factors are present, order noncontrast head CT prior to lumbar puncture (LP) to assess for risk of herniation.
2. Assess clinically and/or evaluate laboratory results to ensure no signs of coagulopathy or thrombocytopenia.
3. Obtain informed consent from patient or medical decision maker, and document discussion of risks and benefits.
4. Gather supplies including LP tray with two spinal needles, four cerebrospinal fluid (CSF) tubes, manometer with three-way valve, local anesthetic, syringe with 18-guage needle to draw up anesthetic and 25-guage needle to inject anesthetic, 0.5% chlorhexidine/70% alcohol, sterile gloves, mask, cap, and drape.
5. Position patient properly (if right-handed, position in left lateral decubitus position, and if left-handed, place in right lateral decubitus position). Maintain the patient's head in a neutral position and flex the patient's knees to their chest.
6. Assess the patient's anatomy in the midline, searching for a palpable area between the vertebrae L4/5 or L5/S1 for spinal needle insertion.
7. Ensure sterile technique: apply mask and cap, carefully wash hands, and don sterile gloves.
8. Prepare LP tray and open CSF tubes so they are ready for fluid collection. Prepare manometer by connecting the two tubes and loosening the manometer tap.
9. Carefully cleanse the patient's skin over desired lumbar puncture area in a circular fashion three times.
10. Anesthetize the space starting with a small intradermal bleb of lidocaine, and advance to slightly deeper areas drawing back on the syringe before injecting the anesthetic.
11. Insert spinal needle into the anesthetized space with the stylet in place. Slowly advance, maintaining a horizontal plane, with a trajectory slightly cephalad until mild resistance is felt at the ligamentum flavum with a subsequent "give" while entering the subarachnoid space.
12. Remove the stylet and wait for CSF to drip from the needle. If it does not drip, replace the stylet and advance an additional 2 mm, and check again for CSF. If resistance is felt, bone is likely being hit. In this case, withdraw the needle to the subcutaneous tissue and palpate landmarks to ensure you are midline, change the angle slightly cephalad, and attempt again.

Lumbar Puncture Checklist (*Continued*)

13. Once CSF is visualized, attach the manometer to the spinal needle for a measurement of opening pressure.
14. Once opening pressure is measured, remove the manometer and collect the CSF, approximately 1 mL in each tube in the order of tubes 1 to 4. Note the color and consistency of the CSF as it drips into the collection tube.
15. Once CSF is collected, replace the stylet into the spinal needle and remove the spinal needle.
16. Apply a sterile dressing to the procedure site.

CHAPTER 175

Central Nervous System Procedures and Devices

Jay G. Ladde

LUMBAR PUNCTURE

Lumbar puncture is considered the gold standard diagnostic procedure to assist clinicians with the evaluation of subarachnoid hemorrhage, meningitis, and other neurologic conditions. Anxiolytics, such as benzodiazepines, may be administered to improve patient comfort, relaxation, and cooperation. Contraindications to lumbar puncture are listed in **Table 175-1**.

If an anxiolytic is used, give a short-acting agent to avoid clouding subsequent clinical assessment. Antiseptic technique should be strictly observed. Scrub the site with povidone-iodine and allow to dry thoroughly to avoid introduction of the chemical and the subsequent production of chemical arachnoiditis.

In adults, a transverse line drawn between the iliac crests crosses the spine at the L4 spinous process. The L4-L5 interspace is the most commonly used interspace for lumbar puncture, although one can also select the L3-L4 interspace. Palpate the L4-L5 interspace while the patient is curled as tightly as possible in a fetal position. Alternatively, the patient may be seated on the edge of a bed or cart leaning over a tray stand. This latter technique is particularly useful when landmarks are uncertain due to body habitus.

Use a $3^1/_2$-inch atraumatic 22-gauge needle in adults. Use of a needle larger than 20-gauge may double the incidence of post–lumbar puncture headache compared with a smaller needle. The use of an atraumatic or pencil-point needle (such as a Whitacre or Sprotte needle) is associated with fewer post–lumbar puncture headaches than a conventional cutting needle[1,2] (**Figure 175-1**). Also, a smaller needle size using the stylet is associated with reduced frequency of post–lumbar puncture headaches.[1]

TECHNIQUE

Assemble all equipment. Then properly position the patient and identify the patient's L4-L5 interspace. Now put on your sterile gown, mask, and gloves. Next, apply povidone-iodine to the area and let dry. Apply sterile

TABLE 175-1 Contraindications to Lumbar Puncture

Skin infection near the site of lumbar puncture
CNS lesion causing increased intracranial pressure, or spinal mass
Platelet count <20,000 mm^3 is an absolute contraindication; platelet counts >50,000 mm^3 are safe for lumbar puncture*
International normalized ratio ≥1.5*
Administration of unfiltrated heparin or low-molecular-weight heparin in past 24 h*
Hemophilia, von Willebrand's disease, other coagulopathies*
Trauma to lumbar vertebrae

*Correct clotting factor and/or platelet levels before lumbar puncture.

drapes. Anesthetize the skin with 1% lidocaine by raising a skin bleb, then directing the needle toward the umbilicus, and injecting the anesthetic in a fan-shaped area around the proposed lumbar puncture site. Make sure to pull back on the plunger to check for blood return before injecting to avoid intravascular injection. Recheck the patient's position, making sure the patient is perpendicular to the horizontal and not slanted. Check the needle and make sure that it is the correct size and that the stylet is easily removed and reinserted. Identify that the needle bevel (Quincke needle) or notch (Whitacre needle) is facing the ceiling. Put together the manometer, making sure you know how the stopcocks work. Assuming you are right-handed, identify the interspinous space with your left hand and position the needle at the L4-L5 interspace, parallel to the horizontal, and direct it firmly and slowly toward the patient's umbilicus. As the needle advances, you may feel a slight "pop," indicating that you have pierced the ligamentum flavum and dura mater. Remove the stylet, note draining cerebrospinal fluid (CSF), and attach the manometer to measure the opening pressure. After collecting at least 1 mL in each of four tubes, disconnect the manometer and replace the stylet before withdrawing the spinal needle (**Figure 175-2**). Do not aspirate because slight negative pressure may facilitate herniation.[1]

If unable to penetrate the subarachnoid space, it is best to withdraw the needle completely, out of the skin, and direct the needle again. In some patients (for example, those who are extremely obese or who have degenerative disease of the spine), it is particularly difficult to successfully perform a lumbar puncture. The use of US guidance or even consultation of a radiologist to perform under fluoroscopy may be necessary.

US imaging of the interspinous processes is superior to palpation with regard to fewer failed attempts.[3] A 5- to 10-MHz linear probe is applied in the sagittal plane to identify the dorsal spinous processes, and the midline is then marked with a sterile marking pen. Lumbar puncture is then performed as outlined above.

For results to be meaningful, measure the opening pressure with the patient lying extended on his or her side. Pressures measured with the patient still curled in extreme flexion or sitting may be artificially elevated. Normal pressure is <170 mm H_2O. Careful repositioning (straightening the curled patient or helping the seated patient to a lying position on his or her side) can be safely performed with the needle in place. Obtain accurate pressure readings only when the patient is in a calm state if possible. Shouting, crying, or coughing can elevate the pressure falsely.[1]

Obtain four tubes, each containing at least 1 mL of CSF. Obtain red and white blood cell counts with differential for tubes 1 and 4. Tube 4 may also be used for culture and Gram staining. Tube 2 is sent for determination of protein and glucose levels. Save tube 3 for other studies that may be required. **Table 175-2** lists normal CSF findings. See chapters 166, "Spontaneous Subarachnoid and Intracerebral Hemorrhage" and 174, "Central Nervous System and Spinal Infections" for further discussion of CSF interpretation.

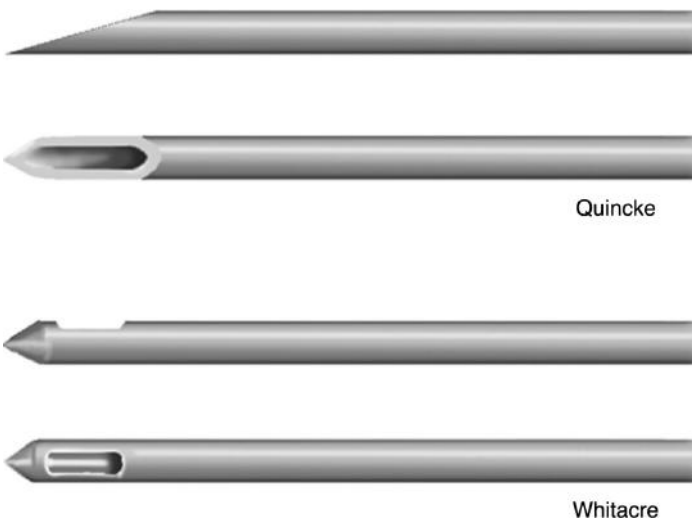

FIGURE 175-1. Two types of needle for lumbar puncture. The Quincke is a bevel-type needle, and the Whitacre is a pencil-point needle.

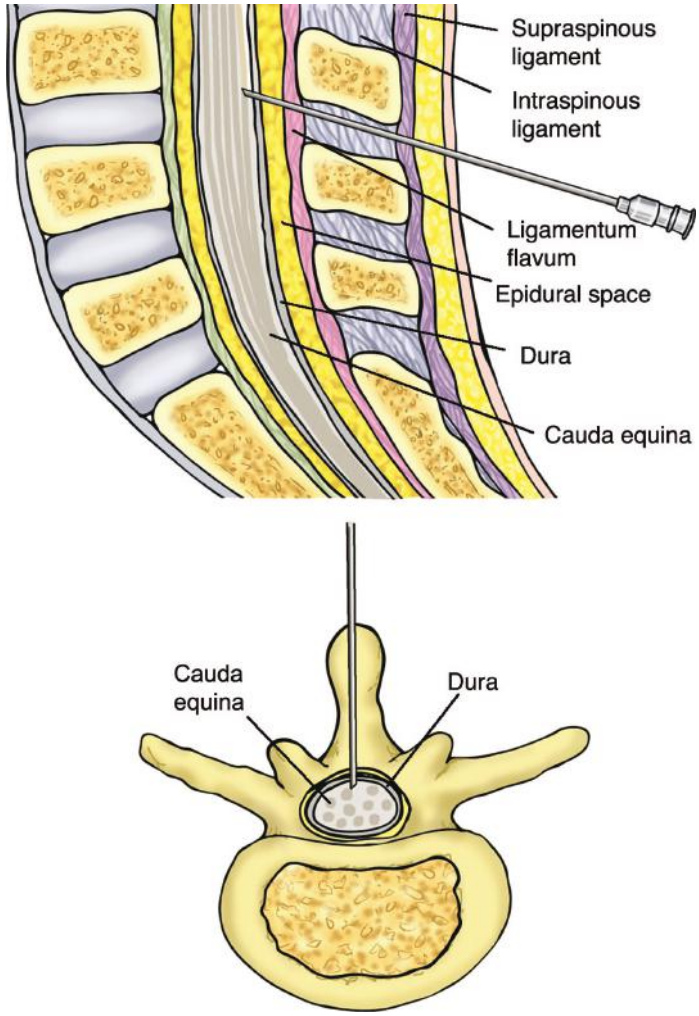

FIGURE 175-2. Anatomy of the lumbar spinal interspaces for lumbar puncture.

TABLE 175-2 Normal Cerebrospinal Fluid Values

Parameter	Value
Opening pressure	50–170 mm H_2O
Appearance	Clear (can be clear with up to 400 cells/mm^3)
Xanthochromia	None
Red blood cells	≤5/mm^3
WBCs	≤5/mm^3 (no polymorphonuclear leukocytes)
Glucose level	>40 milligrams/dL or 60%–70% of serum glucose level
Protein level	<50 milligrams/dL
Gram stain and culture results	Negative

COMPLICATIONS OF LUMBAR PUNCTURE

Local discomfort is to be expected; radicular pain indicates that the needle is too lateral, which necessitates repositioning. Spinal hematoma is a particularly ominous complication. The development of severe or persistent back pain after the procedure, radicular pain, new neurologic symptoms, or sphincter disturbance indicates that a spinal hematoma may be present. Most present within the first 6 hours.[1] Management includes MRI of the spine and neurosurgical consultation.

Post–lumbar puncture headache is the most common complication of lumbar puncture. The cause is thought to be continuous CSF leakage from the dural puncture site. Traction on bridging vessels, dura, and nerves causes headache. Post–lumbar puncture headache usually begins 24 to 48 hours after the procedure and is located in the frontal or occipital area. It is pressure-like and throbbing, with variable intensity. It is intensified when the patient is sitting or standing upright and with Valsalva maneuvers such as coughing. The headache improves or resolves when the patient is supine. It can be associated with nausea, vomiting, and even vertigo and tinnitus. Risk factors for post–lumbar puncture headache include use of a large needle size (>22 gauge), use of a cutting (Quincke) needle, multiple attempts, and failure to replace the stylet when withdrawing the needle.[1,2] Post–lumbar puncture headache does not seem to be related to the opening pressure, the volume of CSF removed, or bed rest after the procedure. Postprocedural bed rest does not prevent this complication.[4] Diagnosis is clinical. Most headaches resolve with rest in the supine position, maintenance of hydration, and administration of antiemetics and analgesics.[1] IV caffeine (500 milligrams IV of caffeine sodium benzoate) is commonly administered, but whether or not it improves headache is controversial.[5] Persistent headache (>24 hours) can be treated with an epidural blood patch. In this procedure, usually performed by an anesthesiologist, a needle is introduced into the epidural space, and 20 to 30 mL of the patient's blood is injected into the epidural space.

CEREBROSPINAL FLUID SHUNTS

Mechanical shunting is the primary treatment for hydrocephalus. Placement of a CSF shunt is the most common pediatric neurosurgical procedure performed in the United States. It is also the neurosurgical procedure with the highest incidence of postoperative complications.[6] Many types of CSF shunt systems exist (**Figures 175-3, 175-4, and 175-5**). Most systems consist of three components, beginning with a silastic tube passed into the ventricle via a burr hole. This tubing is tunneled subcutaneously to a valve chamber. The valve chamber, the second component, establishes a pressure gradient that ensures drainage of fluid away from the ventricle. The valve chamber, or in some cases a separate reservoir, allows access to the shunt system for patency testing, pressure measurement, CSF sampling, medication injection (e.g., chemotherapy, antibiotics), or contrast administration. Distal tubing, which is the third component, connects the valve chamber to a drainage point. The most common drainage site is the peritoneal cavity. Other drainage sites include the right atrium, gallbladder, pleural cavity, and ureter.

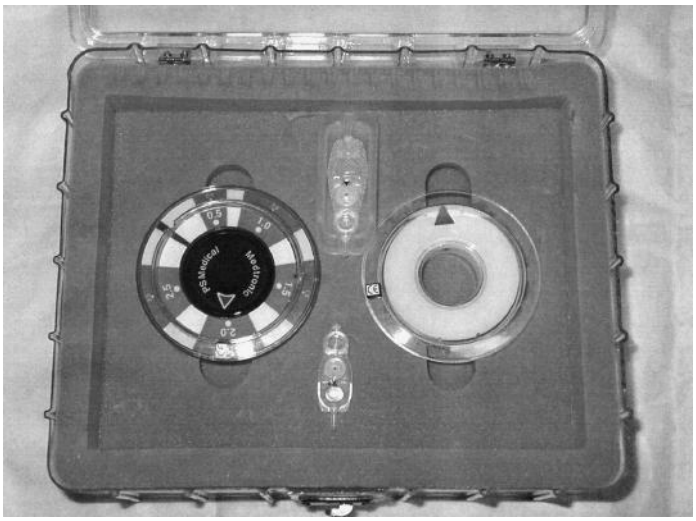

FIGURE 175-3. Example of a shunt kit. Circular objects on the left are a locator and a pressure/performance indicator. Circular object on the right is an adjustment tool. All three are needed to adjust the settings. Two sizes of valves are shown in the middle.

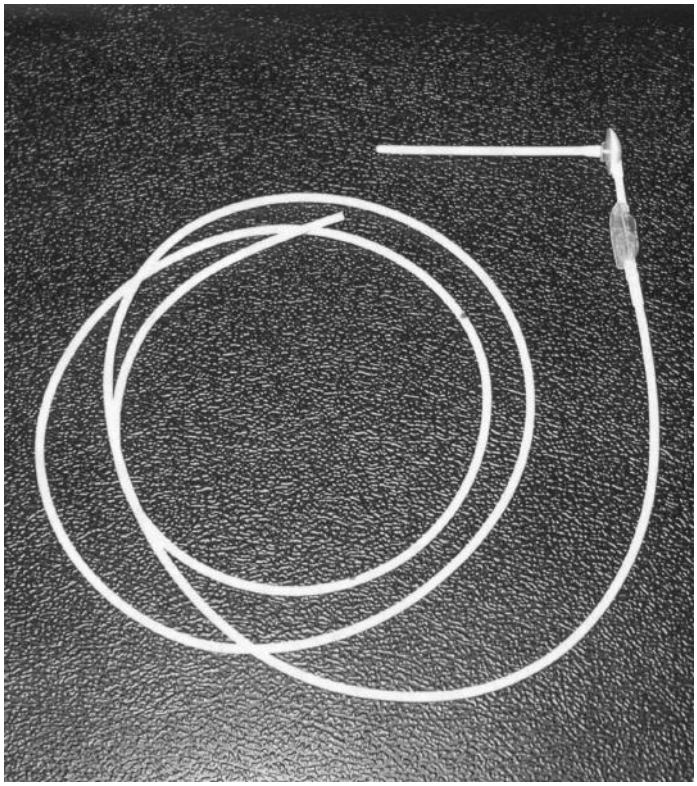

FIGURE 175-4. Typical ventriculoperitoneal shunt.

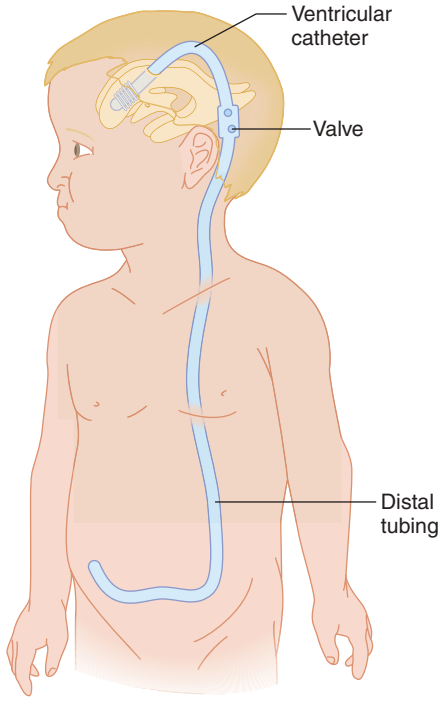

FIGURE 175-5. Ventriculoperitoneal shunt system.

Programmable shunt valves allow for easier control of flow rates, which is particularly useful in previously difficult cases that required frequent adjustments. The valve can be adjusted and tested using a locator and indicator tool to determine the pressure programmed into the valve. An adjustment tool can then be used to increase or decrease the valve's pressure or performance as needed. Typical nonadjustable pressure-type valves are available with low, medium, and high settings. These valves open at a pressure gradient of 2 to 4, 4 to 6, and 8 to 10 cm H_2O for the low, medium, and high settings, respectively. The adjustable valves typically have five preset pressure settings that can be selected or adjusted as clinically warranted. The patient (or family) should have been given a card that documents initial settings and any subsequent adjustments. Pressure setting can also be confirmed by radiography using the radiopaque dials on the valve.

Exposure to strong magnetic fields and some MRI units can change the valve pressure setting, so all patients should have the setting verified after any exposure to strong magnetic fields. Controversy still exists as to whether programmable valves offer an advantage over traditional valves in reducing the number of revisions and extending shunt life.[7-9]

CSF SHUNT MALFUNCTION

Shunt malfunctions are the most common complications encountered with CSF shunts. Shunt malfunction can be due to obstruction, mechanical failure, overdrainage, loculation of ventricles, or abdominal complications.

Obstruction **Obstruction is the most common type of shunt malfunction.** The most frequent location of obstruction is the proximal tubing, followed by the distal tubing, and then the valve chamber. Proximal obstructions usually occur within the first years after shunt insertion. **Table 175-3** lists the common causes of CSF shunt obstruction.

Distal obstruction is the most frequently encountered obstruction in shunts in place for >2 years.[6] Shunt obstruction usually manifests with signs and symptoms of increased intracranial pressure. Infants generally present with vomiting, irritability, and a bulging fontanelle.[10] Older children and adults may present with cephalgia, nausea, vomiting, lethargy, ataxia, and cranial nerve palsies.[10]

Mechanical Failure Mechanical failure of shunts can be secondary to fracture, disconnection, migration, or misplacement. Typically, fractures appear in distal tubing many years after shunt placement; this is due to both degradation of tubing and stress from the growth of the patient.[6] The most common location for a fracture is along the clavicle or lower ribs.[6] Patients present with mild symptoms of increased intracranial pressure. Local symptoms of pain, mild erythema, and edema over the affected area are not uncommon. In fact, it not unusual for a fracture to be found incidentally because the shunt tract often serves as a conduit between the fractured segments.[6] Disconnection often occurs shortly after insertion and manifests as increased intracranial pressure and fluid at the skin site around the disconnection. Migration occurs when a properly placed catheter migrates to a position in which drainage is compromised partially or completely. Misplacement entails the placement of the catheter into brain parenchyma, the choroid plexus, or the temporal horns; it usually manifests postoperatively with evidence of failure.

TABLE 175-3 Causes of CSF Shunt Obstruction

Distal obstruction
Kinking or disconnection of the tube
Pseudocyst formation
Infection

Overdrainage Overdrainage and the slit ventricle syndrome are seen in approximately 5% of patients with shunts. Because of overdrainage, the tissues actually occlude the orifices of the proximal shunt apparatus. As intracranial pressure increases, the same occluding tissue is disengaged, which allows drainage to resume. This phenomenon is cyclical and is responsible for the episodic or waxing and waning aspect of the presenting complaint. Patients present with episodes of elevated intracranial pressure caused by a transient obstruction of the ventricular catheter from a collapsed ventricle. Decreased cerebral compliance may prevent the ventricles from fully expanding as intracranial pressure and volume increase, which further contributes to ventricular collapse. The rate of this complication is lower for currently used shunt systems with antisiphon devices and programmable shunt valves.[8,11]

Loculation Separate, noncommunicating CSF accumulations may develop within a ventricle so that the shunt device is not able to drain the entire ventricular system, leaving behind enlarging pockets of fluid that may have compressive sequelae. Trapped fourth ventricle syndrome occurs when the fourth ventricle becomes loculated, presumably from closure of the sylvian aqueduct.[6] Patients present with typical symptoms of increased intracranial pressure as well as symptoms of brainstem compression, including poor feeding, disconjugate gaze, and difficulty swallowing.

Abdominal Complications Several abdominal processes can secondarily result in shunt malfunction. The most commonly encountered complication is malfunction due to pseudocyst formation. Pseudocysts are localized abdominal fluid collections that form around the peritoneal catheter. Infection is the major cause, with an infection rate of 40%.[12] They often are asymptomatic until they enlarge substantially enough to cause abdominal pain.

CLINICAL PRESENTATION

Symptoms of CSF shunt malfunction usually develop over several days, although rapid deterioration within 24 hours has been reported. **Clinical features include mental status changes, headache, nausea, vomiting, abdominal pain, lethargy, decreased intellectual performance, ataxia, coma, and autonomic instability.** Often, the presenting complaint is vague. No single sign or symptom is accurate in predicting shunt malfunction, although a decrease in level of consciousness may have the highest correlation with shunt malfunction.[6] As intracranial pressure increases, paralysis of upward gaze, dilated pupils, and papilledema may develop. Paralysis of upward gaze (or sundowning) is caused by impingement on the brainstem by the third ventricle as it engorges. Symptoms of slit ventricle syndrome are exacerbated or precipitated when the patient stands or exercises due to excessive CSF drainage and are relieved when the patient lies down or is in the Trendelenburg position.

SHUNT EVALUATION

Identification of shunt type is important, although frequently difficult. Many different types exist, and appropriate assessment depends on the apparatus implanted. For example, many flow control valves have a high set resistance so that flow is quite slow but steady. Conversely, such a flow pattern might indicate obstruction in a low-resistance shunt.[13] Evaluate shunt function by manual testing and radiologic studies. Palpation of the shunt allows the physician to locate the valve chamber. Shunt patency is evaluated somewhat differently for each type of device depending on features such as the presence of valves or dome- or cylinder-shaped reservoirs. Generally, testing follows intuitive expectations but still may prove perplexing to inexperienced clinicians. For a simple device, once the chamber is located, it is gently compressed and observed for refill. **Difficulty compressing the chamber indicates distal flow obstruction, whereas slow refill, defined as refill requiring >3 seconds after compression, generally indicates a proximal obstruction.** Compression is inaccurate for identifying shunt obstruction because up to 40% of obstructed shunts show normal refill during manual palpation.[4] Furthermore, positive predictive value has been found to be as low as 12% for shunt pumping.[13] In any case, further evaluation is required.

A shunt series of plain radiographs includes anteroposterior and lateral radiographs of the skull and an anteroposterior view of the chest and

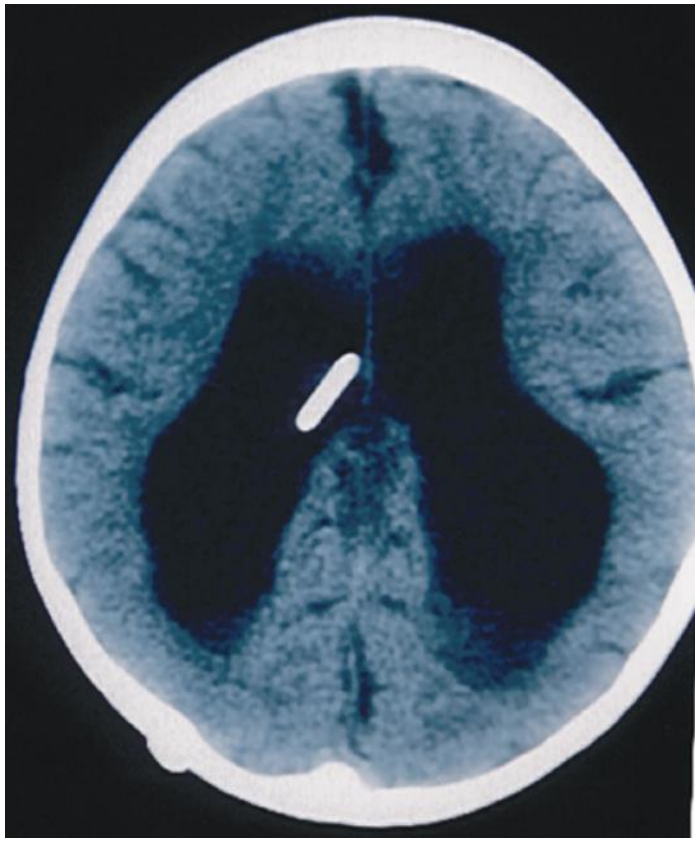

FIGURE 175-6. CT may reveal a persistent hydrocephalus despite the presence of a shunt, which suggests a malfunction. Comparison CTs are helpful when available.

abdomen (for ventriculoperitoneal shunts). Although plain radiography will identify kinking, migration, or disconnection of the shunt system, CT is required to evaluate ventricular size (**Figures 175-6 and 175-7**). **Compare with previous CT scans because many patients with shunts have an abnormal baseline ventricular size.** In one series using either CT or both CT and plain radiography, 24% of patients with documented shunt malfunction showed no radiologic evidence of the malfunction.[14] In another series, radiographs were shown to have a sensitivity of 20% and a negative predictive value of 22%; CT had a sensitivity of 83% and a negative predictive value of 95%.[15] Therefore, in patients with suggestive clinical features, unremarkable findings on CT and/or radiographic shunt series cannot be relied on to exclude shunt obstruction. Thus, **obtain neurosurgical consultation whenever shunt malfunction is suspected**.

FIGURE 175-7. Slit ventricle syndrome often presents with waxing and waning symptoms. The CT is often helpful in distinguishing it from other causes of malfunction.

Perform a shunt tap to make the diagnosis of shunt malfunction, exclude infection, or alleviate life-threatening increased intracranial pressure. Unless a CNS emergency exists, the shunt tap should be performed by a neurosurgeon to avoid damage to the valve apparatus. Emergency physicians should be prepared to perform a shunt tap if a neurosurgeon is unavailable or if a shunt tap is needed to control life-threatening increased intracranial pressure.

To perform a shunt tap, locate and sterilely prepare the site over the valve system or reservoir of the shaved scalp. A 23-gauge needle or butterfly attached to a manometer is inserted into the reservoir. If no fluid returns or flow ceases, a proximal obstruction is likely. Measure the opening pressure while the reservoir outflow is occluded. An opening pressure of ≥20 cm H_2O indicates a distal obstruction, whereas low pressures indicate a proximal obstruction. The normal basal intracranial pressure is 12 ± 2 cm H_2O.

Flash MRI has assumed a growing role in serial examination for shunt function to obviate some of the radiation exposure associated with CT. In certain institutions, single-shot T2-weighted MRI has become the initial imaging modality of choice. With the advent and widespread use of programmable shunts, the concern over shunt failure after MRI exists. The MRI magnetic field can change the valve-pressure setting in programmable valves. Newer programmable valves do not reprogram even at a 3-T magnetic field.[6] In general, the settings of a programmable valve should be checked by the neurosurgeon after a patient undergoes MRI.

TREATMENT OF SHUNT MALFUNCTION

Surgical intervention is generally required in cases of shunt obstruction. As a temporizing measure, intracranial pressure can be lowered by standard methods of hyperventilation and osmotic diuresis (mannitol). **If these measures fail and surgical intervention is not immediately available, intracranial pressure can be lowered by removing CSF via the reservoir if the malfunction is distal.** To prevent choroid plexus bleeding, CSF should be removed slowly, and the process should be discontinued when intracranial pressure reaches 10 to 20 cm H_2O. Stable patients in whom obstruction is suspected require admission and neurosurgical consultation. Observe patients for any neurologic changes, abdominal complaints, or fever.

SHUNT INFECTION

Infection rates range between 0.6% and 21% per procedure.[16-19] The highest infection rates are found in the very young and old and in patients who have had multiple shunt revisions. There is a 26% recurrence rate of shunt infection.[20] Patients who develop shunt infections demonstrate impairment in intellectual development compared with those who do not develop infection. Half of all shunt infections present within the first 2 weeks of placement, 70% present within 2 months, and 80% present within 6 months of placement. Up to 10% of shunt infections present >1 year after surgery.

CSF shunt infections can be categorized into internal and external infections. External infections involve the subcutaneous tract around the shunt, which is usually tender, and there is often an associated fluid collection within the skin. An internal infection involves the shunt and the CSF contained within that shunt. Patients with CSF shunts have a higher risk of developing meningitis from typical pathogens (e.g., *Streptococcus pneumoniae*, and *Neisseria meningitidis*) than the general population. This increased risk may be due to disruption of the blood–brain barrier by foreign material. Shunt infections are reduced with the use of antibiotic-impregnated catheters.[21,22]

The mortality is low if shunt infection is diagnosed and treated in a timely fashion. However, if ventriculitis develops, mortality ranges from 30% to 40%, which underscores the need for prompt diagnosis and aggressive management.[23]

BACTERIOLOGY

CSF shunt infections are typically caused by low-virulence organisms. In adults, the most commonly cultured agent is *Staphylococcus epidermidis*, which accounts for nearly half of all shunt infections, followed by *Staphylococcus aureus* and *Propionibacterium acnes*.[18,20] Gram-negative, anaerobic, and mixed infections account for approximately 5% to 10% of shunt infections. Gram-negative infections are associated with the highest mortality. *Candida* accounts for a small number of infections and should be considered in premature newborns, immunosuppressed patients, and patients on long-term, broad-spectrum antibiotics. It is associated with a 5.8% mortality rate.[20]

CLINICAL FEATURES

The clinical presentation varies with the virulence of the organism and the severity of the infection. Typically, patients present with symptoms of obstruction and meningeal symptoms, including mental status changes, headache, nausea, vomiting, neck stiffness, and irritability. Fever and abdominal pain may also be present. These signs are not universally noted. In fact, the finding of fever is highly variable, and meningismus may be present in only one third of patients with shunt infection.[18] Abdominal pain may be the predominant symptom in patients with ventriculoperitoneal shunts. Swelling, erythema, and tenderness along the site of the shunt tubing are highly suggestive of external shunt infection.[13]

Shunt nephritis involves a chronic complication of vascular shunts. Typically, patients develop a chronic bacteremia from coagulase-negative *Staphylococcus* leading to an immune response. The patient presents with a nephritic syndrome with fever episodes and increased urinary sediment. Treatment of the underlying infection leads to complete resolution of the renal disorder.[18]

DIAGNOSIS

A shunt tap is required to exclude CSF shunt infection (Figure 175-7). **A traditional lumbar puncture often misses CSF shunt infection** and has no meaningful role in the evaluation when shunt infection is suspected.

Analysis of fluid from infected CSF shunts usually reveals an elevated leukocyte count, elevated protein level, and normal glucose level. Almost one fifth of patients evaluated for shunt malfunction have positive CSF culture results despite normal results on CSF analysis. Other (non-CSF) laboratory values are rarely helpful in diagnosing CSF shunt infection. CT and plain radiographs of the shunt (shunt series) are required to exclude mechanical shunt malfunction, which often coexists with shunt infection.[24] Abdominal US or CT is indicated if an abdominal fluid collection, pseudocyst, or abscess is suspected. In patients with ventriculoatrial shunts, blood cultures are helpful in identifying the offending organism. In most other cases, hematogenous dissemination of infection is rare, thus rendering blood cultures of limited value.[24]

TREATMENT

Patients with CSF shunt infection or suspected shunt infection require emergent neurosurgical consultation and admission. Until the infecting agent is identified, therapy with broad-spectrum antibiotics effective against typical pathogens (e.g., ceftriaxone and vancomycin) is recommended. Rifampin has been given along with vancomycin for treatment of recurrent gram-positive infections because it easily penetrates the CSF. Early removal of the colonized device is important.

HALO DEVICES

The halo vest provides one of the most rigid types of cervical immobilization available. The halo vest consists of a lightweight radiolucent ring attached to a lightweight adjustable vest. Current vests allow adjustment of the cervical spine in multiple planes. Titanium pins that do not interfere with MRI are stronger, lighter, and more expensive than older stainless steel pins. Pins are usually tightened to 8 lb of pressure (**Figure 175-8**).[25]

FIGURE 175-8. Demonstration of halo device application by emergency medical technicians at a high school assembly. [Reproduced with permission from North Carolina SAFETeens, Inc.]

Halo devices are indicated for stabilization of an unstable cervical spine, including stabilization of fractures, dislocations, and subluxations, and alignment of severe kyphotic and scoliotic spines. A halo is not applied if there is a sensory deficit that extends beneath the halo vest because this leads to a higher risk of skin breakdown and infection. Pin sites are chosen to avoid nerves, vessels, and muscle while placing the pins in the thickest area of the calvaria possible. Four pins are generally used. The anterior pins are placed in the frontal or temporal regions. Posterior pins are placed in sites approximately opposite to the anterior pin sites.

COMPLICATIONS

Pin loosening is the most common complication encountered in the ED.[26] Obtain neurosurgical consultation and exclude infection of the pin site. **If pin loosening has caused movement of the halo device, assume that the cervical spine is unstable, immobilize the cervical spine using an alternative technique, and obtain radiographs to assess for proper alignment.** Tangential plain radiography, CT, or MRI can be used to exclude penetration of a pin through the inner table of the skull. Pin-site infection is the second most frequently encountered complication. It occurs in approximately 10% to 20% of patients with halo devices.[26] Nearly 50% of infections occur in the first 4 weeks after halo placement, and 60% involve the anterior pins. Careful examination is required to differentiate a localized pin-site infection from less common, more serious infections (<1% of cases), such as cellulitis, osteomyelitis, and abscess formation.[26] Consider these more serious infections if there is persistent pain, continued drainage despite antibiotic therapy, clear drainage, or a history of a fall. Patients with cellulitis often present with fever and systemic signs and symptoms of infection. Patients with osteomyelitis usually have a prolonged infection, pin-site loosening, and radiologic abnormalities. Patients who develop an abscess usually have neurologic changes and evidence of intertable penetration (CSF leak, trauma).

Local pin-site infections are commonly managed with local wound care. The skin around the pin site must be pulled away to allow thorough cleaning of the skin beneath the pin and the skin–pin interface with soap and water four times a day. Obtain culture specimens from the wound site and administer antibiotics effective against skin pathogens (e.g.,

Staphylococcus and *Streptococcus* species). If local infection does not respond to treatment or if cellulitis, osteomyelitis, or abscess is suspected, obtain neurosurgical consultation for admission, IV antibiotics, and possible surgical intervention.

Pin-site discomfort occurs in up to 20% of patients.[26] It is most commonly a result of local inflammation. However, consider infection (localized or systemic) in each case. Sensory and motor deficits or paresthesias indicate nerve damage or pressure, whereas painful mastication indicates temporalis muscle inflammation, which often indicates too lateral a placement of pins. If infection is excluded, a short course of analgesics is recommended. Neurosurgical consultation is required if pain continues or a serious complication is suspected.

Ring migration or loss of immobilization occurs in 10% to 13% of patients. Suspect loss of immobilization in patients complaining of neck pain and change in fit or position of the ring or vest. Immediately immobilize the cervical spine using an alternative technique (e.g., hard collar plus backboard) and obtain radiographs to assess for changes in alignment. Obtain neurosurgical consultation for reapplication of the halo device.

Skin breakdown and pressure sores occur in 11% to 30% of patients. If either is present, inspect the vest for adequate padding and strap position. Urgent referral to a neurosurgeon for refitting may be required.

Dysphagia occurs in 1% to 2% of patients with halo devices.[26,27] Immobilization that holds the head in exaggerated extension is the usual cause of the dysphagia. Halo adjustment will remedy this problem. Alternatively, dysphagia can occur following anterior displacement of a bone graft. This diagnosis can be made by plain radiography or a swallowing study, and emergency surgical intervention is required.

Dural punctures occur in 1% to 2% of patients and are a result of halo system trauma.[26,27] This is rarely attributable to postapplication trauma because newer pin tighteners are designed to fail when torque exceeds 8 lb. Symptoms include headache, malaise, or visual changes. Physical examination may reveal a CSF leak or evidence of skull fracture. All patients with dural punctures require admission and neurosurgical consultation. Treatment includes elevation of the head, IV antibiotics, and pin removal.

In rare cases, CPR is required in patients with halo devices. To perform chest compressions, remove the anterior portion of the vest. Instructions for removing the halo vest are printed on the front of most vests. Intubation is performed with the halo in place. Emergent or semiemergent intubation was required 13% of the time in one series.[27] If orotracheal intubation is unsuccessful, other airway management options include nasotracheal intubation, laryngeal mask airway, and cricothyrotomy.

SPECIAL POPULATIONS

Use of halo devices carries a special risk in the elderly patient. A mortality rate of 21% is reported in patients >79 years of age.[28] Rates of serious complications, such as respiratory depression (8% of cases) and dysphagia (11% of cases), are much higher in elderly patients.[28]

OTHER CENTRAL NERVOUS SYSTEM DEVICES

INTRATHECAL BACLOFEN INFUSION DEVICES

Generalized dystonia occurs in 15% to 25% of patients with cerebral palsy. Baclofen, a γ-aminobutyric acid agonist that acts at the level of the spinal cord by impeding the release of excitatory neurotransmitters, decreases spasticity. Oral baclofen offers patients only mild relief because of its inability to cross the blood–brain barrier and its poor lipid solubility. Intrathecal administration (**Figure 175-9**) is more effective, requires lower dosages, and leads to higher CSF levels. Intrathecal baclofen reduces spasticity and improves gait, sitting ability, and upper extremity function in most patients.[29] Intrathecal baclofen pumps are also used to treat spasticity related to spinal cord injury, multiple sclerosis, brain injury, cerebrovascular accidents, and perinatal infection sequelae.[29,30] Complications observed in patients receiving continuous intrathecal baclofen can be divided into medication-related, mechanical, and infection-related complications and are listed in **Table 175-4**.

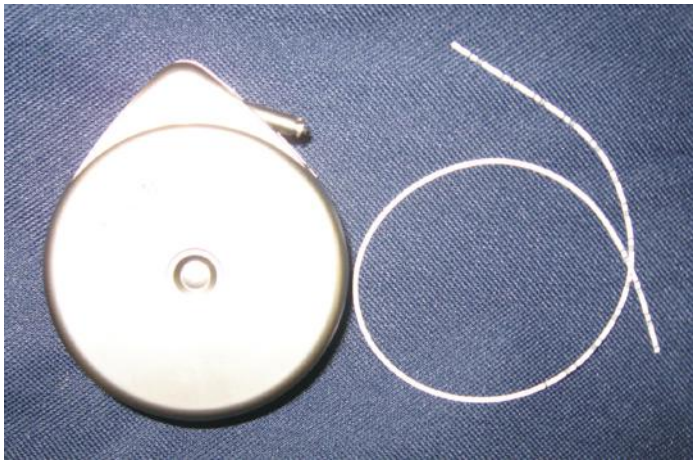

FIGURE 175-9. Typical baclofen pump.

When a complication occurs disrupting the administration of baclofen, withdrawal symptoms can be severe and life-threatening, including extreme hypertonicity and spasms that may lead to rhabdomyolysis. The apparent accelerated spasticity should signal to the provider that a potential complication has arisen. Oral baclofen, dantrolene, and oral or parenteral benzodiazepines may be used to alleviate these symptoms. Complications occur in approximately 20% to 30% of all cases. Infectious complications occur more frequently in children, revised pumps, and those placed subcutaneously.[31,32] Infection rate is 10%, with most infections presenting during the first month after placement.[29] Most infections are caused by *Staphylococcus* species, with a recent increase in methicillin-resistant *S. aureus*.[33] Serious infections and meningitis may arise even without local symptoms.[33] The majority of infections require neurosurgical consultation and IV antibiotics. Direct concerns about baclofen pumps to the neurosurgeon.

IMPLANTABLE CENTRAL NERVOUS SYSTEM STIMULATORS

The pathogenesis of Parkinson's disease is thought to involve unregulated activity of the subthalamic nucleus and globus pallidus interna. High-frequency stimulation with implantable CNS devices is being used for suppression of parkinsonian and essential tremors. Neurostimulation is typically used if drug therapy has failed to control tremors. Neurostimulation is as efficient at controlling tremors as classic thalamotomy but is less invasive. Deep brain stimulation studies have shown a 40% to 75% improvement in motor scores as well as improvement of rigidity, bradykinesia, and postural instability.[34] Reported complication rates range from 7% to 65%, with

Pump failure
Catheter extrusion
Catheter dislodgement
Infection
Local infection
Meningitis
Cerebrospinal fluid fistula formation

a decline in the number of reported complications as physician experience increases.[34] Infection rates approach 3% to 10%.[34] Patients may present to the ED with varied complaints, including problems related to the subcutaneous pulse generator, temporary or permanent paresthesias, dysarthria, disequilibrium, or failure of the neurostimulator to suppress tremors. Neurosurgical consultation is needed because these complaints may represent lead displacement or migration requiring surgical correction or replacement. If the diagnosis remains uncertain, observation with the stimulator in the off position may be required to help differentiate mechanical failure from an acute neurologic deficit.[34]

SPINAL CORD STIMULATION

Spinal cord stimulation is an established modality for treating chronic back pain, multiple sclerosis pain, complex regional pain syndromes, phantom pain, diabetic neuropathy, postherpetic neuralgia, angina pectoris, intractable pain associated with some malignancies, and the pain syndromes associated with vascular disease. Multicontact electrodes are placed in the epidural space, and the distal end of the electrode is connected to an internalized pulse generator. The therapeutic response is thought to be a result of stimulation of one of several dorsal tracts as well as activating the release of inhibitory neurotransmitters.[35,36] Complications include dural puncture, spinal cord compression, CSF leak, hemorrhage, infection, abscess, epidural fibrosis, migration, interruption of wires, corrosion of contacts, and battery failure. The most frequent complication is device failure, accounting for 17% to 25% of complications.[37] The rate of infection is reported between 2.5% and 5%.[36] Patients with these devices should not undergo MRI.

PERIPHERAL NERVE STIMULATION

Peripheral nerve stimulators are used to treat neuropathic pain disorders in patients with chronic intractable pain such as with occipital neuralgia. The device is similar to other stimulators except that the electrodes are placed in the subcutaneous tissue overlying the peripheral nerves. Case reports of interference of stimulators causing pauses in cardiac pacemakers exist and thus must be considered in patients with both a pacemaker and stimulator and a new conduction abnormality.[38]

Toxicology

CHAPTER 176

General Management of Poisoned Patients

Shaun Greene

INTRODUCTION

Poisoning is a worldwide problem that consumes substantial health care resources and causes many premature deaths. The burden of serious poisoning is carried by the developing world[1,2]; however, poisoning-related morbidity and mortality is also a significant public health concern in the developed world.[3-9]

Unintentional poisoning deaths in the United States are increasing, especially as a result of prescription analgesics. This increase has been ascribed to increasing prescription rates and aging of the baby-boom population.[10-12] U.S. poison control centers documented 2.38 million human exposures in 2010, with 1146 associated deaths.[13] Prevention is the key to reducing unintentional poisoning deaths. Pharmacists can that ensure medications are labeled correctly, anticipate potential drug interactions, and educate patients to use medications safely. To prevent pediatric deaths from poisoning, parents have the responsibility to ensure that poisons are placed in childproof, labeled containers stored in adult-only accessible nonfood storage areas. Teachers and healthcare providers can provide age-appropriate education to children about the dangers of poisons. After an exposure, poison control centers staffed by highly trained individuals can provide customized advice to healthcare providers and the public. Poison control centers also participate in prevention, education, and toxico-surveillance activities.

Exposures occur most commonly by ingestion; other routes include inhalation, insufflation, cutaneous and mucous membrane exposure, and injection. Some exposures have minimal risk. The criteria used to determine whether the exposure is nontoxic are: (1) an unintentional exposure to a clearly identified single substance, (2) where an estimate of dose is known, and (3) a recognized information source (e.g., a poison control center) confirms the substance as nontoxic in the reported dose. Asymptomatic patients with nontoxic exposures may be discharged after a short period of observation, providing they have access to further consultation and a safe discharge destination.

Serious clinical effects occur in <5% of acutely poisoned patients presenting to developed-world hospitals, and in-hospital mortality rates are <1%.[9,13]

RESUSCITATION

Resuscitation is the first priority in any poisoned patient. After resuscitation, a structured risk assessment is used to identify patients who may benefit from an antidote, decontamination, or enhanced elimination techniques. Most patients only require provision of good supportive care during a period of observation in an appropriate environment.

Treatment of cardiac arrest in poisoned patients follows Advanced Cardiac Life Support guidelines with the addition of interventions potentially beneficial in toxin-induced cardiac arrest (**Table 176-1**).[14] Prolonged resuscitation is generally indicated, as patients are often young with minimal preexisting organ dysfunction. Utilization of extracorporeal cardiac and respiratory assist devices until organ toxicity resolves may be life-saving.

Stabilization of airway, breathing, and circulation represents initial priorities. Compromised airway patency or reduced respiratory drive may lead to inadequate ventilation; provision of a mechanical airway and assisted ventilation is vital in these circumstances. IV crystalloid bolus (10 to 20 mL/kg) is first-line treatment of hypotension. Since most patients without toxin-induced fluid loss are generally not fluid depleted, avoid administration of excess fluid. Persisting hypotension despite an adequate volume infusion may respond to a specific antidote. Otherwise, cautious administration of an inotropic agent is indicated. Inotrope choice is guided by knowledge of the toxin's toxicodynamic properties and assessment of circulatory status (e.g., cardiac pump failure versus vasodilatory shock).

ANTIDOTES

Stabilization of airway, breathing, and circulation allows further assessment of blood glucose concentration, temperature, and conscious state. Although the proper use of antidotes (**Table 176-2**) is important, only a few are indicated before cardiopulmonary stabilization (e.g., naloxone for opiate toxicity, cyanide antidotes for cyanide toxicity, and atropine for organophosphate poisoning).

HYPOGLYCEMIA

Treat hypoglycemia with IV dextrose (glucose). Patients at risk of Wernicke's encephalopathy also require thiamine, but do not require that it be administered before the dextrose.[15] Altered mental status when hypoglycemia cannot be excluded is an indication for IV dextrose. Supplemental oxygen, thiamine, glucose, and naloxone are often administered empirically as a cocktail in cases of altered mental status. Although relatively safe and affordable in the developed world, this approach may not be cost-effective in developing countries. The decision to administer an antidote should be made after a rapid collateral history is obtained and targeted examination completed. Altered mental status not responding to an antidote or not consistent with exposure history requires further investigation. Metabolic, infective, and surgical (e.g., intracranial injury) causes of altered mental status should be considered.

CARDIAC ARRHYTHMIAS

In general, antiarrhythmic drugs are not first-line treatment for toxin-induced arrhythmias, as most antiarrhythmic drugs have proarrhythmic and negative inotropic properties. Most toxin-induced arrhythmias respond to correction of hypoxia, metabolic/acid–base abnormalities, and administration of an antidote (e.g., digoxin Fab). Sodium bicarbonate is administered for sodium-channel blocker toxicity with cardiovascular complications, such as wide QRS complex tachyarrhythmias. Ventricular tachyarrhythmias may respond to overdrive pacing.

SEIZURES

Drug-induced seizures are treated with titrated doses of IV benzodiazepines, with the exception that isoniazid-induced seizures require pyridoxine. Metabolic disorders, such as hypoglycemia and hyponatremia, can also produce seizures and should be rapidly excluded. Barbiturates are second-line agents for benzodiazepine-resistant seizures (once isoniazid-induced seizures are excluded). **There is no role for phenytoin in the treatment of toxin-induced seizures; it has neither theoretical nor proven efficacy, and may worsen toxicity.**[16]

TABLE 176-1 Potential Interventions in Toxin-Induced Cardiac Arrest[15]

Toxin or Toxin/Drug Class	Intervention
Toxins with a specific antidote (examples) Digoxin Organophosphates Envenomation	Antidote Digoxin Fab Atropine Antivenom
Sodium channel blocker or wide-complex tachycardia	Sodium bicarbonate
Calcium channel blocker or β-blocker	High-dose insulin
Local anesthetic agents Lipophilic cardiotoxins	IV lipid emulsion
Other Therapies to Consider	
Cardiac pacing Intra-aortic balloon pump Extracorporeal membrane oxygenation	

AGITATION

Agitation is treated with titrated doses of benzodiazepines. Large doses may be required and are appropriate in monitored settings where advanced airway interventions are available if required. Although antipsychotic agents are often used as second-line agents for toxin-induced agitation, they have theoretical disadvantages, including anticholinergic and extrapyramidal effects.[17] Droperidol has been associated (rarely) with QT interval prolongation and cardiac arrhythmias.

HYPERTHERMIA AND HYPOTHERMIA

Patients with core temperatures of >39°C (>102.2°F) require aggressive active cooling measures to prevent complications such as rhabdomyolysis, organ failure, and disseminated intravascular coagulation. Sedation, neuromuscular paralysis, and intubation are required if active measures are ineffective. Several toxidromes associated with hyperthermia are treated with specific pharmaceutical agents: sympathomimetic (benzodiazepines), serotonin (cyproheptadine[18]), and neuromuscular malignant syndrome (bromocriptine[19]).

TABLE 176-2 Common Antidotes Used in Resuscitation of the Acutely Poisoned Patient

Antidote	Pediatric Dose	Adult Dose	Indication
Calcium chloride 10% 27.2 milligrams/mL elemental Ca	0.2–0.25 mL/kg IV	10 mL IV	Calcium channel antagonists
Calcium gluconate 10% 9 milligrams/mL elemental Ca	0.6–0.8 mL/kg IV	10–30 mL IV	Hypermagnesemia Hypocalcemia
Cyanide antidote kit Amyl nitrite	Not typically used	1 ampule O_2 chamber of ventilation bag 30 s on/30 s off	Cyanide Hydrogen sulfide (use only sodium nitrite)
Sodium nitrite (3% solution)	0.33 mL/kg IV	10 mL IV	Cyanide
Sodium thiosulfate (25% solution)	1.65 mL/kg IV	50 mL IV	Cyanide
Dextrose (glucose)	0.5 gram/kg IV	1 gram/kg IV	Insulin Oral hypoglycemics
Digoxin Fab Acute toxicity	1–2 vials IV	5–10 vials	Digoxin and other cardioactive steroids
Flumazenil	0.01 milligram/kg IV	0.2 milligram IV	Benzodiazepines
Glucagon	50–150 micrograms/kg IV	3–10 milligrams IV	Calcium channel blockers β-Blockers
Hydroxocobalamin	70 milligrams/kg IV (maximum 5 grams). Can be repeated up to 3 times. Administer with sodium thiosulfate.		Cyanide Nitroprusside
IV lipid emulsion 20%	1.5 mL/kg IV bolus over 1 min (may be repeated two times at 5-min intervals), followed by 0.25 mL/kg per minute	100-mL IV bolus over 1 min, followed by 400 mL IV over 20 min	Local anesthetic toxicity Rescue therapy for lipophilic cardiotoxins
Methylene blue	1–2 milligrams/kg IV Neonates: 0.3–1.0 milligram/kg IV	1–2 milligrams/kg IV	Oxidizing toxins (e.g., nitrites, benzocaine, sulfonamides)
Naloxone	As much as required Start: 0.01 milligram IV	As much as required Start: 0.1–0.4 milligram IV	Opioids Clonidine
Pyridoxine	Gram for gram if amount isoniazid ingested is known		Isoniazid *Gyromitra esculenta* Hydrazine
	70 milligrams/kg IV (maximum 5 grams)	5 grams IV	
Sodium bicarbonate	1–2 mEq/kg IV bolus followed by 2 mEq/kg per h IV infusion		Sodium channel blockers Urinary alkalinization
Thiamine	5–10 milligrams IV	100 milligrams IV	Wernicke's syndrome Wet beriberi

Drug-induced coma with subsequent immobility and environmental exposure or inherent drug toxicity (opioids, phenothiazines, ethanol) may produce hypothermia. A core temperature <32°C (<90°F) is an indication for active rewarming.

NALOXONE

Naloxone is a nontoxic, diagnostic, and therapeutic antidote. It is a competitive opioid antagonist administered IV, IM, or intranasally[20] to reverse opioid-induced deleterious hypoventilation. Naloxone can be used as a diagnostic agent when history and/or examination findings (respiratory rate of <12 breaths/min is a predictor of response to naloxone) suggest possible opioid exposure. Naloxone is titrated to clinical effect using bolus doses, typically 0.1 to 0.4 milligrams. Large initial bolus doses may precipitate vomiting and aspiration, acute opioid withdrawal, or an uncooperative, agitated patient. Miosis is an unreliable indicator of naloxone's adequate clinical effect, as some opioids do not affect pupil size. Doses are titrated to achieve desirable ventilation and conscious state (adequate respiratory rate, normal arterial oxygen saturations on room air, and verbal or motor response to voice). Although naloxone may reverse the effects of opioids for 20 to 60 minutes, the effect of many opioids will outlast this time frame with possible return of respiratory depression. Patients should be observed for 2 to 3 hours after administration of IV naloxone.

INTRAVENOUS LIPID EMULSION

Animal studies demonstrate the potential for IV lipid emulsion to act as an antidote for lipophilic toxins. Provision of an intravascular "lipid sink" is postulated as the predominant mechanism, as sequestration of lipophilic toxins prevents target receptor interaction. Human case reports indicate that IV lipid emulsion may provide benefit in cases of potentially life-threatening toxicity from a local anesthetic agent, haloperidol, tricyclic antidepressant, lipophilic β-blocker, or calcium channel blocker.[21] **Currently, IV lipid emulsion can be considered in life-threatening cardiotoxicity caused by lipophilic cardiotoxins that is resistant to conventional therapies.**

RISK ASSESSMENT

Following initial resuscitation and stabilization, a risk assessment is performed to predict course of clinical toxicity, interventions required, and patient disposition. Risk assessment is formulated using history, examination, and ancillary test results. Acute poisoning is a dynamic process; therefore, risk assessment may change with time and requires ongoing review.

HISTORY

Patients may not provide a clear history due to psychiatric illness, clinical effects of exposure, and fear of arrest or repercussions from family or friends. Information including identity of substances, doses, and route of exposure is crucial in formulating a risk assessment. Obtain collateral information from family, friends, previous medical records, and usual healthcare provider. Prehospital emergency services can provide information regarding empty medication containers or the scene environment (smells, particular materials or substances present). If possible, obtain knowledge of hobbies, occupation, presence of a suicide note, and recent changes in patient behavior.

EXAMINATION

A systematic physical examination can yield important clues to the nature and potential severity of an exposure (**Table 176-3**). Examine the skin folds, body cavities if appropriate, and clothing for retained tablets or substances.

TOXIDROMES

Substances belonging to a particular pharmaceutical/chemical class often produce a cluster of symptoms and signs, or "toxidrome" (**Table 176-4**), enabling the identification of potential toxins when a clear history is unavailable.

TABLE 176-3 Examination of the Poisoned Patient

Organ System	Examination	Example of Finding (Possible Significance)
General appearance	General demeanor and dress Signs of injury Odors Mental state Nutritional state Temperature	Unkempt (psychiatric illness) Scalp hematoma (intracranial injury) Malnourished (IV drug use, HIV infection) Smell of bitter almonds (cyanide toxicity)
Central nervous	Conscious state Pupil size and reactivity Eye movements Cerebellar function/gait	Miosis (opioids, organophosphates, phenothiazines, clonidine intoxication) Nystagmus/ataxia (anticonvulsant and ethanol toxicity)
Cardiovascular	Heart rate/blood pressure Cardiac auscultation	Murmur (endocarditis/IV drug abuse)
Respiratory	Oxygen saturation Respiratory rate Chest auscultation	Fever/crepitations/hypoxia (aspiration pneumonia) Bronchorrhea/crepitations/hypoxia (organophosphate toxicity)
Gastrointestinal	Oropharynx Abdomen Bladder	Urinary retention (anticholinergic toxicity) Oral cavity burns (corrosive ingestion) Hypersalivation (cholinergic toxidrome)
Peripheral nervous	Reflexes Tone Fasciculations Tremor Clonus	Tremor/fasciculations (lithium toxicity) "Lead pipe" rigidity (neuromuscular malignant syndrome) Clonus/hyperreflexia (serotonin toxicity)
Dermal/peripheral	Bruising Cyanosis Flushing Dry/moist skin Injection sites Bullae	Bruising (coagulopathy, trauma, coma) Flushing /warm, dry skin (anticholinergic toxicity) Warm, moist skin (sympathomimetic toxicity) Bullae (prolonged coma, barbiturates)

DIAGNOSTIC TESTING

A serum acetaminophen concentration is a routine screening test in poisoned patients. Early acetaminophen poisoning is often asymptomatic and does not have a readily identifiable toxidrome at the time when antidotal treatment is most efficacious. Acetaminophen screening is especially important in patients presenting with altered mental status or a self-harm ingestion, for whom an accurate history may not be available.

An electrocardiogram is a useful test to detect cardiac conduction abnormalities and identify patients at increased risk of toxin-induced adverse cardiovascular events.[22]

Measurement of drug or toxin concentrations in body fluids is not required in most poisonings, but in some exposures, measurement of serum drug concentrations does influence management (**Table 176-5**).

Toxicologic screening tests of the urine and/or blood can be done in a central laboratory or performed with point-of-care drug screening

TABLE 176-4 Common Toxidromes

Toxidrome	Examples of Agents	Examination Findings (most common in bold)
Anticholinergic	Atropine, *Datura* spp., antihistamines, antipsychotics	**Altered mental status, mydriasis, dry flushed skin, urinary retention, decreased bowel sounds, hyperthermia, dry mucous membranes** Seizures, arrhythmias, rhabdomyolysis
Cholinergic	Organophosphate and carbamate insecticides Chemical warfare agents (Sarin, VX)	**Salivation, lacrimation, diaphoresis, vomiting, urination, defecation, bronchorrhea, muscle fasciculations, weakness** Miosis/mydriasis, bradycardia, seizures
Ethanolic	Ethanol	**Central nervous system depression, ataxia, dysarthria, odor of ethanol**
Extrapyramidal	Risperidone, haloperidol, phenothiazines	**Dystonia, torticollis, muscle rigidity** Choreoathetosis, hyperreflexia, seizures
Hallucinogenic	Phencyclidine Psilocybin, mescaline Lysergic acid diethylamide	**Hallucinations, dysphoria, anxiety** Nausea, sympathomimetic signs
Hypoglycemic	Sulfonylureas Insulin	**Altered mental status, diaphoresis, tachycardia, hypertension** Dysarthria, behavioral change, seizures
Neuromuscular malignant	Antipsychotics	**Severe muscle rigidity, hyperpyrexia, altered mental status** Autonomic instability, diaphoresis, mutism, incontinence
Opioid	Codeine Heroin Morphine	**Miosis, respiratory depression, central nervous system depression** Hypothermia, bradycardia
Salicylate	Aspirin Oil of Wintergreen (methyl salicylate)	**Altered mental status, respiratory alkalosis, metabolic acidosis, tinnitus, tachypnea, tachycardia, diaphoresis, nausea, vomiting** Hyperpyrexia (low grade)
Sedative/hypnotic	Benzodiazepines Barbiturates	**Central nervous system depression, ataxia, dysarthria** Bradycardia, respiratory depression
Serotonin	SSRIs MAOIs Tricyclic antidepressants Amphetamines Fentanyl St. John's wort	**Altered mental status, hyperreflexia and hypertonia (>lower limbs), clonus, tachycardia, diaphoresis** Hypertension, flushing, tremor
Sympathomimetic	Amphetamines Cocaine Cathinones	**Agitation, tachycardia, hypertension, hyperpyrexia, diaphoresis** Seizures, acute coronary syndrome

Abbreviations: MAOI = monoamine oxidase inhibitor; SSRI = selective serotonin reuptake inhibitor.

assays.[23] However, the results seldom directly influence patient management, and toxicology screening has limitations (**Table 176-6**).

Toxicologic screening may be appropriate for medicolegal reasons, especially in pediatric cases when inappropriate drug administration or nonaccidental injury is suspected. A positive urine drug screen for an illicit substance is an indication to involve local child protection services.

TABLE 176-5 Drug Concentrations That May Assist Patient Assessment or Management

Acetaminophen	Methanol
Carbamazepine	Methotrexate
Carbon monoxide	Paraquat
Digoxin	Phenobarbital
Ethanol	Phenytoin
Ethylene glycol	Salicylate
Iron	Theophylline
Lithium	Valproic acid
Methemoglobin	

TABLE 176-6 Limitations of Toxicologic Drug Screening Assays

Nonspecific	Most tests use enzyme-immunoassays that only detect *typical* drugs within a class: opioids, amphetamines, benzodiazepines, cannabinoids, cocaine, barbiturates. Amphetamine screens do not detect methylenedioxymethamphetamine. Opioid screens do not detect meperidine. Benzodiazepine screens do not detect flunitrazepam.
Time frame	Drugs may be detected days to weeks after exposure. A positive test may not account for current clinical findings.
Cross-reactivity	Carbamazepine, cyproheptadine, and chlorpromazine test positive for tricyclic antidepressants. Selegiline, methylphenidate, and pseudoephedrine test positive for amphetamines.
Noninclusive	A negative drug screen does not exclude a rare exposure.
Sampling error	Assay may be negative if dilute urine is tested.

DECONTAMINATION

Decontamination is required for toxic exposures affecting large dermal areas. Healthcare providers wearing personal protective equipment (if indicated) or observing universal precautions (gown, gloves, eye protection) should assist with undressing and washing the patient using copious amounts of water. Contaminated clothing is collected, bagged, and properly disposed. Decontamination ideally occurs in a separate area adjacent to the ED, minimizing cross-contamination.

OCULAR DECONTAMINATION

Eye exposures may require local anesthetic (e.g., 0.5% tetracaine) instillation and lid retractors to facilitate copious irrigation with crystalloid solution. Alkalis produce greater injury than acids due to deep tissue penetration via liquefaction so that prolonged irrigation (1 to 2 hours) may be required. Ten minutes after irrigation (allowing equilibration of crystalloid and conjunctival sac pHs), conjunctival sac pH is tested. Irrigation continues until pH is <7.4. Ophthalmologic consultation is indicated for all ocular alkali injuries.

GASTROINTESTINAL DECONTAMINATION

Gastric decontamination is not a routine part of poisoned-patient management; there is minimal evidence demonstrating positive benefit, and there are associated complications (**Table 176-7**). Gastric decontamination may be considered in individual patients after a three-question risk-benefit analysis: (1) Is this exposure likely to cause significant toxicity? (2) Is gastrointestinal decontamination likely to change clinical outcome? (3) Is it possible that gastrointestinal decontamination will cause more harm than good?[24]

Emesis Traditionally, ipecac syrup was administered to induce vomiting, theoretically emptying the stomach of poisons. No published evidence supports the induction of emesis, and adverse outcomes associated with emesis are documented.[25] The American Association of Poison Control Centers guideline[25] comments that ipecac may be used in rare circumstances in remote locations, but this recommendation has been questioned.[26] There is no role for the induction of emesis in the ED.[27]

Orogastric Lavage Once a widely practiced intervention, attempted removal of ingested toxin from the stomach by aspiration of fluid placed via an orogastric tube is now rarely indicated. No published evidence demonstrates that orogastric lavage changes outcome, and the procedure has numerous complications.[28] Gastric lavage may be considered in cases of ingestion of a life-threatening amount of poison within the previous hour where institution of supportive care and antidotal therapy would not ensure full recovery. When orogastric lavage is performed in a resuscitation area:

- Ensure a protected airway if consciousness level is reduced.
- Use a 36 to 40F-gauge orogastric tube (22 to 24F in children).
- Position the patient on the left side with the head down 20 degrees.
- Pass lubricated tube down the esophagus a distance equal to that between chin and xiphoid process.
- Confirm tube position by insufflation of air.
- Gently lavage with 200 mL (10 mL/kg in children) of warm tap water.
- Continue until returned fluid is clear.
- Consider administration of activated charcoal via orogastric tube before removal.

Single-Dose Activated Charcoal Super-heating carbonaceous material produces activated charcoal, a highly porous substance, which is suspended in solution and given PO as a slurry. Toxins within the gastrointestinal lumen are adsorbed onto the activated charcoal and carried through the gastrointestinal tract, limiting absorption.[29] Activated charcoal does not effectively adsorb metals, corrosives, and alcohols. The decision to give activated charcoal requires individual patient risk assessment and is not considered routine management.

Activated charcoal may be effective when given >60 minutes after ingestion of substances known to slow gastrointestinal motility (e.g., anticholinergics)[30] or after massive ingestion of a substance associated with bezoar formation (e.g., salicylates). Activated charcoal mixed with ice cream improves palatability for children. Activated charcoal can be administered to intubated patients using an orogastric or nasogastric tube. There are insufficient published data supporting the routine use of a cathartic agent added to activated charcoal.[31]

TABLE 176-7 Indications, Contraindications, and Complications of Gastrointestinal Decontamination Procedures

Orogastric Lavage	
Indications	Rarely indicated Consider for recent (<1 hour) ingestion of life-threatening amount of a toxin for which there is no effective treatment once absorbed
Contraindications	Corrosive/hydrocarbon ingestion Supportive care/antidote likely to lead to recovery Unprotected airway Unstable, requiring further resuscitation (hypotension, seizures)
Complications	Aspiration pneumonia/hypoxia Water intoxication Hypothermia Laryngospasm Mechanical injury to gastrointestinal tract Time consuming, resulting in delay instituting other definitive care
Activated Charcoal	**Adults 50 grams orally, children 1 gram/kg orally**
Indications	Ingestion within the previous hour of a toxic substance known to be adsorbed by activated charcoal, where the benefits of administration are judged to outweigh the risks
Contraindications	Nontoxic ingestion Toxin not adsorbed by activated charcoal Recovery will occur without administration of activate charcoal Unprotected airway Corrosive ingestion Possibility of upper gastrointestinal perforation
Complications	Vomiting Aspiration of the activated charcoal Impaired absorption of orally administered antidotes
Whole-Bowel Irrigation	**Polyethylene glycol 2 L/h in adults, children 25 mL/kg per hour (maximum 2 L/h)**
Indications (potential)	Iron ingestion >60 milligrams/kg with opacities on abdominal radiograph Life-threatening ingestion of diltiazem or verapamil Body packers or stuffers Slow-release potassium ingestion Lead ingestion (including paint flakes containing lead) Symptomatic arsenic trioxide ingestion Life-threatening ingestions of lithium
Contraindications	Unprotected airway Gastrointestinal perforation, obstruction or ileus, hemorrhage Intractable vomiting Cardiovascular instability
Complications	Nausea, vomiting Pulmonary aspiration Time consuming; possible delay instituting other definitive care

Whole-Bowel Irrigation Polyethylene glycol is an osmotically balanced electrolyte solution. Administration in large quantities mechanically forces substances through the gastrointestinal tract, limiting toxin absorption.[32] Polyethylene glycol can be administered orally to cooperative, awake patients, but consider formal airway control if consciousness is likely to deteriorate. Minimize risk of pulmonary aspiration during whole-bowel irrigation by patient positioning (head up 30 degrees), ensuring bowel sounds are present during fluid administration, 1:1 nursing with suctioning of the oral cavity during infusion, and utilization of cuffed endotracheal tubes.

Evidence supporting whole-bowel irrigation is limited to volunteer studies and case reports[32] from which potential indications have been developed (**Table 176-7**). Nonsurgical treatment of asymptomatic body drug packers using whole-bowel irrigation is increasingly common, although no randomized clinical trials exist.[33] An antiemetic such as the prokinetic agent metoclopramide may be required to control polyethylene glycol–induced gastric distension and vomiting. The endpoint of whole-bowel irrigation treatment is clear rectal effluent and imaging demonstrating absence of foreign bodies.

ENHANCED ELIMINATION

MULTIDOSE ACTIVATED CHARCOAL

Multidose activated charcoal increases elimination of toxins with enteroenteric, enterohepatic, or enterogastric recirculation. Lipophilic drugs with low volume of distribution, protein binding, and molecular weight may pass down a concentration gradient between intravascular space and activated charcoal in the gut lumen. Multidose activated charcoal may also adsorb residual intraluminal toxins; this is more likely for substances slowing gastric motility or forming bezoars (**Table 176-8**). Although animal studies, volunteer studies, case reports, and case series demonstrate increased elimination rates (in some cases comparable to those of hemodialysis or charcoal hemoperfusion) of carbamazepine, dapsone, phenobarbital, quinine, and theophylline, there is limited evidence that multidose activated charcoal changes clinical outcome.[34]

Multidose activated charcoal may be administered by an orogastric or nasogastric tube to intubated patients. Regular aspiration of stomach contents helps avoid gastric distension. Multidose activated charcoal should not be given when bowel sounds are absent. Continued requirement for further multidose activated charcoal should be reviewed regularly during therapy.

URINARY ALKALINIZATION

Alkaline urine favors ionization of acidotic drugs within renal tubules, preventing resorption of the ionized drug back across the renal tubular epithelium and enhancing elimination through the urine.[35] Urinary alkalinization is most effective for weak acids primarily eliminated by the renal tract that are also readily filtered at the glomerulus and have small volumes of distribution (**Table 176-8**). Hypokalemia will reduce the effectiveness of urinary alkalinization. The primary indication for urinary alkalinization is moderate to severe salicylate toxicity when criteria for hemodialysis have not been met. Urinary alkalinization for adult patients can be instituted as follows:

- Correct any existing hypokalemia.
- Administer a 1 to 2 mEq/kg IV sodium bicarbonate bolus.
- Infuse 100 mEq of sodium bicarbonate mixed with 1 L of D5W at 250 mL/h.
- 20 mEq of potassium chloride may be added to the solution to maintain normokalemia.
- Monitor serum potassium and bicarbonate every 2 to 4 hours to detect hypokalemia or excessive serum alkalinization.
- Check urine pH regularly (every 15 to 30 minutes), aiming for a pH of 7.5 to 8.5.
- A further IV bolus of 1 mEq/kg of sodium bicarbonate may be necessary if sufficient alkalinization of the urine is not achieved.

Although urinary acidification can enhance the elimination of weak bases including amphetamines and phencyclidine, associated risks (e.g., rhabdomyolysis) outweigh potential benefit. Forced diuresis has no indication for any poisoning, with the exception of chlorophenoxy herbicides (see chapter 201, Pesticides).

TABLE 176-8 Indications, Contraindications, and Complications of Enhanced Elimination Procedures

Multidose Activated Charcoal	Initial dose: 50 grams (1 gram/kg children), repeat dose 25 grams (0.5 gram/kg children) every 2 hours
Indications	Carbamazepine coma (reduces duration of coma) Phenobarbital coma (reduces duration of coma) Dapsone toxicity with significant methemoglobinemia Quinine overdose Theophylline overdose if hemodialysis/hemoperfusion unavailable
Contraindications	Unprotected airway Bowel obstruction Caution in ingestions resulting in reduced gastrointestinal motility
Complications	Vomiting Pulmonary aspiration Constipation Charcoal bezoar, bowel obstruction/perforation
Urinary Alkalinization	
Indications	Moderate to severe salicylate toxicity not meeting criteria for hemodialysis Phenobarbital (multidose activated charcoal superior) Chlorophenoxy herbicides (2-4-dichlorophenoxyacetic acid and mecoprop): requires high urine flow rate 600 mL/h to be effective Chlorpropamide: supportive care/IV dextrose normally sufficient
Contraindications	Preexisting fluid overload Renal impairment Uncorrected hypokalemia
Complications	Hypokalemia Volume overload Alkalemia Hypocalcemia (usually mild)

EXTRACORPOREAL REMOVAL

Extracorporeal removal techniques, including hemodialysis, hemoperfusion, and continuous renal replacement therapies, have limited indications in poisoned patients (**Table 176-9**). These procedures require a critical care setting, are expensive and invasive, are not always available, and have complications. Extracorporeal removal techniques were utilized in less than 0.1% of cases reported to U.S. poison control centers in 2010.[13]

A toxin must possess a number of properties to be effectively removed by an extracorporeal technique in a clinically meaningful timeframe: low volume of distribution (<1.0 L/kg), low molecular weight (<500 Da), relatively low protein binding, and low endogenous clearance.[36] In general, extracorporeal removal must improve endogenous clearance rate by >30% to be clinically beneficial. Hemoperfusion uses a charcoal (or other adsorbent) filter, which comes into direct contact with blood, partially overcoming molecular weight and protein-binding limitations.

Continuous renal replacement therapies (including venovenous hemofiltration and venovenous hemodiafiltration) are widely available and easily instituted in most hospitals. However, there is sparse evidence demonstrating any benefit in poisoning, primarily due to slow clearance rates.[36] A patient who requires extracorporeal removal should undergo hemodialysis or hemoperfusion, if available. Continuous renal replacement therapy can be used if hemodialysis or hemoperfusion is unavailable or will not be

TABLE 176-9 Indications, Contraindications, and Complications of Extracorporeal Removal Techniques

Hemodialysis	**Movement of solute down a concentration gradient across a semipermeable membrane**	
Toxin requirements	Low volume of distribution, low protein binding, low endogenous clearance, low molecular weight	
Indications	**Life-threatening poisoning by:**	
	Lithium	Methanol/ethylene glycol
	Metformin lactic acidosis	Metformin-induced lactic acidosis
	Phenobarbital	Potassium salts
	Salicylates	Theophylline
	Valproic acid	
Contraindications	Hemodynamic instability	Poor vascular access
	Infants (generally)	Significant coagulopathy
Hemoperfusion	**Movement of toxin from blood, plasma, or plasma proteins onto a bed of activated charcoal (or other adsorbent)**	
Toxin requirements	Low volume of distribution, low endogenous clearance, bound by activated charcoal	
Indications	**Life-threatening poisoning caused by:**	
	Theophylline (high-flux hemodialysis is an alternative)	
	Carbamazepine (multidose activated charcoal or high-efficiency hemodialysis also effective)	
	Paraquat (theoretical benefit only if instituted early after exposure)	
Contraindications	Hemodynamic instability	Significant coagulopathy
	Infants (generally)	Toxin not bound to activated charcoal
	Poor vascular access	
Continuous Renal Replacement Therapies	**Movement of toxin and solute across a semipermeable membrane in response to hydrostatic gradient. Can be combined with dialysis.**	
Indications (potential)	Life-threatening ingestions of toxins when hemodialysis or hemoperfusion is indicated, but is unavailable, or hemodynamic instability precludes their utilization	
Contraindications	Hemodialysis or hemoperfusion is available	
	Poor vascular access	
	Significant coagulopathy	

Complications of Extracorporeal Removal Techniques	
Fluid/metabolic disruption	Limited by hypotension (not continuous renal replacement therapy)
Removal of antidotes	Infection/bleeding at catheter site
Limited availability	Intracranial hemorrhage secondary to anticoagulation

tolerated (e.g., due to hypotension).[36] Extracorporeal removal techniques including high-flux hemodialysis are constantly evolving, so discussion with an intensivist or nephrologist may be beneficial when this approach is considered.

DISPOSITION

Planning for patient disposition from the ED should be part of initial risk assessment. Admission is indicated if the patient has persistent and/or severe toxic effects or will require a prolonged course of treatment. In most cases, a 6-hour observation period is sufficient to exclude the development of serious toxicity. Onset of clinical toxicity can be delayed after a number of exposures, including (but not limited to) modified-release preparations of calcium channel antagonists, selective norepinephrine reuptake inhibitors (tramadol, venlafaxine), and newer antipsychotics (amisulpride); hence a period of extended observation is indicated. In the developed world, toxicity will resolve within 24 hours in most poisoned patients requiring noncritical care inpatient management, and so these patients can be efficiently and safely managed in a toxicology or short-stay ward, if available. Patients who have deliberately self-poisoned require appropriate mental health assessment before disposition.

CHAPTER 177

Cyclic Antidepressants

Frank LoVecchio

INTRODUCTION

Cyclic antidepressants were the first-generation of drugs developed to treat depression. Their use for treating depression has declined greatly as safer agents have been developed. Cyclic antidepressants are now occasionally used to treat obsessive-compulsive disorder, attention-deficit disorder, panic and phobia disorders, anxiety disorders, and a variety of other conditions.

In 2013, cyclic antidepressants were the most commonly identified antidepressants associated with overdose-related deaths.[1,2] Roughly half of all cyclic antidepressant exposures involve other drugs as well, and most co-ingestants increase the incidence and severity of cyclic antidepressant overdose toxicity.

Eight cyclic antidepressants are currently available in the United States (**Table 177-1**), with more agents available in other countries. Therapy is initially started at the lowest therapeutic level and slowly increased until the desired therapeutic response is achieved. This approach allows patients to become acclimated to adverse effects such as sedation and dry mucous membranes. Two related antidepressants, amoxapine and maprotiline, have structural differences from traditional cyclic antidepressants but have similar toxicity in overdose. Cyclobenzaprine is a muscle relaxant that is almost structurally identical

TABLE 177-1 Cyclic Antidepressants and Related Drugs

Generic Name	Typical Adult Outpatient Daily Dose (milligrams)	Recommended Maximal Adult Outpatient Daily Dose (milligrams)	Active Metabolites
Amitriptyline	75–150	300	Nortriptyline
Amoxapine*	50–300	400	7-Hydroxyamoxapine (minor) 8-Hydroxyamoxapine (major)
Clomipramine	25–50	250	Desmethylclomipramine
Cyclobenzaprine*	15–30	30	None
Desipramine	75–200	300	None
Doxepin	75–300	300	Desmethyldoxepin
Imipramine	75–200	300	Desipramine
Maprotiline*	75–150	225	Desmethylmaprotiline
Nortriptyline	75–150	150	None
Protriptyline	15–60	60	None
Trimipramine	75–200	300	Desmethyltrimipramine

*See text for clarification.

to amitriptyline but lacks antidepressant activity, and serious toxicity from overdose is rare.[3]

Cyclic antidepressant–related drug toxicity can occur at therapeutic dosages from one or more of seven possible mechanisms (**Table 177-2**).

PHARMACOLOGY

The cyclic antidepressants are named after their chemical structure, which consists of a three-ring central structure plus a side chain, thus the common term *tricyclic antidepressants*. Maprotiline is a tetracyclic (also termed a *heterocyclic*), with a four-ring central structure plus a side chain. Cyclic antidepressants are subdivided into two categories: tertiary and secondary amines. Tertiary amines have two methyl groups at the end of the side chain. The five tertiary amines—amitriptyline, clomipramine, doxepin, imipramine, and trimipramine—are generally more potent in blocking reuptake of serotonin compared with norepinephrine. Tertiary tricyclics also cause more anticholinergic side effects (e.g., constipation or blurred vision) and are also highly sedating because of their central effects on histamine receptors.

Secondary amines—desipramine, nortriptyline, and protriptyline—have one methyl group at the end of the side chain and are more potent in blocking reuptake of norepinephrine. Desipramine is the active (demethylated) metabolite of imipramine, and nortriptyline is the active (demethylated) metabolite of amitriptyline. The tetracyclic maprotiline has a side chain identical to that of the secondary amines; thus it is more potent in blocking reuptake of norepinephrine.

TABLE 177-2 Mechanisms for Cyclic Antidepressant Drug Toxicity at Therapeutic Dosages

Administration of high therapeutic dosages to naive individuals
Drug interactions with medications sharing similar pharmacologic actions
Elevated levels of cyclic antidepressants due to genetically slow hepatic metabolism
Drug interactions with other medications that inhibit hepatic metabolism (cytochrome P-450 system)
Additional toxicity from other active ingredients (e.g., antipsychotics) contained in some combination cyclic antidepressant formulations
Preexisting cardiovascular or CNS disease that predisposes patients to toxicity
Development of serotonin syndrome, usually in combination with serotoninergic medications

TABLE 177-3 Pharmacologic Profile of Cyclic Antidepressants

Pharmacologic Activity	Clinical Presentation
Antagonism of postsynaptic histamine receptors	Sedation
Antagonism of postsynaptic muscarinic receptors	Sedation, coma, agitation, confusion, hallucinations, ataxia, seizures, mydriasis, dry mucous membranes, dry skin, flushed skin, tachycardia, mild hypertension, hyperthermia, ileus, urinary retention, tremor
Antagonism of postsynaptic α-adrenergic receptors	Sedation, miosis, orthostatic hypotension, reflex tachycardia
Inhibition of norepinephrine reuptake	Agitation, mydriasis, diaphoresis, tachycardia, early hypertension
Inhibition of serotonin reuptake	Sedation, mydriasis, myoclonus, hyperreflexia (see later discussion of inhibition of amine reuptake and chapter 178, "Atypical and Serotonergic Antidepressants")
Inhibition of voltage-gated sodium channels	Impaired conduction, wide QRS complex, other conduction abnormalities; impaired cardiac contractility; wide-complex tachycardia, Brugada pattern, ventricular ectopy Hypotension
Inhibition of voltage-gated rectifier potassium channels	Prolongation of QT interval, ventricular ectopy, torsades de pointes

Amoxapine has a three-ring central structure and a side chain that differs from the other tricyclics. It is a potent norepinephrine reuptake inhibitor and also blocks postsynaptic dopamine receptors. Thus, it is the only antidepressant that has antipsychotic effects and can produce seizures with minimal warning and normal QRS complex.

Cyclic antidepressants are nonselective agents with multiple pharmacologic effects (**Table 177-3**) with considerable variation in potency at therapeutic dosages.[4] However, these differences become less important at the higher plasma levels typically seen in overdose. Inhibition of amine reuptake (norepinephrine, serotonin) and antagonism of postsynaptic serotonin receptors are believed to produce the therapeutic effects of these agents. The remaining pharmacologic actions are seemingly without therapeutic benefit in treating major depression but significantly contribute to cyclic antidepressant–related adverse effects and overdose toxicity.

ANTIHISTAMINIC EFFECTS

Cyclic antidepressants are potent inhibitors of peripheral and central postsynaptic histamine receptors.[4] Antagonism of central histamine receptors produces sedation and contributes significantly to the depressed level of consciousness and coma frequently seen in cyclic antidepressant overdose.

ANTIMUSCARINIC EFFECTS

Cyclic antidepressants are competitive inhibitors of acetylcholine at central and peripheral muscarinic receptors but not at nicotinic receptors.[4] Thus, they are antimuscarinic agents and not truly anticholinergic drugs. Central antimuscarinic symptoms vary from agitation to delirium, confusion, amnesia, hallucinations, slurred speech, ataxia, sedation, and coma. Peripheral antimuscarinic symptoms include dilated pupils, blurred vision, tachycardia, hyperthermia, hypertension, decreased oral and bronchial secretions, dry skin, ileus, urinary retention, increased muscle tone, and tremor. Antimuscarinic symptoms are especially common when cyclic antidepressants are combined with other medications that also have antimuscarinic activity, such as antihistamines, antipsychotics, antiparkinsonian drugs, antispasmodics, and some muscle relaxants. Antimuscarinic symptoms and signs are common findings in cyclic antidepressant overdose, making them an important clinical marker for toxicity, but these effects are not directly responsible for cyclic antidepressant–related deaths, and they do not require specific therapy other than supportive care.[5]

INHIBITION OF α-ADRENERGIC RECEPTORS

Inhibition of postsynaptic central and peripheral α-adrenergic receptors is a characteristic action of most cyclic antidepressants.[4] Cyclic antidepressants have a much greater affinity for α_1-adrenergic than for α_2-adrenergic receptors. Inhibition of α_1-receptors produces sedation, orthostatic hypotension, and pupillary constriction. This action frequently offsets pupillary dilatation induced by antimuscarinic activity. Thus patients with cyclic antidepressant toxicity can present with mid-sized or small pupils despite having other antimuscarinic signs. Orthostatic hypotension is often associated with reflex tachycardia. The antihypertensive effect of clonidine can be negated by cyclic antidepressants because of their ability to block the binding of clonidine to α_2-receptors.

INHIBITION OF AMINE REUPTAKE

Inhibition of amine reuptake is believed to be the most important mechanism for treating depression.[6] Cyclic antidepressants are potent inhibitors of norepinephrine and serotonin reuptake but produce little inhibition of dopamine reuptake, except for amoxapine, which does inhibit dopamine reuptake. Inhibition of neurotransmitter reuptake leads to increased synaptic levels and subsequent augmentation of the neurotransmitter response. Inhibition of norepinephrine reuptake is thought to produce the early sympathomimetic effects occasionally seen in some cyclic antidepressant overdoses and may contribute to the development of cardiac dysrhythmias. Myoclonus and hyperreflexia are attributed to increased serotonin activity. Serotonin syndrome results from increased serotonin brainstem activity that can be produced by cyclic antidepressants that are particularly potent serotonin uptake inhibitors, such as clomipramine and amitriptyline (see chapter 178). In general, cyclic antidepressants produce serotonin syndrome only when used in combination with other serotonergic agents.

SODIUM CHANNEL BLOCKADE

Cyclic antidepressant–induced cardiotoxicity is the most important factor contributing to patient mortality.[7] Cardiac conduction abnormalities occur during cyclic antidepressant poisoning because inhibition of the fast sodium channels in the His-Purkinje system and myocardium decreases conduction velocity, increases the duration of repolarization, and prolongs absolute refractory periods. Severe sodium channel blockade culminates in depressed myocardial contractility, hypotension, various types of heart blocks, cardiac ectopy, bradycardia, widening of the QRS complex, and/or the Brugada pattern. Mechanisms that contribute to hypotension during overdose include decreased contractility from reduced calcium release during depolarization within the ventricular myocytes and peripheral vasodilatation from blockade of α_1-adrenergic receptors. Rapid influx of sodium is necessary for the release of intracellular calcium stores and subsequent myocardial contractility. Some of the negative chronotropic effects of sodium channel blockade can be attenuated by the sinus tachycardia secondary to antimuscarinic activity.

Cyclic antidepressant cardiotoxicity produces ECG changes, such as prolongation of the PR interval and QRS duration, frontal plane right axis deviation, and the Brugada pattern (incomplete right bundle-branch block with ST-segment elevation in leads V_1 to V_3).[7,8] The right axis deviation is most pronounced in the terminal 40 milliseconds of limb leads, demonstrated by a terminal R wave in ECG lead aVR and an S wave in ECG lead I. The Brugada pattern is seen in approximately 10% to 15% of all patients with significant cyclic antidepressant overdose admitted to an intensive care unit but is rarely seen in other types of overdose.[8,9] **Therefore, the Brugada pattern strongly suggests a cyclic antidepressant overdose.**

Slow electrical conduction can produce various types of heart blocks. Local changes in electrical conduction can predispose to ventricular dysrhythmias by establishing reentry loops. Bradycardia, when accompanied by QRS complex widening, indicates profound sodium channel blockade.

POTASSIUM CHANNEL ANTAGONISM

Cyclic antidepressants block myocardial potassium channels and inhibit the efflux of potassium during repolarization.[7] This effect is seen on the ECG as QT interval prolongation, which is more pronounced at slower heart rates.[10,11] Torsades de pointes is rarely seen in cyclic antidepressant overdoses in the presence of sinus tachycardia, which is partially protective against severe QT interval prolongation and after-potential generation.

PHARMACOKINETICS

All cyclic antidepressants share similar pharmacokinetic properties.[4] They are highly lipophilic, readily cross the blood–brain barrier, and achieve peak plasma levels between 2 and 6 hours after ingestion at therapeutic doses. In overdose, GI absorption can be prolonged because of the antimuscarinic effect on gut motility. Bioavailability is only 30% to 70% because of extensive first-pass hepatic metabolism. Cyclic antidepressants are highly protein bound to α_1-acid glycoproteins, with a large apparent volume of distribution, ranging from 10 to 50 L/kg. Tissue cyclic antidepressant levels are commonly 10 to 100 times greater than plasma levels, and only 1% to 2% of the total body burden of cyclic antidepressants is found in the blood. These pharmacokinetic properties explain why it is unproductive to attempt removal of cyclic antidepressants by hemodialysis, hemoperfusion, peritoneal dialysis, or forced diuresis.

Cyclic antidepressants are eliminated almost entirely by hepatic oxidation, which consists of *N*-demethylation of the amine side-chain groups and hydroxylation of ring structures. The removal of a methyl group from the tertiary amine side chain usually produces an active metabolite designated by the desmethyl prefix (Table 177-1). Clinical toxicity from cyclic antidepressants usually lasts longer than explained by the activity of the parent drug because of the production of active metabolites. These active metabolites often have different pharmacologic activities compared with the parent compounds. Secondary amines such as desipramine, nortriptyline, and protriptyline are not believed to have active metabolites. Amoxapine and maprotiline both have active metabolites. Some cyclic antidepressants undergo enterohepatic circulation prior to their eventual oxidation, conjugation, and renal elimination, but this does not significantly contribute to their toxicity.

The average elimination half-life of cyclic antidepressants is approximately 24 hours (range, 6 to 36 hours) at therapeutic dosages, but this can increase to 72 hours after overdose. Inhibition of cyclic antidepressant metabolism by other drugs that use the same hepatic enzymes can prolong the half-life of cyclic antidepressants.

Cyclic antidepressants undergo significant postmortem drug redistribution.[12] Plasma levels can increase significantly after death as tissue binding sites release cyclic antidepressants back to the blood. This is a time-dependent process, and therefore, the diagnostic accuracy of postmortem cyclic antidepressant levels is inversely proportional to the time after death at which the measurement sample was obtained, among other factors.

TOXICITY

Therapeutic dosages of cyclic antidepressants are variable, generally ranging from 1 to 5 milligrams/kg per day (Table 177-1). Ingestions of <1 milligram/kg are generally nontoxic.[13] Life-threatening symptoms usually occur with ingestions of >10 milligrams/kg in adults, and fatalities are commonly associated with ingestions of >1 gram. Children are particularly susceptible to antimuscarinic effects and show clinical toxicity at lower dosages.[5] The majority of adult intentional ingestions and pediatric accidental exposures of >2.5 milligrams/kg are expected to result in some clinical toxicity based on the low therapeutic index of cyclic antidepressants.[13] In addition, patients at higher risk for cyclic antidepressant toxicity include patients who have co-ingested cardiotoxic or sedative-hypnotic medications, geriatric patients, and patients with underlying heart or neurologic disease.

Desipramine is the most potent sodium channel blocker among the cyclic antidepressants and is able to precipitate severe cardiotoxicity (e.g., wide QRS complex, hypotension) without producing significant antimuscarinic symptoms. It is associated with a higher case-fatality rate than the other cyclic antidepressants.[14] Amoxapine and maprotiline have historically been associated with greater toxicity than other cyclic antidepressants, especially in regard to causing seizures.[14]

Quantitative measurement of plasma levels of cyclic antidepressants is helpful in monitoring long-term drug therapy, but results are rarely

available during the time of patient evaluation. Patients with a combined plasma level of parent cyclic antidepressant and metabolite of >1000 nanograms/mL (>3500 nmol/L) are at greater risk for developing seizures and cardiotoxicity. However, the severity of clinical toxicity does not always correlate with the degree of plasma cyclic antidepressant elevation.[7] Serious toxicity rarely develops at therapeutic levels, typically 75 to 300 nanograms/mL (300 to 1000 nmol/L) for most agents.

CLINICAL FEATURES

The clinical presentation of cyclic antidepressant toxicity varies from mild antimuscarinic symptoms to severe cardiotoxicity secondary to sodium channel blockade. Antimuscarinic symptoms commonly serve as markers for cyclic antidepressant toxicity (e.g., dry mouth and axillae, sinus tachycardia), but they alone are rarely responsible for fatalities. Moreover, antimuscarinic symptoms are not uniformly present in cyclic antidepressant toxicity. Altered mental status is the most common symptom reported after cyclic antidepressant exposure.[5,15-17] A Glasgow coma scale score of <8 in the ED is a strong predictor of serious complications such as seizures and cardiac dysrhythmias.[6,7] Sinus tachycardia is the most frequent dysrhythmia noted in cyclic antidepressant toxicity, occurring in up to 70% of symptomatic patients.[7,15-17]

Mild to moderate cyclic antidepressant toxicity presents as drowsiness, confusion, slurred speech, ataxia, dry mucous membranes and axillae, sinus tachycardia, urinary retention, myoclonus, and hyperreflexia. Antimuscarinic syndrome is classically associated with decreased bowel sounds and ileus, but bowel function is fairly resistant to inhibition, so the presence of active bowel sounds does not exclude antimuscarinic syndrome. Mild hypertension is occasionally present and rarely requires treatment. Overflow urinary incontinence may be mistaken for normal micturition in diaper-dependent children or older adults.

Most cyclic antidepressant overdose fatalities occur within the initial hours after ingestion, often before the patient reaches the hospital. **If serious toxicity is going to occur, it almost always is seen within 6 hours of ingestion and consists of the following features: coma, cardiac conduction delays, supraventricular tachycardia, hypotension, respiratory depression, ventricular tachycardia, and seizures.**[14] Secondary complications from serious toxicity include aspiration pneumonia, pulmonary edema, anoxic encephalopathy, hyperthermia, and rhabdomyolysis. Seizures are more commonly reported in maprotiline and trimipramine overdoses.[18] Seizures are usually generalized, of brief duration, and occur with other signs of serious toxicity.[6] **The exception to this rule is amoxapine overdoses; this agent can cause status epilepticus without warning or QRS complex widening.** Cyclobenzaprine overdoses are usually characterized by prolonged CNS sedation and antimuscarinic toxicity with minimal cardiotoxicity compared to amitriptyline.[3]

DIAGNOSIS

Cyclic antidepressant toxicity is diagnosed using a combination of four criteria: history of exposure, clinical symptomatology, characteristic ECG findings, and positive cyclic antidepressant urine drug screen results. Other toxic exposures may produce similar symptoms, signs, and ECG changes; the essential point is that the initial treatment for toxicity due to any of these medications is identical and should not be delayed until definitive drug test results become available. At least half of all cyclic antidepressant exposures involve coingestion of other substances, which can significantly increase or alter toxic manifestations.

False-positive results on qualitative cyclic antidepressant urine drug screens occur for carbamazepine, cetirizine, cyclobenzaprine, cyproheptadine, diphenhydramine, hydroxyzine, quetiapine, and phenothiazines (e.g., thioridazine).[19] The false-positive cyclic antidepressant screen result is generally dose dependent and is more common following a supratherapeutic dose of these medications. Most of these medications are structurally similar to cyclic antidepressants, producing the same ECG abnormalities and clinical toxicity in overdose as cyclic antidepressants. Conversely, false-negative results on cyclic antidepressant drug tests are extremely unusual with clinical toxicity.

ECG abnormalities are common with cyclic antidepressant toxicity and are useful in identifying patients at increased risk for seizures and ventricular dysrhythmias.[20] The classic ECG with cyclic antidepressant toxicity shows sinus tachycardia, right axis deviation of the terminal 40 milliseconds, and prolongation of the PR, QRS, and QT intervals (**Figure 177-1**). Right axis deviation is demonstrated as a positive terminal R wave in lead aVR and a negative S wave in lead I (Figure 177-1). **This classic ECG pattern is seen frequently in moderate to severe cyclic antidepressant toxicity, but its absence does not eliminate the possibility of toxicity, and life-threatening complications can occur in the absence of significant ECG abnormalities, especially following amoxapine ingestion.** Moderate prolongation of the QT interval is noted frequently, even at therapeutic cyclic antidepressant dosages. Nonspecific ST-segment and T-wave abnormalities are observed commonly in cyclic antidepressant overdose. Less common ECG abnormalities include right bundle-branch block and high-degree atrioventricular blocks. The Brugada pattern is seen in roughly 10% to 15% of patients with cyclic antidepressant poisoning who require intensive care unit admission.

The risk of seizures increases if the QRS complex is >100 milliseconds, and ventricular dysrhythmias are more common if the QRS duration is >160 milliseconds.[7,20] Widening of the QRS complex from baseline and positive deflection of the terminal QRS complex in lead aVR are usually seen together but can occur independently of each other. The development of right axis deviation of the terminal 40 milliseconds and/or QRS complex widening appear to be less predictive of cyclic antidepressant–induced cardiotoxicity in young children because pediatric ECGs tend to have a wider range of acceptable variant features, and this complicates the identification of cyclic antidepressant toxicity on the ECG.

ECG abnormalities develop within 6 hours of ingestion and typically resolve over 36 to 48 hours.[7] These ECG abnormalities in isolation are not 100% specific for cyclic antidepressant toxicity, so because prior ECGs may not be available for comparison, any observed ECG abnormalities should be assumed attributable to cyclic antidepressant exposure and managed accordingly.

TREATMENT

Evaluate patients for alterations of consciousness, hemodynamic instability, and respiratory impairment. Establish an IV line, initiate continuous cardiac rhythm monitoring, and obtain serial ECGs. Suggested laboratory studies include serum electrolytes, creatinine, and glucose. To identify co-ingestants, obtain serum acetaminophen and salicylate levels. Blood gas measurement is required for symptomatic patients. In patients with antimuscarinic symptoms, urinary catheterization may be required to prevent urinary retention, and a nasogastric tube may be needed if ileus is present. **Patients who are initially asymptomatic may deteriorate rapidly and therefore should be monitored closely for 6 hours.** Treatment recommendations (**Table 177-4**) are based primarily on cohort or case-control studies resulting in only moderate strength of evidence for those measures discussed below.[21]

GI DECONTAMINATION

Do not use ipecac syrup or gastric lavage.[13,22-24] **Give a single 1 gram/kg dose of activated charcoal PO** if patients are awake, have a patent airway, and arrive within 1 hour of ingestion.[13,25] Activated charcoal effectively binds cyclic antidepressants and decreases absorption. Neither multidose activated charcoal nor whole-bowel irrigation is warranted.[22,26] Asymptomatic patients with reliable histories of minimal cyclic antidepressant ingestion can be treated with activated charcoal alone and observed for toxicity.

SODIUM BICARBONATE

Sodium bicarbonate is used to treat cardiac conduction abnormalities, ventricular dysrhythmias, or hypotension refractory to IV fluid.[21] **Administer sodium bicarbonate as an initial IV bolus of 1 to 2 mEq/kg,** and repeat until patient improvement is noted or until blood pH is between 7.50 and 7.55 (**Figure 177-2**). Additional

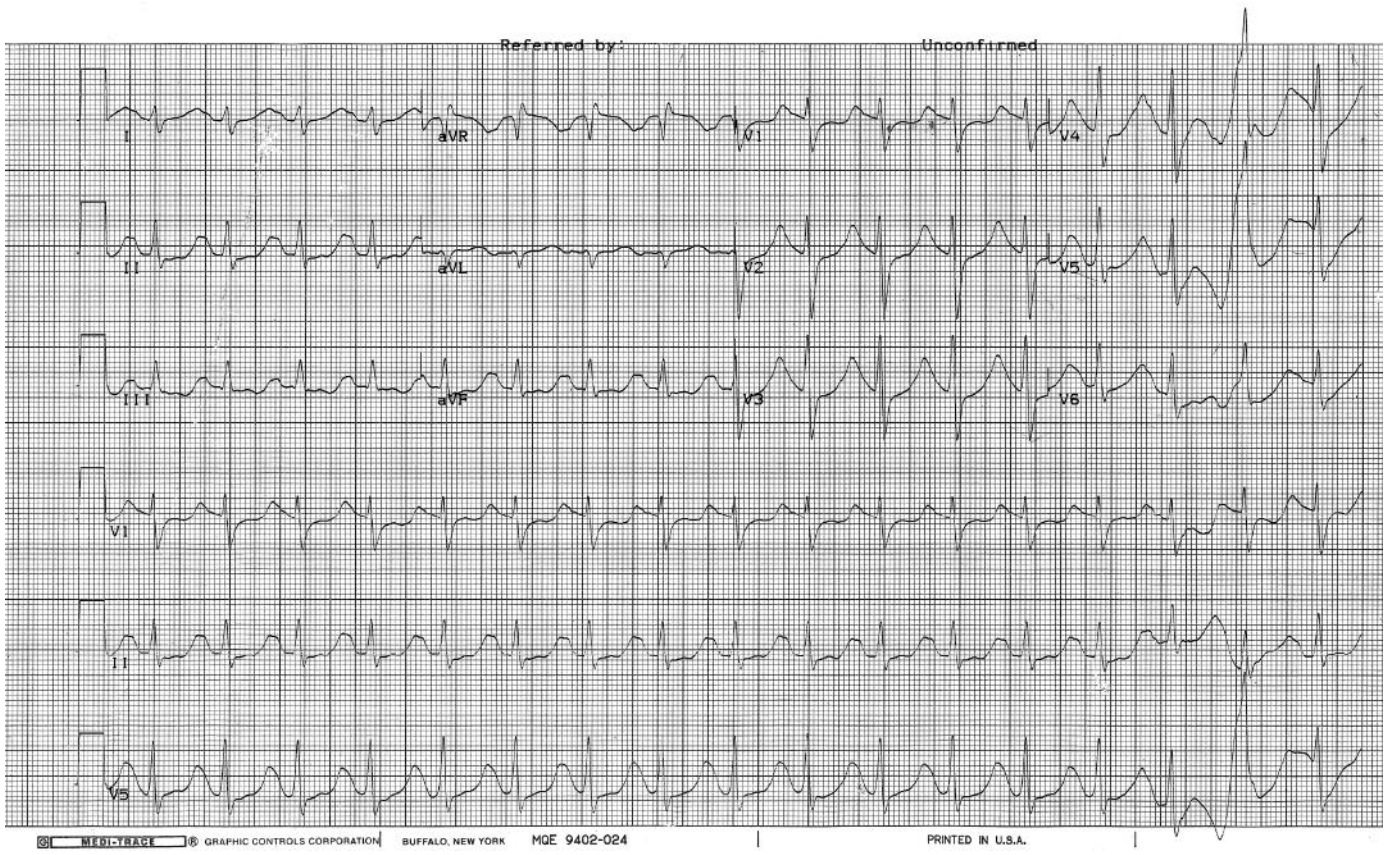

FIGURE 177-1. Twelve-lead ECG showing classic cyclic antidepressant ECG abnormalities: sinus tachycardia; prolonged PR, QRS, and QT intervals; and right axis deviation of the terminal 40 milliseconds of the QRS complex.

alkalization beyond this point can be deleterious to oxygen extraction and serum electrolytes.

As an alternative of repeat boluses, continuous infusions of sodium bicarbonate can be administered as 150 mEq added to 1 L of 5% dextrose in water (or 100 mEq added to 5% dextrose in 0.45% saline, creating a slightly hypertonic solution with the sodium bicarbonate added) and infused IV at a rate of 2 to 3 mL/kg per hour. Adjustments in the IV rate are made based on blood pH measurements and clinical response to therapy. Monitor serum electrolytes during the sodium bicarbonate infusion. Hypernatremia is not of particular concern using this dose of sodium bicarbonate.[16] Serum potassium will decrease during sodium bicarbonate therapy, and IV potassium supplementation may be required.[16]

ALTERED LEVEL OF CONSCIOUSNESS

Antagonism of postsynaptic muscarinic, histaminic, and α-adrenergic receptors contributes to the development of depressed mentation in cyclic antidepressant overdose. Coma from cyclic antidepressant toxicity

TABLE 177-4 Treatment of Cyclic Antidepressant Overdose

Treatment	Dose	Indication	Comments
GI decontamination	Activated charcoal 1 gram/kg PO	Within 1 h of ingestion as long as airway is stable and patient is awake	Do not give multidose charcoal; do not do whole-bowel irrigation
Initial treatment of hypotension or dysrhythmias	Sodium bicarbonate, 1–2 mEq/kg IV bolus; repeat bolus or add 150 mEq in 1 L 5% dextrose in water at 2–3 mL/kg per hour	For dysrhythmias, conduction abnormalities (QRS >100 ms), or hypotension refractory to IV fluid	Keep blood pH 7.50–7.55
Hypokalemia	Replace potassium as needed	Serum potassium <3.5 mEq/L	Bicarbonate will decrease potassium
Seizures or agitation	Benzodiazepines for seizures or agitation	Phenobarbital 10–15 milligrams/kg for seizures refractory to benzodiazepines; watch for hypotension; secure airway with intubation	Do not give physostigmine, flumazenil, or phenytoin
Hypotension	Treat hypotension with normal saline, up to 30 mL/kg	Use norepinephrine or epinephrine if refractory to IV normal saline	Case reports of glucagon, 1 milligram IV bolus
Torsades de pointes and refractory dysrhythmias	Magnesium sulfate 2 grams IV; 3% saline 1–3 mL/kg IV over 10 min; overdrive pacing	Consider lipid emulsion for refractory dysrhythmias, but no convincing evidence of effectiveness	**Do not give** class I antiarrhythmics (i.e., procainamide, lidocaine, phenytoin, flecainide), β-blockers, calcium channel blockers, or class III antiarrhythmics (i.e., amiodarone, sotalol, ibutilide)

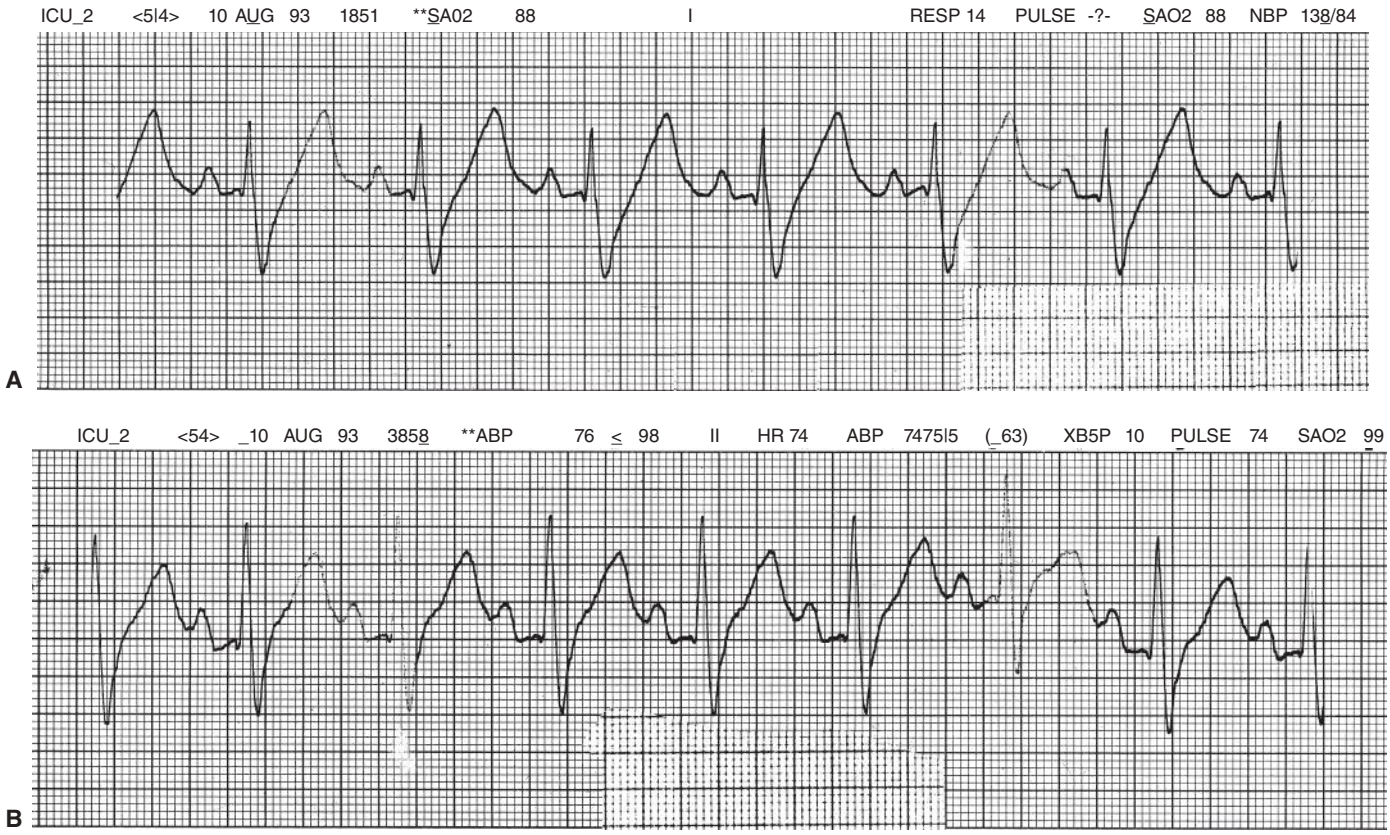

FIGURE 177-2. ECG before and after bicarbonate treatment. **A.** Cardiac rhythm strip of a patient with a wide QRS complex recorded 3 hours after ingestion of amitriptyline. **B.** Narrowing of the QRS complex in the same patient after administration of an IV bolus of sodium bicarbonate.

typically is rapid in onset and is a predictive factor for cardiotoxicity and/or seizures.[6] Pulmonary aspiration is common among comatose cyclic antidepressant overdose patients. Agitation is observed commonly prior to the onset of coma, as well as during awakening. Agitation is best controlled with reassurance, decreased environmental stimulation, and benzodiazepines. **Do not give flumazenil or physostigmine for mixed cyclic antidepressant–benzodiazepine or cyclic antidepressant–anticholinergic overdoses, respectively.**

SEIZURES

Most seizures occur within the first 3 hours following ingestion and are typically generalized and of brief duration.[6] Multiple seizures are reported in approximately 10% to 30% of cases of cyclic antidepressant overdose. Focal seizures and status epilepticus are atypical and should prompt further neurologic evaluation. Seizures are especially common with maprotiline and amoxapine ingestions and require aggressive management, because status epilepticus is frequently associated with these two particular antidepressants.[14] **Benzodiazepines (e.g., diazepam, lorazepam) are the anticonvulsants of choice to stop seizure activity.** Barbiturates (e.g., phenobarbital) are indicated to treat seizures resistant to benzodiazepines. The initial IV dose of phenobarbital is 10 to 15 milligrams/kg, but this can be increased in patients with continued seizure activity and adequate blood pressure. Other therapy for refractory seizures includes continuous-infusion midazolam or propofol. Hypotension is a major side effect of IV phenobarbital administration.

Endotracheal intubation and respiratory support are typically required when benzodiazepines are combined with barbiturates or propofol. **Phenytoin, sodium bicarbonate, and physostigmine do not stop cyclic antidepressant–induced seizures.** Neuromuscular blockers will stop the physical manifestations of seizures and their secondary effects, which include metabolic acidosis, hyperthermia, rhabdomyolysis, and renal failure, but they do not stop brain seizure activity. Therefore, following the induction of muscle paralysis, continue anticonvulsant therapy and consider electroencephalographic monitoring.

HYPOTENSION

Hypotension should be treated initially with isotonic crystalloid fluids in IV boluses in increments of 10 mL/kg to a maximum of 30 mL/kg.[21] With impaired cardiac contractility, pulmonary edema can develop if excessive fluids are administered. Hypotension that does not improve with appropriate fluid challenges should be treated with sodium bicarbonate (regardless of QRS complex duration). Vasopressors should be used when hypotension is unresponsive to fluids and sodium bicarbonate therapy. **Norepinephrine and epinephrine are the most effective vasopressors because they directly compete with the cyclic antidepressants at the α-adrenergic receptors.** Start the IV infusion at 1 microgram/min and titrate according to blood pressure. Vasopressin can be tried if there is no response to norepinephrine or epinephrine.[27] Dopamine is less effective than norepinephrine in reversing cyclic antidepressant–induced hypotension because it has primarily indirect α-adrenergic agonist activity and, at lower dosages, promotes vasodilation through its β-adrenergic and dopaminergic actions.

Placement of a pulmonary artery catheter for monitoring in patients whose hypotension is refractory to fluid, sodium bicarbonate, and vasopressor therapy may precipitate life-threatening conduction abnormalities and ventricular dysrhythmias as the catheter passes through the right ventricle. Mechanical support of the circulation with cardiopulmonary bypass, overdrive pacing, or aortic balloon pump assistance may be warranted in patients with refractory hypotension, although no studies document the effectiveness of these measures. There are isolated case reports suggesting that glucagon administered as 1 milligram IV boluses

might be effective in patients with refractory cyclic antidepressant–induced hypotension.[28]

CARDIAC CONDUCTION ABNORMALITIES AND DYSRHYTHMIAS

Cyclic antidepressants frequently alter cardiac rate, conduction, and contractility. These negative cardiac effects are increased with acidosis, which occurs in patients with respiratory depression or seizures. Asymptomatic patients with sinus tachycardia, isolated PR interval prolongation, or first-degree atrioventricular block do not require specific pharmacologic therapy. Conduction blocks greater than first-degree atrioventricular block are worrisome because they can progress rapidly to complete heart block secondary to impaired infranodal conduction.

The controversial issue is whether asymptomatic or mildly toxic patients with isolated QRS complex prolongation should be treated with sodium bicarbonate therapy.[21] There are no controlled human trials demonstrating benefits in otherwise asymptomatic patients with QRS complex prolongation. Nonetheless, many physicians use sodium bicarbonate therapy in asymptomatic or minimally toxic patients with cyclic antidepressant overdose if the QRS duration is >100 milliseconds. Hyperventilation represents a reasonable alternative to sodium bicarbonate therapy in the setting of renal failure, pulmonary edema, or cerebral edema, although hyperventilation is less effective in reversing toxicity.[29]

Ventricular dysrhythmias should be treated with sodium bicarbonate. Consider 3% hypertonic saline, 1 to 3 mL/kg IV over 10 minutes, to decrease ventricular ectopy or dysrhythmia in a patient with cardiotoxicity refractory to sodium bicarbonate therapy.[30]

Torsades de pointes should be treated initially with 2 grams of IV magnesium sulfate. Identify and treat electrolyte disorders that are associated with torsades de pointes. Overdrive pacing may be considered for refractory tachydysrhythmias. Older case reports indicate that IV isoproterenol may be of some benefit when overdrive pacing is not available. **The following medications are contraindicated in the treatment of cyclic antidepressant–induced dysrhythmias: all class I antiarrhythmic agents, β-blockers, calcium channel blockers, and all class III antiarrhythmic agents. Lidocaine, a sodium channel blocker, has unclear benefits in cyclic antidepressant–induced dysrhythmias, and there are no convincing data to support its effectiveness.**

LIPID EMULSION

Cyclic antidepressants are highly lipid soluble, and it has been postulated that intravenous lipid emulsion creates a "lipid sink" that sequesters the drug and prevents toxicity.[31] Case descriptions report both benefit[32-36] and complications.[31,37] Currently, there is no consensus or convincing evidence for the use of lipid emulsion in cyclic antidepressant toxicity.[21,38,39] In patients with cardiotoxicity refractory to other measures, it seems reasonable to infuse a 20% lipid emulsion in an amount based on that recommended for local anesthetic systemic toxicity: 100 mL IV bolus (1.5 mL/kg) over 2 to 3 minutes, followed by an infusion of 18 mL (0.25 mL/kg) per minute to a total dose of 10 mL/kg.[40]

DISPOSITION AND FOLLOW-UP

Patients who remain asymptomatic after 6 hours of observation do not require hospital admission for toxicologic reasons.[13] All symptomatic patients require hospital admission to a monitored bed. Patients demonstrating signs of moderate to severe toxicity should be admitted to an intensive care unit. Hospitalized patients can be cleared medically after 24 hours if they are asymptomatic, with a normal or baseline ECG, normal mental status, and resolution of all antimuscarinic symptoms. Patients with an intentional overdose require mental health evaluation.

CHAPTER 178

Atypical and Serotonergic Antidepressants

Frank LoVecchio
Erik Mattison

INTRODUCTION

Atypical and serotonergic antidepressants are commonly referred to as *newer* or *second-generation antidepressants*, to distinguish them from the first-generation monoamine oxidase inhibitors and cyclic antidepressants. As a group, these antidepressants are the most popular form of psychopharmacologic therapy for the treatment of major depression, obsessive-compulsive disorder, panic disorders, and eating disorders.[1] These antidepressants produce less severe toxicity in overdose and are associated with fewer fatalities than either cyclic antidepressants or monoamine oxidase inhibitors.[2,3] This favorable overdose profile is tempered by the U.S. Food and Drug Administration black box warning regarding the use of some agents by patients <24 years old due to increased suicidal ideation and behavior.

PHARMACOLOGY

This group of antidepressants is a heterogeneous collection of drugs that differ significantly in chemical structure, mechanism of action, pharmacokinetic characteristics, and adverse effect profile.[1] Nonetheless, they also share many important similarities.

Most possess serotonergic activity and, especially in combination with other serotonergic agents, have the potential to produce serotonin syndrome. Thus, they all carry specific warnings about this syndrome, particularly against their combination with monoamine oxidase inhibitors and other high-potency agents.

Most of these antidepressants do not significantly inhibit cardiac sodium, calcium, or potassium ion channels, with a lower risk for cardiac toxicity, which in large part explains their greater safety in overdose compared with cyclic antidepressants. These agents do not inhibit monoamine oxidase activity and are not associated with tyramine-like reactions. Unlike monoamine oxidase inhibitor toxicity, indirect sympathomimetics can be used for hypotension induced by these atypical antidepressants.

These agents have negligible affinity for acetylcholine, dopamine, γ-aminobutyric acid, glutamate, and β-adrenergic receptors. Although their exact mechanism of action remains poorly understood, it is traditionally attributed to inhibition of neurotransmitter reuptake or interruption of negative feedback loops.

These antidepressants are metabolized primarily by hepatic enzyme systems (cytochrome P-450 pathways). If two drugs are given that interact with a common metabolic pathway, drug levels can increase or decrease depending on the interaction. In addition, hepatic dysfunction can lead to elevated drug levels and subsequent drug toxicity. These antidepressants are not detected by routine hospital serum and urine drug screens. Specialty laboratories can measure parent drug and metabolite plasma levels, but this information is useful only for the confirmation of suspected drug overdose. Specific levels are not immediately available, nor do they affect patient management. Postmortem drug redistribution is likely to occur with these agents, which affects forensic investigation.

ATYPICAL ANTIDEPRESSANTS

The atypical antidepressants have unique chemical structures different from each other and from the other antidepressant classes (**Table 178-1**). They possess some unique clinical features at therapeutic doses and with overdoses.

TABLE 178-1 Atypical Antidepressants

Agent	Recommended Maximum Daily Adult Dose (milligrams)	Elimination Half-Life (h)	Major Active Metabolite
Bupropion	450	10–21	Hydroxybupropion
Mirtazapine	45	20–40	Desmethylmirtazapine
Trazodone	400	3–6 (first phase) 5–9 (second phase)	*Meta*-chlorophenylpiperazine

TABLE 178-2 Treatment of Bupropion Overdose

IV access, cardiac rhythm monitor, and ECG
Anticipate seizures; be prepared to treat with benzodiazepines
Single-dose activated charcoal if ingestion within 1 h, especially if extended-release formulation
Sodium bicarbonate for QRS complex prolongation >110 ms
Magnesium sulfate for QTc interval prolongation >500 ms
Consider IV lipid emulsion therapy for refractory cardiovascular instability

BUPROPION

Bupropion has a monocyclic phenylaminoketone chemical structure that resembles the phenylethylamines (e.g., amphetamine), but does not produce stimulant effects or drug-addictive behavior at therapeutic dosages. The therapeutic mechanism of action of bupropion is primarily inhibition of neuronal reuptake of norepinephrine and dopamine with very minimal serotonergic activity.[4]

Bupropion is absorbed rapidly after oral administration, with peak plasma levels within 2 hours for regular-release tablets and within 3 hours for sustained-release preparations. Bupropion undergoes extensive first-pass hepatic metabolism, is highly protein bound, has an extremely large volume of distribution, and readily crosses the blood–brain barrier. The active metabolite, hydroxybupropion, although less potent than bupropion, preferentially inhibits norepinephrine reuptake and may contribute to seizure development.

Bupropion antidepressant therapy is well tolerated. It does not produce mental status depression, orthostatic hypotension, or cardiovascular changes, or impair sexual function at therapeutic dosages. The most commonly reported adverse effects at therapeutic dosages are mild and include dry mouth, dizziness, agitation, nausea, headache, constipation, tremor, anxiety, confusion, blurred vision, and increased motor activity.[5] Seizures with therapeutic dosages are rare, but the incidence increases drastically at dosages of >450 milligrams/d. Bupropion infrequently produces catatonia, hallucinations, psychosis, and paranoia, which are likely related to its dopaminergic activity. Abrupt discontinuation of bupropion has not been associated with withdrawal symptoms, but as a dopamine agonist, it may pose a slight theoretical risk of precipitating neuroleptic malignant syndrome after discontinuation.

Clinical Features Bupropion differs from other atypical antidepressants in that it has a narrow therapeutic index. Toxicity can occur at dosages equal to or just slightly greater than the maximum therapeutic dose of 450 milligrams/d. **Conversely, significant toxicity is not expected in pure bupropion overdose with adult ingestions of <450 milligrams.** The most commonly reported symptoms in pure bupropion overdose include agitation, dizziness, tremor, nausea and vomiting, drowsiness, and tachycardia.[6,7] Mild hyperthermia is reported occasionally. Sinus tachycardia is the most common ECG abnormality seen following overdose, but QRS widening and QT interval prolongation have been reported.[8] Hypotension is unexpected in pure bupropion overdoses but has been reported in mixed-drug overdoses. Hypertension may occur but is usually of only mild to moderate severity. Coma and cardiac arrest have been reported in severe bupropion overdoses.

Seizures are more common with bupropion toxicity than with other atypical antidepressants[7,9] and usually are accompanied by other signs such as sinus tachycardia or altered mental status.[6,7,10] Unfortunately, **seizures can develop suddenly in otherwise asymptomatic patients**. Seizures usually occur within the first 1 to 4 hours after ingestion of immediate-release bupropion, but their appearance may be delayed for up to 8 hours.[6] Ingestions of extended-release preparations may predispose patients to seizures up to 24 hours after exposure.[10]

Treatment Establish a peripheral IV line, initiate cardiac rhythm monitoring, and obtain an ECG (**Table 178-2**). GI decontamination with activated charcoal is recommended provided it can be done within 1 hour of ingestion.[7] There is no evidence to support multidose activated charcoal or whole-bowel irrigation, even in overdoses of sustained-release products. Ipecac syrup is contraindicated due to the risk of seizures. Early onset of generalized seizures should be anticipated in all cases of bupropion ingestion and treated with benzodiazepines followed by phenobarbital, if necessary.

Hospital admission is recommended for all patients with seizures, persistent sinus tachycardia, or lethargy. Asymptomatic patients who have ingested only regular-release bupropion should be observed for 8 hours before discharge. **Adult patients ingesting >450 milligrams of extended-release bupropion require monitoring for at least 24 hours.**[10]

MIRTAZAPINE

Mirtazapine is a tetracyclic compound structurally unrelated to other currently available antidepressants. In contrast to other atypical antidepressants, mirtazapine does not inhibit neuronal amine uptake.[1] Instead, it blocks central presynaptic α_2-adrenergic receptors and postsynaptic 5-HT_2 and 5-HT_3 receptors. This has the therapeutic effect of increasing central norepinephrine and serotonin neurotransmission. Mirtazapine has a high affinity for blocking histamine-1 receptors and a moderate affinity for blocking muscarinic receptors. These effects commonly produce somnolence, especially in overdose.

Mirtazapine has a pharmacokinetic profile similar to other atypical antidepressants. It is absorbed rapidly with peak plasma levels within 2 hours after ingestion. Bioavailability is approximately 50% due to significant first-pass hepatic metabolism. The elimination half-life for mirtazapine is shorter in males than females, attributed to decreased cytochrome P-450 metabolism in females. Mirtazapine is highly protein bound (85%) and has a large volume of distribution (5 L/kg). Agranulocytosis is a rare but potentially serious complication of chronic mirtazapine use.

Clinical Features Mirtazapine produces limited toxicity in overdose; the most common features are sedation, confusion, sinus tachycardia, and mild hypertension.[11-13] The risk of coma and respiratory depression is greatest at larger doses or when mirtazapine is combined with other sedative drugs.[13] Cardiac abnormalities such as sinus tachycardia or QT interval prolongation are rarely of clinical significance.[11-13]

Treatment Isolated mirtazapine overdose is managed with supportive care alone in the majority of ingestions.[11-13] Administer single-dose activated charcoal if the ingestion has occurred within the past hour. Ipecac syrup is contraindicated, and multidose activated charcoal or whole-bowel lavage is unnecessary. Symptomatic patients should be admitted to a monitored bed, but significant cardiac toxicity is very unlikely. Asymptomatic patients can be discharged after 6 hours of observation.

TRAZODONE

Trazodone is a triazolopyridine derivative that is structurally unrelated to other antidepressants. The antidepressant action is believed to be due to a combination of serotonin reuptake inhibition and antagonism of

postsynaptic serotonin type 2 (5-HT_2) receptors.[1] Trazodone is a moderately potent nonselective α-adrenergic receptor blocker with at least five times greater affinity for α_1-adrenergic than α_2-adrenergic receptors. Consequently, trazodone is frequently associated with orthostatic hypotension, which is maximal within the first 6 hours after ingestion, so the harmful consequences can be minimized by taking the medication at bedtime. Sedation, which is a common side effect of trazodone therapy, is believed to be secondary to inhibition of central α-adrenergic and histamine receptors.

Trazodone is absorbed rapidly and completely, with peak plasma levels occurring between 1 and 2 hours following oral administration. It is highly protein bound (89% to 95%) and has a moderate volume of distribution (1.2 L/kg). Trazodone primarily undergoes hepatic oxidation by the cytochrome P-450 isoenzyme system producing one active metabolite, *meta*-chlorophenylpiperazine, which has a complex pharmacologic profile, including inhibition of serotonin uptake, stimulation and inhibition of multiple postsynaptic serotonin receptors, and interactions with other neurotransmitter systems.

The adverse effect profile for trazodone during therapeutic use is very favorable except that **trazodone is one of the most common causes of drug-induced priapism,** with an estimated incidence ranging from 1 to 10 per 10,000 patients. Trazodone should be discontinued immediately in any patient with a history of increased frequency of, increased duration of, or inappropriate penile or clitoral engorgement. Rare case reports describe reversible elevation of liver enzyme levels, jaundice, and abnormal liver histologic findings in association with trazodone therapy. Trazodone has been reported occasionally to be arrhythmogenic during therapeutic use, especially in patients with underlying cardiac risk factors such as conduction abnormalities or ischemic heart disease.

Clinical Features The most common symptom of acute trazodone poisoning is CNS depression. Other neurologic symptoms include ataxia and dizziness, and rarely, coma and seizures. Coma and seizures are more common when another epileptogenic drug is co-ingested. Pupils are usually of normal size and remain reactive. Trazodone-induced neurologic symptoms show marked improvement within 6 to 12 hours after ingestion and almost always resolve by 24 hours. Orthostatic hypotension is the most frequently reported cardiovascular abnormality noted in trazodone overdose and usually responds to fluid administration. The most common ECG abnormality is moderate prolongation of the QT interval.[14] Polymorphic ventricular tachycardia (torsades de pointes) has been reported in rare cases.[15] Commonly reported GI complaints include nausea, vomiting, and nonspecific abdominal pain. Respiratory depression is unlikely with pure trazodone overdoses.

Treatment Establish IV access, initiate cardiac rhythm monitoring, and obtain an ECG (**Table 178-3**). GI decontamination with single-dose activated charcoal can be used in appropriate patients who present within 1 hour. Patients who ingest >2 grams of trazodone or co-ingest other substances are at increased risk for serious toxicity with coma, seizures, respiratory arrest, cardiac dysrhythmias, and cardiac arrest.

Hypotension is treated initially with isotonic IV fluid administration. For persistent hypotension, use a direct-acting vasopressor (e.g., norepinephrine). Drugs with β-adrenergic receptor activity (e.g., dopamine) theoretically can worsen the hypotension in the presence of trazodone-induced α-adrenergic receptor antagonism. Treat QT interval prolongation and/or torsades de pointes dysrhythmia with IV magnesium sulfate, followed by cardiac pacing as needed.[15]

Patients who have remained asymptomatic for at least 4 to 6 hours can be discharged safely from the ED, provided that necessary psychiatric evaluation has been completed or arranged. Patients with neurologic and/or cardiac symptoms require hospital admission to a monitored bed.

TABLE 178-3 Treatment of Trazodone Overdose

IV access, cardiac rhythm monitor, and ECG
Single-dose activated charcoal if ingestion within 1 h
Treat seizures with IV benzodiazepines
IV fluids for hypotension
Direct-acting vasopressor (norepinephrine) for persistent hypotension and circulatory shock
Magnesium sulfate for QTc interval prolongation and/or torsades de pointes

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Selective serotonin reuptake inhibitors (SSRIs) are a structurally heterogeneous group of drugs that share selective affinity for inhibiting presynaptic serotonin reuptake without significantly affecting norepinephrine or dopamine reuptake (**Table 178-4**).[1] As with most antidepressants, acute alterations in biogenic amine levels do not correlate with immediate clinical response to drug therapy. It is currently believed that secondary receptor and cellular compensatory mechanisms play an important role in their mechanism of action. SSRIs are essentially devoid of direct presynaptic or postsynaptic receptor interactions. Thus they are associated with fewer unwanted pharmacologic actions, in contrast with cyclic antidepressants.

SSRIs are the most common form of pharmacotherapy for depression in the United States.[1] This class of antidepressants is the most frequently reported to be involved in drug overdoses, but fatalities are uncommon due to the high therapeutic index of these drugs.[2,3]

The SSRIs have similar pharmacokinetic profiles, including rapid and complete oral absorption, peak plasma levels occurring 4 to 8 hours after ingestion (except citalopram and escitalopram, which achieve peak plasma levels at 2 to 4 hours), significant first-pass hepatic metabolism, a high degree of protein binding (except citalopram and escitalopram), and a large volume of distribution. Fluoxetine is unique in that the active metabolite, norfluoxetine, is as potent as the parent compound. The half-life of norfluoxetine is 7 to 14 days, so the clinical effects of fluoxetine may last for up to 5 weeks after the last dose due to norfluoxetine.

The SSRIs are metabolized almost entirely by the hepatic cytochrome P-450 isoenzyme system, and these agents can inhibit the metabolism of other drugs dependent on that system. **The most serious drug-related adverse effect of SSRI psychopharmacotherapy is serotonin syndrome** (see "Serotonin Syndrome" below).

Adverse effects with therapeutic doses include hyponatremia, which is believed to be secondary to inappropriate secretion of antidiuretic hormone.[1] Sexual dysfunction (e.g., anorgasmia) is a relatively common adverse effect and is reversible with drug discontinuation. Priapism has been reported but is extremely rare. A withdrawal syndrome consisting of nonspecific neurologic, psychiatric, and GI symptoms has been described in conjunction with abrupt discontinuation. It is less likely to occur with fluoxetine due to its long-acting metabolite. Paroxetine is more likely to be associated with weight gain and sexual dysfunction.

Other neurologic adverse effects associated with SSRIs include headache, sedation, insomnia, dizziness, weakness or fatigue, tremor, and

TABLE 178-4 Selective Serotonin Reuptake Inhibitors

Agent	Recommended Maximum Daily Adult Dose (milligrams)	Elimination Half-Life (h)	Active Metabolite
Citalopram	40	35	Monodesmethylcitalopram Didesmethylocitalopram
Escitalopram	20	27–32	Desmethylcitalopram
Fluoxetine	80	96–144	Norfluoxetine
Fluvoxamine	300	16	None
Paroxetine	50	21	None
Sertraline	200	26	Desmethylsertraline

nervousness.[1] Seizures are uncommon but have been reported with all of these agents, with citalopram associated with the highest incidence of seizures among the SSRIs.[1] Serotonin has varying effects on the dopaminergic system. In many cases, extrapyramidal symptoms such as dystonic reactions, akathisia, dyskinesia, hypokinesia, and parkinsonian symptoms have been reported in association with SSRI therapy.[16] Consequently, SSRIs should be used cautiously with antipsychotic agents because they can potentiate antidopaminergic activity. Patients taking SSRIs commonly report GI complaints, such as nausea, diarrhea, constipation, vomiting, and anorexia. Other adverse effects less commonly reported include dry mouth, increased sweating, and blurred vision.

CLINICAL FEATURES

The greatest amount of human SSRI overdose experience has been with fluoxetine.[17] Information from case series involving the other SSRIs is consistent with the information accumulated on fluoxetine.[18,19] Fortunately, all of the SSRIs are characterized by a high therapeutic index, and fatalities are uncommon with pure overdoses.[2,3] Most adult and pediatric patients remain asymptomatic following SSRI overdose. The most common clinical features in symptomatic patients from overdose include nausea, vomiting, sedation, tremor, and sinus tachycardia. Less frequently observed are mydriasis, seizures, diarrhea, agitation, hallucinations, hypertension, and hypotension.

Sinus bradycardia is observed more frequently in fluvoxamine overdoses than in overdoses of other SSRIs. **Prolongation of the QRS complex and QT interval occurs in association with significant citalopram and escitalopram ingestions.**[20-24] Other SSRIs have been reported rarely to produce similar ECG abnormalities. In most cases, the ECG abnormalities gradually resolve over 24 hours. Tachycardia, mild hypotension, and lethargy are seen more commonly when SSRIs are combined with ethanol. Mixed-drug ingestions can produce a wide variety of additional symptoms depending on the toxicity of the co-ingestant. **About 10% of instances of serotonin syndrome occur as a consequence of acute overdose.**

TREATMENT

In patients who intentionally overdose, establish a peripheral IV line, initiate cardiac rhythm monitoring, and obtain an ECG (**Table 178-5**). Pure SSRI overdoses are associated with limited toxicity except for the infrequent development of life-threatening complications such as generalized seizures and serotonin syndrome. Based on the high therapeutic index and unlikelihood of serious toxicity, treatment with single-dose activated charcoal is logical for patients presenting within 1 hour of ingestion. Gastric lavage, ipecac syrup, multidose activated charcoal, and whole-bowel irrigation are not recommended.

Benzodiazepines are recommended as initial anticonvulsant therapy, followed by phenobarbital if seizures persist. Aside from citalopram and, potentially, escitalopram, the SSRIs generally have very little effect on the QRS or QT intervals. Activated charcoal decreases QTc prolongation after citalopram overdose.[20] Delayed-onset serotonin syndrome and extrapyramidal reactions are possibilities, especially with sustained-release compounds.

Patients should be observed for 6 hours, during which time supportive care is generally adequate. Hospital admission with continuous cardiac rhythm monitoring is recommended for all patients who remain tachycardic, have altered mental status, ingested citalopram or escitalopram, demonstrate cardiac conduction abnormalities, or have features of the serotonin syndrome.

TABLE 178-5 Treatment of Selective Serotonin Reuptake Inhibitor Overdose

IV access, cardiac rhythm monitor, and ECG
Single-dose activated charcoal if ingestion within 1 h
Treat seizures with IV benzodiazepines
Sodium bicarbonate for prolonged QRS complex
Magnesium sulfate for QTc interval prolongation and/or torsades de pointes

SEROTONIN/NOREPINEPHRINE REUPTAKE INHIBITORS

The serotonin/norepinephrine reuptake inhibitors (SNRIs) available in the United States are venlafaxine (a bi-cyclic compound that is structurally different from other antidepressants), desvenlafaxine (an analog of the known active metabolite of venlafaxine), duloxetine, and a new agent levomilnacipran (**Table 178-6**).[1]

In contrast to the SSRIs, these agents are primarily nonselective inhibitors of serotonin and norepinephrine reuptake with a very small amount of dopamine reuptake inhibition.[1] These drugs have no significant direct effect on presynaptic or postsynaptic neurotransmitter receptors. The SNRIs differ in their degree of protein binding and apparent volume of distribution, from venlafaxine with 27% protein binding and 6 to 7 L/kg volume of distribution, to duloxetine with 95% protein binding and a 1640 L/kg volume of distribution. Venlafaxine is absorbed the fastest after ingestion, achieving peak levels at 2 hours, whereas duloxetine reaches peak blood levels 6 to 10 hours after ingestion.

The adverse effect profile during therapeutic use for these medications is similar to that for SSRIs.[25] Venlafaxine is a notable exception, able to produce mild to moderate hypertension when dosages exceed 225 milligrams/d, probably secondary to inhibition of norepinephrine reuptake. Duloxetine appears to have more GI side effects, such as nausea, dizziness, and vomiting, but causes less hypertension than venlafaxine.[26]

CLINICAL FEATURES

All SNRIs cause sympathetic nervous system stimulation via inhibition of norepinephrine reuptake, which predisposes patients to tachycardia, hypertension, diaphoresis, tremor, and mydriasis. Most of these effects are of moderate severity and can usually be managed with supportive care alone.[27] Patients may display alterations in level of consciousness, with mild to moderate sedation being fairly common and progressing to coma on rare occasions. Generalized seizures are more common after overdose with venlafaxine than after most SSRI exposures.[9] Seizures are particularly worrisome because they tend to occur early after ingestion. Subclinical rhabdomyolysis has been observed in about 25% of patients without seizures and 60% of patients with seizures following a venlafaxine overdose.[28] Large overdoses of venlafaxine can produce severe global impairment of left ventricular systolic contraction with a markedly reduced ejection fracture.[29]

ECG abnormalities are common following intentional SNRI overdoses. Sinus tachycardia is the most common ECG abnormality observed, but QRS widening and QT interval prolongation have also been reported.[8] Mortality is low in isolated overdose.[30]

TREATMENT

Establish a peripheral IV line, initiate cardiac rhythm monitoring, and obtain an ECG (**Table 178-7**). Single-dose activated charcoal is logical therapy for most SNRI overdoses.[31] Gastric lavage and ipecac syrup are contraindicated due to the potential for seizures and aspiration. Consider whole-bowel irrigation with a large venlafaxine ingestion.[31] Benzodiazepines are the anticonvulsants of choice. Hypertension and sinus tachycardia rarely require specific pharmacologic therapy, and β-blockers have the theoretical disadvantage of allowing unopposed α-adrenergic receptor stimulation. Treat hypotension with fluids and direct-acting α-agonists.

TABLE 178-6 Serotonin/Norepinephrine Reuptake Inhibitors

Agent	Recommended Maximum Daily Adult Dose (milligrams)	Elimination Half-Life (h)	Major Active Metabolites
Desvenlafaxine	100	11	None
Duloxetine	120	12	None
Levomilnacipran	120	12	None
Venlafaxine	375	5	Desmethylverlafaxine

TABLE 178-7 Treatment of Serotonin/Norepinephrine Reuptake Inhibitor Overdose

IV access, cardiac rhythm monitor, and ECG
Single-dose activated charcoal if ingestion within 1 h
Consider whole-bowel irrigation with large (>4000 milligrams) venlafaxine overdoses
Treat seizures with IV benzodiazepines
IV fluids for rhabdomyolysis
Sodium bicarbonate for prolonged QRS complex
Magnesium sulfate for QTc interval prolongation
IV fluids and direct-acting vasopressors for hypotension

Asymptomatic patients should be observed for 6 hours. Symptomatic patients should be admitted to a monitored bed. Patients ingesting extended-release preparations require additional observation for at least 24 hours due to the possibility of delayed onset of toxicity.

SEROTONIN SYNDROME

Serotonin syndrome is a potentially life-threatening adverse drug reaction to serotonergic medications. It can be produced by any drug or, more commonly, by a combination of drugs that increase central serotonin neurotransmission (**Table 178-8**).[32-36] Antidepressants are the drug class most commonly associated with serotonin syndrome. This important fact can be easily overlooked if the patient does not have a history of depression and is taking the medication for treatment of a different disorder. Serotonin syndrome is characterized by a combination of alterations in cognition and behavior, autonomic nervous system function, and neuromuscular activity.[32-36] The degree of abnormality in any one area is highly variable. The stimulation of specific postsynaptic serotonin receptors is required for full expression of this syndrome, primarily the 5-HT_{1A} and 5-HT_{2A} receptors, but other receptor subtypes may contribute. Drugs that block postsynaptic serotonin receptors are incapable of inducing this syndrome and are often used as a form of treatment.

TABLE 178-8 Serotonergic Drugs

Antidepressants	
Monoamine oxidase inhibitors: phenelzine, tranylcypromine, isocarboxazid, pargyline, rasagiline, and selegiline	
Selective serotonin reuptake inhibitors: fluoxetine, sertraline, paroxetine, fluvoxamine, citalopram, and escitalopram	
Serotonin/norepinephrine reuptake inhibitors: venlafaxine, desvenlafaxine, levomilnacipran, and duloxetine	
Cyclic antidepressants: amitriptyline, clomipramine, desipramine, doxepin, imipramine, nortriptyline, protriptyline, and trimipramine	
Miscellaneous: trazodone (moderate potency), bupropion (low potency)	
Other Agents	
Amantadine (low potency)	L-Tryptophan and 5-hydroxytryptophan (high potency)
Amphetamines (moderate potency)	Lysergic acid diethylamide (moderate potency)
Bromocriptine (low potency)	Meperidine (high potency)
Buspirone (moderate potency)	Mescaline (moderate potency)
Carbamazepine (low potency)	Metoclopramide (low potency)
Cocaine (moderate potency)	Pentazocine (low potency)
Codeine (low potency)	Pergolide (low potency)
Dextromethorphan (high potency)	Reserpine (low potency)
Fentanyl (moderate potency)	St. John's wort (moderate potency)
Levodopa (moderate potency)	Sumatriptan and related triptans (high potency)
Linezolid (high potency)	Tramadol (high potency)
Lithium (high potency)	

TABLE 178-9 Clinical Features of Serotonin Syndrome

	Major	Minor
Cognitive	Altered level of consciousness Agitation	Insomnia Restlessness Anxiety
Autonomic	Hyperthermia Diaphoresis	Tachycardia Hypertension or hypotension Tachypnea Mydriasis
Neuromuscular	Muscle rigidity Hyperreflexia Myoclonus Tremor	Akathisia Incoordination

CLINICAL FEATURES

The triad of cognitive, autonomic, and neuromuscular effects is a classic feature of the serotonin syndrome (**Table 178-9**). The vast majority of serotonin syndrome cases occur in patients taking serotonergic drugs at therapeutic dosages, but approximately 10% of cases develop after an overdose of serotonergic medication. Serotonin syndrome usually occurs within 2 to 24 hours after the dosage of a serotonin agonist (e.g., a monoamine oxidase inhibitor or an SSRI) has been increased or after a second serotonergic agent (e.g., dextromethorphan) has been added.

The importance of serotonin syndrome in emergency practice is twofold. First, the diagnosis of serotonin syndrome is very challenging because of its nonspecific symptomatology.[37] Mild cases of serotonin syndrome frequently are misinterpreted as other psychiatric and medical disorders, and severe cases are often misdiagnosed as neuroleptic malignant syndrome.[38,39] Without proper recognition of patients at risk for serotonin syndrome, emergency physicians may inadvertently precipitate serotonin syndrome by administering serotonergic agents (e.g., meperidine, tramadol, dextromethorphan). To prevent iatrogenic precipitation of the serotonin syndrome, the emergency provider can use drug databases and other resources to evaluate for potential drug interactions.

The severity of serotonin syndrome varies (**Table 178-10**). The most commonly reported signs and symptoms associated with serotonin syndrome are altered mental status, hyperthermia, and increased muscle tone.[32-36] **Myoclonus is a common finding in serotonin syndrome and is an important distinguishing feature, because myoclonus is rarely seen in other conditions that mimic serotonin syndrome** (see chapters 179, "Monoamine Oxidase Inhibitors," and 180, "Antipsychotics").[38,39]

Muscle rigidity, when present, is especially prominent in the lower extremities, which serves as another valuable clinical marker for serotonin syndrome. Patients with ataxia should be examined carefully for lower extremity hypertonia. Unilateral muscle rigidity and focal neurologic findings are not expected. Seizures are always generalized and usually short-lived. Hyperthermia is usually of moderate severity, but temperatures >41°C (106°F) have been reported and are a marker of a poor prognosis. Hypertension is twice as common as hypotension and is associated with a more favorable prognosis.

There are no confirmatory laboratory tests for serotonin syndrome. Therefore, the diagnosis of serotonin syndrome is based entirely on

TABLE 178-10 Severity Pattern of Serotonin Syndrome

Category	Clinical Features
Mild	Mild agitation, mild fever (<40°C), tremor, myoclonus, hyperreflexia, diaphoresis, mydriasis, elevated blood pressure and heart rate
Moderate	Marked agitation, hyperthermia (>40°C), myoclonus, hyperreflexia, ocular clonus, increased bowel sounds
Severe	Hyperthermia (>41.1°C), delirium, marked muscle rigidity, marked swings in blood pressure and heart rate

TABLE 178-11 Treatment of Serotonin Syndrome

Stop all serotonergic therapy
Initiate cardiopulmonary monitoring, establish peripheral IV access, and obtain ECG
IV fluid rehydration
External cooling measures for hyperthermia
Benzodiazepines for agitation
Use short-acting IV antihypertensives (nitroprusside or esmolol) for severe hypertension
Use direct-acting IV vasopressors (norepinephrine, epinephrine, or phenylephrine) for hypotension resistant to IV fluid resuscitation
Consider cyproheptadine for moderate to severe clinical features refractory to supportive care

clinical assessment and exclusion of other psychiatric and medical conditions. Published diagnostic criteria for serotonin syndrome emphasize exposure to a known serotonergic drug and the presence of muscle clonus alone or at least one or two of the other common features.[32-36]

TREATMENT

The cornerstone of treating serotonin syndrome is discontinuing all serotonergic drugs and providing appropriate supportive care (Table 178-11).[32-36] All patients with serotonin syndrome should be admitted to the hospital until their symptoms have completely resolved. Severely ill patients require admission to an intensive care unit. Approximately 25% of patients require endotracheal intubation and ventilatory support. Most patients show dramatic improvement within 24 hours of symptom onset. Mortality varies according to the severity of the syndrome and aggressiveness of care.[33-36] The most common cause of death is severe hyperthermia.

Benzodiazepines are nonspecific serotonin antagonists and can be used to decrease patient discomfort and promote muscle relaxation. Patients with severe serotonin syndrome should be sedated, undergo neuromuscular blockade with a nondepolarizing agent, have an endotracheal tube placed, be started on mechanical ventilation, and be admitted to the intensive care unit.

Cyproheptadine appears to be the most effective antiserotonergic agent in humans.[33-36] Unfortunately, it is available only in an oral tablet or syrup formulation, so it is usually given via a nasogastric tube in severely symptomatic patients. The initial dose is 8 to 12 milligrams, with repeat doses of 2 milligrams every 2 hours until clinical improvement is seen. Cyproheptadine therapy should be discontinued if no response is observed after administration of 32 milligrams during the first 24 hours. Patients who respond to cyproheptadine are usually given 4 to 8 milligrams every 6 hours for 48 hours to prevent relapse.

Chlorpromazine is an antagonist of 5-HT_{2A} receptors and has been successfully used to treat serotonin syndrome.[33,35] The advantage of chlorpromazine is that it is available in a parenteral form, but a potential disadvantage is that it can cause hypotension. It also blocks dopamine receptors, which can promote muscle rigidity, lower seizure threshold, and exacerbate neuroleptic malignant syndrome. The use of dopamine agonists (e.g., bromocriptine) has no accepted role in treating patients with serotonin syndrome.[34] Dantrolene is a nonspecific muscle relaxant that is used occasionally in the management of serotonin syndrome, but clinical benefit is unproven.[34]

Patients with muscle rigidity, seizures, or hyperthermia should be monitored closely for rhabdomyolysis and/or metabolic acidosis. Clinical features of the serotonin syndrome usually resolve within 24 hours after the inciting drug is stopped, an exception being fluoxetine, due to its long half-life and that of the active metabolite. Once a patient recovers from serotonin syndrome, avoid future exposure to serotonergic drugs (Table 178-4), although the risk of recurrence is unknown.

CHAPTER 179

Monoamine Oxidase Inhibitors

Frank LoVecchio

INTRODUCTION

Monoamine oxidase inhibitors (MAOIs) were the first class of antidepressants, but current use of these agents is primarily limited to treating atypical and refractory cases of depression (**Table 179-1**).[1] Newer antidepressants have a more favorable side effect profile, less overdose toxicity, and no dietary restrictions. The declining popularity of oral MAOIs for the treatment of depression is partially offset by increasing use of agents in this class for the treatment of Parkinson's disease.[2] In addition, a transdermal method of selegiline administration is approved for use in major depression and appears to avoid some of the worrisome aspects associated with traditional oral therapy.[3-5]

Safety and effectiveness of MAOIs in children have not been established, and the four agents used for treatment of depression have the identical U.S. Food and Drug Administration–mandated black box warning stating that patients <24 years old may have increased suicidal thinking and behavior while taking any type of antidepressant medication.

MAOIs are associated with tyramine reactions, serotonin syndrome, and medication incompatibilities that are unique to this class of antidepressants. Overdoses of MAOIs are considered life-threatening emergencies, and **even one pill could potentially kill a toddler**. The onset of clinical toxicity is often delayed to between 6 and 24 hours after ingestion, which can lead to misdiagnosis and mismanagement.

MAOI antidepressants with improved safety and tolerability, such as moclobemide, are available in Canada, Australia, and Europe, but not the United States. **St. John's wort (*Hypericum perforatum*)** contains many active ingredients, some of which have the ability to inhibit monoamine oxidase and block serotonin reuptake.[6] St. John's wort is considered generally safe when taken at recommended dosages, but even modest monoamine oxidase inhibition may become clinically significant in overdose, may contribute to serotonin syndrome, or may participate in a drug–drug interaction.

Some medications have monoamine oxidase inhibition as an unrelated pharmacologic action, such as linezolid, procarbazine, furazolidone, and methylene blue.[7,8] Patients taking these medications have the potential to develop serotonin syndrome when they are combined with other serotonergic agents.

PHARMACOLOGY

Monoamine oxidase is an intracellular enzyme bound to the outer mitochondrial membrane.[9,10] It has been identified in most human cells except erythrocytes, which do not contain mitochondria. Monoamine oxidase removes amine groups from both endogenous and exogenous biogenic amines. This oxidative deamination process is the primary mechanism by which endogenous biogenic amines, such as norepinephrine, dopamine, and serotonin, become inactivated. A second important function of monoamine oxidase is to decrease the systemic availability of absorbed dietary biogenic amines (e.g., tyramine) via hepatic and intestinal metabolism. Thus, inhibition of monoamine oxidase leads to the accumulation of neurotransmitters in presynaptic nerve terminals (both centrally and peripherally) and increased systemic availability of dietary amines. Monoamine oxidase has a negligible role in metabolizing circulating catecholamines, either secreted endogenously (e.g., by the adrenal gland) or administered parenterally (e.g., epinephrine). Circulating catecholamines are metabolized by the enzyme catechol-O-methyltransferase that is located extraneuronally and is not affected by MAOIs.

Monoamine oxidase exists as two different isoenzymes, designated *monoamine oxidase isoenzyme A* (MAO-A) and *monoamine oxidase isoenzyme B* (MAO-B). Each isoenzyme has its own relative preference for different neurotransmitters, dietary amines, and inhibitory drugs.[9]

TABLE 179-1 U.S. Food and Drug Administration Approved Monoamine Oxidase Inhibitors

Agent	Indication	Formulation	Average Daily Therapeutic Dose	Maximum Daily Therapeutic Dose	Selectivity
Isocarboxazid	Major depression	10-milligram tablet	10–40 milligrams	60 milligrams	Nonselective
Phenelzine	Major depression	15-milligram tablet	45–75 milligrams	90 milligrams	Nonselective
Tranylcypromine	Major depression	10-milligram tablet	20–40 milligrams	60 milligrams	Nonselective
Selegiline	Major depression	6 milligrams, 9 milligrams, and 12 milligrams per 24-h patch	6 milligrams per 24-h patch	12 milligrams per 24-h patch	Nonselective (as a skin-patch formulation)
Rasagiline	Parkinson's disease	0.5- and 1.0-milligram tablets	0.5–1.0 milligram	1 milligram	MAO-B
Selegiline	Parkinson's disease	5-milligram tablet	10 milligrams	10 milligrams	MAO-B (as an oral formulation)
		1.25-milligram oral disintegrating tablet	1.25 milligrams	2.5 milligrams	MAO-B (as an oral formulation)
Moclobemide*	Major depression, social anxiety	150- and 300-milligram tablets	300 milligrams	600 milligrams	MAO-A

Abbreviations: MAO-A = monoamine oxidase isoenzyme A; MAO-B = monoamine oxidase isoenzyme B.

*Not available in the United States.

During normal physiology, MAO-A is primarily responsible for the breakdown of serotonin and norepinephrine, whereas MAO-B preferentially metabolizes phenylethylamine; MAO-A and MAO-B have equal ability to metabolize dopamine or tyramine. These preferences are entirely dose dependent and can be overcome at higher substrate concentrations or inhibitor doses (e.g., selegiline).

Overall, the human brain contains more MAO-B, and this predominance increases with advancing age. Dopaminergic neurons lack MAO-B activity and have limited MAO-A activity,[2] but significant MAO-B activity is present in surrounding astrocytes and glial cells. Thus dopamine inactivation depends on astrocyte and glial cell metabolism. Serotonergic neurons exclusively contain MAO-B, which allows more serotonin to be recycled while metabolizing more other nonserotonin neurotransmitters. Intestinal monoamine oxidase activity is mostly due to MAO-A, whereas approximately equal proportions of both isoenzymes are found in the liver, affording the body protection against ingested exogenous amines that can cause toxicity (e.g., tyramine reaction).

Blockade of MAO-A in the GI tract is responsible for a severe hypertensive crisis that can occur after patients on MAOIs ingest foods containing the sympathomimetic tyramine. Tyramine is usually metabolized in the GI tract, but the blockade of MAO-A allows it to flow into the general circulation. Although the accepted "MAOI diet" has been liberalized in recent years,[11] there are still several dietary restrictions to which patients on these medications must adhere.

MAOIs share structural similarities with endogenous amines that allow them to act as potential substrates for the enzyme. The antidepressant activity of phenelzine, tranylcypromine, isocarboxazid, and transdermal selegiline has been primarily attributed to their ability to increase norepinephrine and serotonin neurotransmission by increasing presynaptic concentrations of both amines. Their antidepressant effect correlates with >80% MAO-A inhibition. Additional mechanisms by which they exert their therapeutic effects are probably related to delayed postsynaptic receptor modifications (e.g., downregulation), indirect release of neurotransmitters, and inhibition of neurotransmitter reuptake.

The therapeutic benefit of selective MAO-B inhibitors in Parkinson's disease is related to increased striatal dopamine neurotransmission and protection against neuronal damage from oxidative stress.[2] MAO-B inhibition of >80% correlates with the observed therapeutic effect of selegiline and rasagiline in Parkinson's disease. At therapeutic doses, there is limited inhibition of MAO-A with modest effects on norepinephrine and serotonin metabolism.[2] However, at large doses (e.g., selegiline >20 milligrams/d) increasing MAO-A inhibition increases presynaptic norepinephrine and serotonin concentrations and thus has the potential to produce drug-related toxicity similar to that of the nonselective agents (phenelzine, tranylcypromine, and isocarboxazid).

Traditional MAOIs, such as isocarboxazid, phenelzine, tranylcypromine, rasagiline, and selegiline, form irreversible covalent bonds with the enzyme, rendering it permanently inactive. Once an irreversible inhibitor drug has been discontinued, it takes approximately 2 weeks before new enzyme synthesis restores activity to 50% of normal and up to 40 days to regain 100% activity.[10] Reversible inhibitors, on the other hand, competitively inhibit enzyme activity. After the reversible inhibitor drug is stopped, monoamine oxidase function recovers over a period of hours as the drug–enzyme complex spontaneously dissociates. Moclobemide and toloxatone are reversible MAOIs available in most of the world, but not in the United States.

PHARMACOKINETICS

MAOI tablets are absorbed rapidly and completely from the GI tract but have relatively low bioavailability because of a large first-pass effect of hepatic metabolism.[10] The skin patch form of selegiline allows for more parent drug to bypass first-pass liver metabolism; this results in elevated blood levels that have nonselective monoamine oxidase activity, and hence, it works as an antidepressant.[4] The oral form of selegiline has lower blood levels secondary to first-pass effects, retains its MAO-B selectivity, and does not have antidepressant qualities. Metabolism by hepatic cytochrome P-450 predisposes MAOIs to potential interactions with other drugs requiring similar hepatic enzyme pathways. Peak drug levels usually occur within 1 to 3 hours of ingestion. These drugs are highly protein bound and have relatively large volumes of distribution. Elimination half-life is relatively short, and an important feature of clinical toxicity is that it is usually delayed until well after most of the drug has already been metabolized. **Hence, blood levels do not correlate with clinical toxicity.**

Selegiline has many active metabolites, including desmethylselegiline, amphetamine, and methamphetamine.[5,12] Tranylcypromine does not produce amphetamine metabolites at normal therapeutic doses, but amphetamine has been noted in the serum following tranylcypromine overdose. Phenelzine metabolism results in multiple active metabolites such as β-phenylethylamine, which is metabolized by MAO-B. Rasagiline does not have any active metabolites.[2] Transdermal selegiline offers the advantage of continuous absorption over a 24-hour period without any peak effects. However, its absorption can be drastically increased by external heat application (e.g., sauna, heating pad).[4,5] The pharmacokinetic profile of most MAOIs indicates that attempts at extracorporeal removal (e.g., hemodialysis) or administration of repeat doses of activated charcoal would be unsuccessful in significantly reducing plasma drug levels.

DRUG INTERACTIONS

Long-term MAOI therapy predisposes to many potentially significant drug–drug interactions; some have been well established, whereas others

are based on single case reports or solely on theoretical considerations.[11] Controlled human studies are impossible due to the life-threatening nature of these reactions, and animal studies often have limited applicability to human toxicity. **Therefore, emergency physicians should never administer medications to patients taking MAOIs unless absolutely necessary.** Compatibility should always be confirmed before a new drug is administered, and the lowest effective dose should be used.

Drug–drug interactions involving MAOIs can be grouped into two categories: pharmacodynamic or pharmacokinetic. The most common pharmacodynamic reaction involves indirect-acting sympathomimetics. They have the potential to produce a hyperadrenergic condition similar to the tyramine reaction and can be found in over-the-counter preparations, drugs of abuse, and some prescription products. Pharmacokinetic interactions have been noted between certain drugs and MAOIs because these drugs are metabolized through the cytochrome oxidase enzyme system and thus can inhibit the metabolism of each other. A notable example of this type of drug interaction is the ability of ciprofloxacin and cimetidine to inhibit the metabolism of rasagiline, which can double its serum concentration.[2] Tranylcypromine and phenelzine have been shown to increase insulin release and predispose to hypoglycemia, especially in patients taking oral sulfonylurea agents.

SEROTONIN SYNDROME

Serotonin syndrome (see chapter 178, "Atypical and Serotonergic Antidepressants") is a rare, potentially life-threatening, often iatrogenic reaction. It occurs most commonly when MAOIs are combined with other serotonergic agents. **The important principle for emergency physicians is not to use meperidine, dextromethorphan, tramadol, linezolid, propoxyphene, a selective serotonin reuptake inhibitor, or a selective serotonin-norepinephrine reuptake inhibitor in a patient on MAOI therapy.** Patients should be warned about concomitant use of illicit drugs in general but especially, cocaine, MDMA (3,4-methylenedioxy-methamphetamine popularly known as ecstasy), and methamphetamine. Even after a patient discontinues therapy, 2 weeks are required before 50% of monoamine oxidase enzyme activity returns. **Consequently, there should be at least a 2-week abstinence period between the time an MAOI is discontinued and when any contraindicated drug is started; this recommendation is particularly important to prevent the development of serotonin syndrome.**

Awareness of which medications are generally considered safe for patients taking MAOIs is useful (**Table 179-2**). Aspirin, acetaminophen, ibuprofen, morphine, and most antibiotics have been used in combination with MAOIs without complications. Morphine should be given in decreased dosages due to impairment of morphine metabolism and enhancement of opiate effects. Direct-acting sympathomimetic agents (e.g., norepinephrine) can be given with caution, but use the lowest possible effective dosage. Direct-acting sympathomimetics do not rely on the release of neurotransmitters for their activity, and circulating sympathomimetics do not require monoamine oxidase for deactivation.

TABLE 179-2 Medications Considered Safe in Combination with Monoamine Oxidase Inhibitors*

Direct-Acting Sympathomimetics	Miscellaneous Drugs
Albuterol aerosol	Acetaminophen
Dobutamine	Antibiotics (except linezolid and furazolidone)
Epinephrine	Barbiturates
Isoproterenol	Benzodiazepines
Methoxamine	Calcium channel blockers
Norepinephrine	Corticosteroids
Terbutaline	Lidocaine
Vasopressin	Morphine
	Nitroglycerin
	Nitroprusside
	Nonsteroidal anti-inflammatory drugs
	Phentolamine
	Procainamide

*Always use the lowest effective dosage.

CLINICAL FEATURES

MAOIs have a low ratio of toxic to therapeutic dose. This characteristic predisposes patients to significant drug toxicity with ingestions just slightly larger than normal therapeutic doses. For isocarboxazid, phenelzine, or tranylcypromine, acute ingestions of 1 to 2 milligrams/kg may produce mild to moderate toxicity, ingestions more than 2 to 3 milligrams/kg can be life-threatening, and the lethal dose is estimated to be between 4 and 6 milligrams/kg.[13] Selegiline overdose experience is extremely limited, but because selectivity is lost after a 30-milligram ingestion, it should be assumed to produce toxicity similar to that of the traditional nonselective MAOIs.[12] Rasagiline is a far more selective MAO-B inhibitor than selegiline. It was given to healthy volunteers at doses 20 times the normal therapeutic dose without any significant toxicity. However, there are no published cases of rasagiline overdose, so prudence dictates that it should be subject to the same precautions as other agents in this class. Toxicity from moclobemide overdose alone is usually mild, even with large ingestions. But when combined with a serotonergic agent, serotonin syndrome is common and can be severe.[14]

An important clinical aspect of MAOI overdose is that the appearance of toxic symptoms is characteristically delayed to between 6 and 12 hours after ingestion, and the delay can be as long as 24 hours. The delayed onset of toxicity is attributed to the gradual accumulation of norepinephrine and serotonin in the brain and peripheral sympathetic neurons. Symptoms of MAOI overdose are most consistent with a hyperadrenergic state secondary to excessive stimulation of α-adrenergic and β-adrenergic receptors, but symptoms related to excessive serotonin receptor activity are also seen. Patients receiving long-term therapy may show earlier signs of toxicity due to preexisting enzyme inhibition. In severe cases, the hyperadrenergic state can be followed rapidly by hypotension and CNS depression resembling a sympatholytic condition. Toxicity usually persists for 1 to 4 days after ingestion.

Published descriptions of MAOI toxicity indicate tremendous variation in presentation: **there is no "typical" presentation of MAOI toxicity and no orderly progression of symptoms.**[12,13,15,16] The initial symptoms of overdose are reported to include headache, agitation, irritability, nausea, palpitations, and tremor. The earliest signs of toxicity include sinus tachycardia, hyperreflexia, hyperactivity, fasciculations, mydriasis, hyperventilation, nystagmus, and generalized flushing. In cases of moderate toxicity, opisthotonus, muscle rigidity, diaphoresis, chest pain, hypertension, diarrhea, hallucinations, combativeness, confusion, marked hyperthermia, and trismus may become evident. A peculiar ocular finding described as "ping-pong gaze" has been observed in some cases of MAOI toxicity and refers to bilateral wandering horizontal eye movements.[17] The cause for this gaze disorder is unknown, and it resolves gradually as the patient improves. Because the signs and symptoms of acute MAOI toxicity are often nonspecific and thus can easily be misattributed to other conditions, even in its most severe form, toxicity can resemble numerous other conditions, which can lead to misdiagnosis (**Table 179-3**).

Severe toxicity is accompanied by coma, seizures, bradycardia, hypotension, hypoxia, and worsening hyperthermia. Hypotension is an ominous finding and commonly remains resistant to therapy. Fetal death, cerebral edema, pulmonary edema, and intracranial hemorrhage have been reported in association with MAOI overdoses. The most common ECG abnormality seen with toxicity is sinus tachycardia, but T-wave abnormalities are occasionally seen. Moclobemide overdose may produce QT interval prolongation but without associated dysrhythmias.[18] Death is usually secondary to multiorgan failure.

DIAGNOSIS

MAOI overdose is a clinical diagnosis based solely on history. Plasma drug levels do not correlate with clinical toxicity, nor are such tests routinely available in most hospital laboratories. Routine urine drug

TABLE 179-3 Differential Diagnosis of Monoamine Oxidase Inhibitor Overdose

Intoxications	Medical conditions	Adverse drug reactions
Amphetamines	Heat stroke	Dystonic reactions
Antimuscarinics	Hypoglycemia	Malignant hyperthermia
Cathinone	Hyperthyroidism	Serotonin syndrome
Cocaine	Pheochromocytoma	Tyramine reaction
Methylphenidate		Spontaneous hypertensive crisis
MDMA (3,4-methylene-dioxymethamphetamine)	**Withdrawal states**	Neuroleptic malignant syndrome
	Ethanol (delirium tremens)	Malignant catatonia
Phencyclidine	Sedative-hypnotics	**Infectious diseases**
Phenylpropanolamine	Clonidine	Encephalitis
Strychnine	β-Blockers	Meningitis
Theophylline		Rabies
Tricyclic antidepressants (early)		Sepsis
		Tetanus

screens do not detect drugs of this class. Selegiline is likely to produce amphetamine metabolites, which can be detected on most urine drug screens. Tranylcypromine has the potential to produce amphetamine metabolites in overdose, but these are rarely detected. Laboratory tests can assist in the differential diagnosis and identify possible complications, including hypoxia, rhabdomyolysis, renal failure, hyperkalemia, metabolic acidosis, hemolysis, and disseminated intravascular coagulation. Leukocytosis and thrombocytopenia are seen commonly with toxicity.

The differential diagnosis includes drugs and medical conditions capable of producing a hyperadrenergic state, altered mental status, and/or muscle rigidity (Table 179-3). In addition, toxicity can be associated with a sympatholytic presentation. As noted, MAOI toxicity is difficult to diagnose without a history of exposure to the drug.

An elevated blood pressure in a patient receiving long-term MAOI therapy presents a dilemma. At therapeutic doses, hypertension can result from tyramine reactions, spontaneous hypertensive crisis, or serotonin syndrome.[9] Tyramine reactions are likely to occur in close relation to ingestion of food or drugs containing indirect sympathomimetics. Spontaneous hypertensive crisis is a rare condition, usually occurring in relation to recent drug dosing.[9] Serotonin syndrome most commonly occurs shortly after exposure to other serotonergic agents and usually is associated with significant cognitive-behavioral and neuromuscular abnormalities.

TREATMENT

GENERAL CARE

There are no known antidotes for MAOI toxicity. ED management therefore is directed toward supportive care and early treatment of complications. Place at least one preferably large-bore peripheral IV line and a cardiac monitor. Obtain laboratory studies, especially to identify hyperkalemia, metabolic acidosis, and rhabdomyolysis. Onset of toxicity is usually gradual and delayed, sometimes up to 24 hours after ingestion. However, the abrupt development of seizures, coma, respiratory insufficiency, hyperadrenergic storm, and cardiovascular collapse is possible. For any given dose of inhibitor, toxicity is predicted to be greater for patients with significant underlying medical problems, children, the elderly, and patients co-ingesting other drugs.

There is no accepted need or best method for GI decontamination in an MAOI overdose.[19] Ipecac syrup is contraindicated.[20] Gastric lavage is generally not recommended.[19,21] MAOIs are absorbed rapidly, so delayed gastric lavage or whole-bowel irrigation is unlikely to be of clinical benefit.[22] **If presentation is within 1 hour, consider activated charcoal administered as a single dose**, but multidose administration is not expected to be useful.[23] Hemodialysis, hemoperfusion, and peritoneal dialysis have no established role in the treatment of MAOI poisoning. Urinary acidification is not recommended because it is ineffective in enhancing MAOI elimination and predisposes to acute renal failure secondary to myoglobin precipitation within renal tubules.

HYPERTENSION

Treat hypertension only with short-acting IV antihypertensive agents because of the potential for development of precipitous hypotension. In many cases, an intra-arterial catheter is required for accurate blood pressure monitoring. The recommended antihypertensive agents are phentolamine and nitroprusside. Phentolamine is a nonspecific α-adrenergic receptor blocker usually administered in 2.5- to 5.0-milligram IV boluses every 10 to 15 minutes until the elevated blood pressure is controlled. It also can be given as a continuous infusion (0.2 to 0.5 milligram/min) for maintenance therapy. Phentolamine use is commonly associated with reflex tachycardia.

Nitroprusside is as effective as phentolamine. It is given as a continuous IV infusion starting at a rate of 1 microgram/kg per minute and is then titrated according to blood pressure response. Prolonged administration of high doses of nitroprusside can predispose to cyanide toxicity, but this potential complication is not relevant to initial treatment. Nitroglycerin is indicated for the relief of anginal chest pain and in patients with signs of myocardial ischemia. β-Blockers pose a theoretical risk of increasing blood pressure through unopposed vasoconstriction and are relatively contraindicated.

HYPOTENSION

Hypotension indicates a poor prognosis after MAOI overdose. Give IV normal saline fluid boluses initially. **When vasopressors are required, a direct-acting agent such as norepinephrine is preferred, and all indirect-acting agents such as dopamine should be avoided.** Patients receiving long-term MAOI therapy usually demonstrate an increased sensitivity to vasopressors, so use low initial dosages.

DYSRHYTHMIAS

Sinus tachycardia rarely calls for specific drug therapy unless it is producing cardiac ischemia. Lidocaine and procainamide are the most effective antiarrhythmics for treating the ventricular dysrhythmias seen with toxicity. Bradycardia may degrade quickly into asystole in the later stages of toxicity and requires pacemaker placement. Pharmacologic treatment of bradycardia includes atropine, isoproterenol, and dobutamine.

SEIZURES

Benzodiazepines such as lorazepam and diazepam are the anticonvulsants of choice in treating MAOI-induced seizures. Barbiturates such as phenobarbital are as effective as benzodiazepines but may cause hypotension, especially at higher dosages. Phenytoin is generally ineffective in stopping drug-induced seizures. General anesthesia and muscle paralysis may be necessary in cases of status epilepticus to prevent the metabolic acidosis, hyperthermia, and rhabdomyolysis that commonly accompany persistent seizure activity. Muscle paralysis is best accomplished using nondepolarizing neuromuscular blocking agents, because the action of succinylcholine may be enhanced by these MAOIs. **Vecuronium is preferred to pancuronium** because of the latter's propensity to produce elevations in heart rate and blood pressure. Electroencephalographic monitoring is required when muscle paralysis is used to control the peripheral manifestations of seizure activity.

HYPERTHERMIA

Antipyretics are not effective in lowering drug-induced fever. Benzodiazepines such as lorazepam or diazepam are useful first-line agents to reduce muscle hyperactivity and thus decrease secondary heat production. Increasing evaporative and conductive heat loss is essential for the successful treatment of drug-induced hyperthermia. This is best accomplished by using cool mist sprays and evaporative fans or cooling blankets.

Hyperthermia is often resistant to treatment as long as there is persistent muscle rigidity. Muscle paralysis (using nondepolarizing agents) should be considered when diffuse rigidity is refractory to benzodiazepine therapy. Anecdotally, dantrolene is an effective relaxant in resistant cases of muscle rigidity, given at a dose of 0.5 to 2.5 milligrams/kg IV every 6 hours, but should only be used when other measures have failed to relieve muscle rigidity.

DISPOSITION AND FOLLOW-UP

All patients with intentional MAOI overdoses or accidental ingestions of isocarboxazid, phenelzine, or tranylcypromine >1 milligram/kg require admission to an intensive care unit or equivalent. Patients with accidental exposures of <1 milligram/kg still require hospital admission but, because they are less likely to develop life-threatening complications, can be admitted to a bed with less frequent monitoring. Consultation with a medical toxicologist and regional poison control center is strongly recommended. Asymptomatic patients should be monitored for at least 24 hours before discharge. Dietary and medication restrictions should be followed meticulously during the hospitalization. All patients should be instructed to avoid contraindicated foods and medications for a minimum of 2 weeks after MAOI drug exposure. Patients who require transfer to hospitals with intensive care units should be transferred as soon as possible to avoid the problems anticipated with delayed onset of toxicity. All patients being transferred should be accompanied by medical personnel capable of performing advanced life support and airway management. **Even a single MAOI tablet may produce life-threatening drug interactions under the right circumstances.**

TYRAMINE REACTION

Tyramine is an exogenous dietary amine that is normally metabolized by intestinal and hepatic monoamine oxidase.[11,24,25] Tyramine can be found in small amounts in many foods but is present at much higher levels in aged, cured, smoked, pickled, or fermented dietary products. The body normally has multiple levels of protection to prevent tyramine and other similar exogenous amines from entering the systemic circulation, but this protection is lost once the normal activity of MAO-A is inhibited by >80%. Therefore, all nonselective inhibitors predispose to tyramine reactions; however, tranylcypromine is associated more frequently with tyramine reactions than either phenelzine or isocarboxazid. Selective MAO-B inhibitors and reversible inhibitors are associated with a much lower incidence of tyramine reactions because they leave intestinal and hepatic MAO-A unaffected to metabolize tyramine. Selegiline (MAO-B selective) is unlikely to produce a tyramine reaction if taken in oral form at therapeutic doses, but at elevated doses, its selectivity is lost and it functions the same as the nonselective inhibitors. Dietary restrictions are unnecessary with rasagiline because of its greater selectivity for MAO-B at therapeutic dosages.[2]

Tyramine is structurally similar to amphetamine and is classified as an indirect sympathomimetic. Like most indirect sympathomimetics, tyramine enters the presynaptic neuron through amine uptake pumps. Once inside the neuron, indirect sympathomimetics are capable of releasing presynaptic stores of norepinephrine and, to a lesser degree, serotonin and dopamine. Tyramine also can displace epinephrine from the adrenal gland. A similar effect occurs with ingestion of foods that contain large amounts of dopamine, such as broad (fava) beans. It has been reported that <30% of patients taking MAOIs adhere to the recommended tyramine-restricted diet. In addition, approximately 4% to 8% of adherent patients experience a tyramine reaction during their course of therapy. Many of the previously restricted food sources are no longer considered dangerous, and newer guidelines call for avoiding only a few high-risk food groups such as meats or fish that are not fresh, sauerkraut, aged meats and cheeses, alcohol (tap or unpasteurized beers), pickled fish (herring), concentrated yeast extracts, banana peels, soy sauce, tofu, and broad beans.[11,24,25]

The tyramine reaction is typically of rapid onset, occurring within 15 to 90 minutes of ingestion of the dietary amine. The severity of this reaction is highly variable and is partially related to the total amount of tyramine ingested. **The hallmark symptom of the tyramine reaction is a severe occipital or temporal headache.** Other associated symptoms include hypertension, diaphoresis, mydriasis, neck stiffness, pallor, neuromuscular excitation, palpitations, and chest pain. Most symptoms resolve gradually over 6 hours without specific therapy, but fatalities have been reported in rare cases, usually due to intracranial hemorrhage or myocardial infarction. An ECG should be obtained for all patients with tyramine-associated chest pain. Focal neurologic findings or a persistent, severe headache warrants investigation with a CT scan of the head.

In cases of severe hypertension, the recommended drug is phentolamine, given as 2.5- to 5.0-milligram IV doses every 5 to 15 minutes until the blood pressure is controlled. The half-life of phentolamine is approximately 20 minutes, and its duration of action is <1 hour. Nitroprusside is another rapidly acting direct vasodilator that is administered as a continuous IV infusion (1 to 4 micrograms/kg per minute). In cases of moderate hypertension, nifedipine and prazosin have been reported to be effective. Recommendations for the treatment of accelerated chronic hypertension discourage the use of nifedipine due to concerns of excessive blood pressure reduction, but these concerns may not apply to the acute hypertension seen in tyramine reactions. β-Adrenergic blockers are contraindicated because of unopposed α-receptor stimulation. Hospital admission should be strongly considered for patients whose symptoms do not resolve completely within 6 hours of onset. Patients who are asymptomatic after 4 hours of observation can safely be discharged home.

CHAPTER 180

Antipsychotics

Michael Levine
Frank LoVecchio

ANTIPSYCHOTICS

INTRODUCTION

Developed starting in the 1950s, the typical antipsychotics are effective against the positive signs of psychosis (e.g., delusions, hallucinations, disorganized thought), but they provided no treatment for the negative signs (e.g., avolition, alogia, social withdrawal). In addition, numerous adverse side effects associated with these agents lead to poor patient compliance. The second-generation drugs, or atypical antipsychotics, have been available starting in the 1990s. These drugs are characterized by minimal extrapyramidal side effects when taken at effective dosages and have activity against the negative signs of schizophrenia (**Table 180-1**). Third-generation agents are being developed to minimize the adverse side effects seen with the first- and second-generation agents.

Antipsychotics were originally referred to as *major tranquilizers*, because of their ability to calm patients, but because they are not simply sedatives, this term is inappropriate. These drugs were also termed *neuroleptics*, which refers to their ability to slow movement. With the advent of the atypical antipsychotics, it became clear that antipsychotic properties do not necessarily parallel neuroleptic properties. For this reason, the preferred term is *antipsychotics*. Although *antipsychotic* is a useful term, these drugs are sometimes administered to treat other conditions, such as agitation, nausea and emesis, various headache conditions; to suppress hiccups; and to control various involuntary motor disorders, such as Tourette's syndrome, Huntington's chorea, and basal ganglia disorders.

TABLE 180-1 Common Antipsychotics

First-Generation or Typical Antipsychotics	
Phenothiazines	
Aliphatic compounds	Chlorpromazine
	Levomepromazine
	Methotrimeprazine
	Promazine
	Promethazine
	Triflupromazine
Piperazines	Flupentixol
	Fluphenazine
	Perphenazine
	Prochlorperazine
	Trifluoperazine
Piperidines	Mesoridazine
	Thioridazine
Nonphenothiazines	
Butyrophenones	Droperidol
	Haloperidol
Diphenylbutylpiperidine	Pimozide
Dihydroindolone	Molindone
Thioxanthenes	Chlorprothixene
	Flupenthixol
	Thiothixene
	Zuclopenthixol
Second-Generation or Atypical Antipsychotics	
Benzadines	Amisulpride
	Remoxipride
	Sulpiride
Benzepines	Clozapine
	Loxapine
	Olanzapine
	Quetiapine
Indoles	Iloperidone
	Risperidone
	Sertindole
	Ziprasidone
Third-Generation Antipsychotic	
Quinolinone	Aripiprazole

PATHOPHYSIOLOGY

Currently more than 50 different antipsychotics are available worldwide. Classification by structure is difficult; a more useful method is classification according to their relative receptor-binding profiles (**Table 180-2**).[1] **In overdose, the clinical toxicity is primarily an exaggerated effect of the pharmacologic activity.**

Virtually all antipsychotics bind to (and inhibit) presynaptic and postsynaptic dopamine-2 (D_2) receptors in the CNS. When antipsychotic treatment is initiated, blockade of the D_2 receptor results in increased production and release of dopamine from the presynaptic cell. However, with continued use, depolarization inactivation occurs, and decreased production and release develop, along with continued postsynaptic receptor blockade.

The blockade of dopamine receptors in different regions of the brain produces varying effects. Blockade of D_2 receptors in the mesocortical and mesolimbic system is associated with antipsychotic efficacy, whereas D_2 receptor blockade in the area postrema (chemotactic trigger zone) is responsible for antiemetic activity. Aripiprazole is different for other antipsychotics; it is a partial D_2-agonist, with specific effects dependent on the concentration of dopamine. At low levels of dopamine, aripiprazole will stimulate the D_2 receptors, and at high levels of dopamine, aripiprazole will inhibit the D_2 receptors.

Blockade of the D_2 receptors in other regions of the brain produces many of the adverse effects associated with antipsychotics. Antagonism of the D_2 receptors in the tuberoinfundibular region is associated with hyperprolactinemia, which can cause galactorrhea, gynecomastia, and sexual dysfunction.[1] Blockade of the D_2 receptors in the nigrostriatal region is associated with the development of extrapyramidal symptoms. Agents with greater D_2 receptor affinity (e.g., haloperidol or fluphenazine) have a greater likelihood of inducing extrapyramidal symptoms, whereas agents with less receptor affinity (e.g., clozapine) are less likely to cause extrapyramidal symptoms. Blockade of the D_2 receptors in the anterior hypothalamus (preoptic area) can produce alterations in body temperature.

In addition to blocking dopamine receptors, many antipsychotics have activities at the α-adrenergic, muscarinic, histaminergic, and serotoninergic receptors. Antagonism of the α_1-adrenergic receptors leads to orthostatic hypotension and reflex tachycardia. Antagonism of the muscarinic receptors can produce anticholinergic symptoms, including hyperthermia, tachycardia, mydriasis, dry mucosal membranes, and urinary retention. Blockade of the histaminergic receptors primarily results in sedation.

Among the first-generation antipsychotics, potency is inversely related to the likelihood of sedation but directly correlated with extrapyramidal effects. Therefore, high-potency agents such as haloperidol, fluphenazine, and thiothixene are less sedating but more likely to cause extrapyramidal symptoms than are lower potency agents such as chlorpromazine and thioridazine.

Antagonism of the serotonin receptors is associated with a reduced likelihood of inducing extrapyramidal symptoms.[2] Because serotonin receptor antagonism inhibits dopamine release in the nigrostriate and prefrontal cortex, blockade of the serotonin subtype 2A ($5\text{-}HT_{2A}$) receptors is associated with increased efficacy in treatment of negative symptoms, while providing reduced risk of extrapyramidal symptoms. Agents that are partial $5\text{-}HT_{1A}$ receptor agonists, such as ziprasidone and aripiprazole, have similar effects.

PHARMACOKINETICS

Most of the antipsychotics have similar pharmacokinetic profiles. After oral administration, absorption occurs rapidly, the drugs undergo significant first-pass metabolism, and peak plasma concentrations typically occur within 1 to 6 hours. Following IM injection, peak plasma concentrations typically occur within 60 minutes for immediate-release products, but can be delayed up to 1 day with depot preparations. Nearly all antipsychotics have high protein binding and a large volume of distribution. Metabolism is primarily through the cytochrome P-450 enzyme system, with isoenzymes 2D6, 1A2, and 3A4 accounting for the majority of drug metabolism. Because of the near-complete hepatic metabolism of these drugs, renal impairment rarely requires dosage adjustments (notable exceptions include sulpiride and remoxipride).

CLINICAL FEATURES

Isolated overdose of antipsychotics is rarely fatal, and most patients develop only mild to moderate symptoms.[3-6] Toxicity is largely a function of the dose ingested, habituation, comorbid conditions, and age. Following overdose, CNS depression is frequent but is less severe in patients receiving long-term therapy, because tolerance to the sedative effects develops after days to weeks of regular use. CNS effects range from lethargy, ataxia, dysarthria, and confusion to coma with respiratory depression in cases of severe overdose.[5,6] The ingestion of a single pill of some of the atypical or typical antipsychotics can cause significant CNS and respiratory depression in young children.[7] Respiratory depression is more common in multidrug overdoses.

Paradoxical agitation and delirium may occur in mixed overdoses, especially those involving agents with antimuscarinic properties.

TABLE 180-2 Relative Receptor Affinity of Selected Antipsychotics

		Receptor				
Agent	Brand Name in the United States	D_2	H_1	M_1	α_1-Adrenergic	5-HT_{2A}
Aripiprazole	Abilify®	3+	2+	0	2+	3+
Asenapine	Saphris®	3+	3+	0	3+	3+
Chlorpromazine	Thorazine®	2+	2+	1+	3+	3+
Clozapine	Clozaril®	1+	3+	3+	3+	3+

Ziprasidone	Geodon®	3+	0	0	3+	0

Notes: 0 = no affinity; 1+ = slight affinity; 2+ = moderate affinity; 3+ = high affinity; ? = unknown.

Abbreviations: D_2 = dopamine-2; H_1 = histamine-1; 5-HT_{2A} = serotonin subtype 2A; M_1 = muscarinic-1.

Seizures occur in approximately 1% of individuals after overdose, with the incidence higher for loxapine and clozapine. Gastric pharmacobezoars have been reported with quetiapine extended-release overdose.[8]

Many of the antipsychotics have antimuscarinic properties (Table 180-2). Thus, patients can manifest signs or symptoms that are consistent with **antimuscarinic toxicity**, including tachycardia, dry mucous membranes, dry skin, mydriasis, decreased bowel sounds, urinary retention, agitation, delirium, and hyperthermia. Due to the α-adrenergic antagonism of many of these agents, mydriasis expected with pure anticholinergic agents is less likely to be present.

The most common cardiovascular manifestations of antipsychotic overdose are **sinus tachycardia and orthostatic hypotension**. **ECG changes** include prolongation of the PR, QRS, and QT intervals, depressed ST segments, T-wave abnormalities (widening, flattening),[9] and increased U-wave amplitude. Ventricular dysrhythmias are rare,[7] with the exception of amisulpride (not available in the United States) overdoses.[10]

DIAGNOSIS

Routine laboratory analysis should include a CBC, basic chemistry tests, and a pregnancy test for women of childbearing age. Obtain an ECG to assess the conduction intervals. Obtain a CBC for a patient with a fever while taking clozapine or chlorpromazine, even if in therapeutic amounts.

TREATMENT

Treatment for patients with antipsychotic poisoning is largely supportive.[3-6] For patients who are known to have ingested or are suspected of having ingested a significant amount, establish IV access and monitor cardiac rhythm. Patients with respiratory depression should receive ventilatory support. Patients with depressed consciousness should receive oxygen supplementation, continuous pulse oximetry, assessment of blood glucose, and consideration for administration of naloxone and thiamine. Seizures should be treated with a benzodiazepine such as lorazepam.

Treat hypotension with aggressive fluid resuscitation. Adults without previously known or suspected cardiac disease should receive at least 1 to 2 L of isotonic crystalloid. Children should receive 20 to 40 mL/kg. If hypotension persists, direct-acting α-adrenergic agonists, such as **phenylephrine or norepinephrine**, are the preferred vasopressors for treatment. Dopamine, an indirect-acting vasopressor, is not recommended as a first-line agent for treatment of hypotension following an antipsychotic overdose.

Patients with a QT_c interval of >500 milliseconds are at increased risk for **torsade de pointes**.[11,12] Assuming there are no contraindications to magnesium supplementation, and regardless of the serum magnesium level, adults with a QT_c interval of >500 milliseconds should receive **magnesium sulfate**, 2 grams IV over 10 minutes.[5] Patients with torsade de pointes should receive 2 grams of magnesium sulfate as a bolus, followed by an infusion of 2 to 4 milligrams/min, regardless of the magnesium concentration. Overdrive pacing can also be useful, especially in cases that prove refractory to magnesium.[13]

Patients with an intraventricular conduction delay (e.g., prolonged QRS complex) and ventricular arrhythmias should be treated with **sodium bicarbonate**, 1 to 2 mEq/kg IV bolus, followed by intermittent boluses or a continuous infusion. Lidocaine is an acceptable alternative or second-line agent for ventricular dysrhythmias. Do not use types Ia (e.g., quinidine, procainamide), Ic (e.g., propafenone), III (e.g., amiodarone), and IV antiarrhythmics in patients with cardiac conduction disturbances or ventricular arrhythmias, because their use can potentiate such cardiotoxicity. Consider **intravenous lipid emulsion** for severe quetiapine overdoses with cardiovascular instability refractory to conventional therapy.[14-16]

DISPOSITION AND FOLLOW-UP

Following ingestion, observe the patient for at least 6 hours. Because of the potential for orthostatic hypotension, obtain orthostatic pulse and blood pressures prior to disposition. The patient can be judged free of toxicity if there are no mental status changes, pulse and blood pressure abnormalities, orthostatic hypotension, and QT_c interval prolongation after 6 hours of observation from the time of ingestion.[17] Patients with evidence of toxicity (e.g., sinus tachycardia or QT interval prolongation) should be admitted to a monitored bed for observation. Patients who develop severe symptoms (e.g., seizure, respiratory depression,

hypotension, acidosis) during the observation period in the ED should be admitted to an intensive care unit.

ADVERSE EFFECTS OF THERAPEUTIC DOSING

CARDIOVASCULAR

Both atypical and typical antipsychotics can affect myocardial conduction and repolarization. At therapeutic dosages, this is usually evidenced by prolongation of the QT interval. Of the typical agents, thioridazine, pimozide, and IV haloperidol cause the greatest degree of QT prolongation.[11,18] The prescribing information for haloperidol contains a warning that QT interval prolongation and torsade de pointes can occur, especially when administered IV or in doses higher than typically used. The warning advises caution when treating patients who have other QT interval–prolonging conditions or are taking drugs known to prolong the QT interval. This warning also emphasizes that haloperidol is not approved for IV administration and that electrocardiographic monitoring is recommended if IV haloperidol is given. Among the atypical antipsychotics, ziprasidone, sertindole, and amisulpride are associated with the greatest degree of QT prolongation in therapeutic dosing.[11,18]

EXTRAPYRAMIDAL SYMPTOMS

Extrapyramidal symptoms result from D_2 receptor blockade in the basal ganglia (nigrostriatal region). Although high-potency typical agents cause the highest rate of extrapyramidal symptoms, all antipsychotic agents are capable of producing these symptoms.[19] Blockade of the 5-HT_{2C} receptors may contribute to the induction of extrapyramidal symptoms as well by inhibiting dopamine release in the nigrostriatal and mesolimbic pathways. Many of the atypical antipsychotic agents bind to the 5-HT_{2C} receptors.

Extrapyramidal symptoms can be classified into three major patterns: (1) early-onset reversible syndromes, (2) delayed-onset reversible syndromes, and (3) potentially irreversible syndromes. The early-onset reversible syndromes typically start within hours to days and include **acute dystonia** and **akathisia**. The delayed-onset reversible syndromes occur days to weeks after the antipsychotic is started and include **parkinsonism** and neuroleptic malignant syndrome. The potentially irreversible syndromes typically begin months to years after therapy is started and include **focal perioral tremor** and **tardive dyskinesia**.

Acute dystonia is a hyperkinetic movement disorder characterized by intermittent, uncoordinated, involuntary contractions of the muscles of the face, tongue, neck, trunk, or extremities. Clinical manifestations include tongue protrusions, facial grimacing, trismus, oculogyric crisis, blepharospasm, opisthotonus, tortipelvis, and abnormal postures and gait. Although distressing to patients, these effects are not life threatening.

Akathisia is a subjective sensation of motor restlessness. It typically occurs within minutes to days of initiating or increasing the dose of an antipsychotic.[20,21] Occasionally, akathisia can be misinterpreted as increasing agitation related to an underlying psychiatric condition and can thereby prompt additional medication administration. Although akathisia is more likely to occur with the use of high-potency D_2 receptor antagonists, it can occur with large doses, rapid escalation of doses, or parenteral administration of all antipsychotics.[22]

The treatment of **akathisia** or **acute dystonia** includes the administration of diphenhydramine, 25 to 50 milligrams, or benztropine, 1 to 2 milligrams, either orally or parenterally, with parenteral administration preferred in severe cases. Benzodiazepines may serve as adjunctive therapy or can be used primarily if there is a concern about the administration of anticholinergic agents. Because of the prolonged effects of the dystonia-inducing agent, oral therapy with either diphenhydramine or benztropine should be continued for approximately 2 days after parenteral treatment.

Parkinsonism typically occurs weeks to months after initiation of therapy. It is characterized by cogwheel-type muscle rigidity, pill-rolling tremor, mask facies, shuffling gait, bradykinesia or akinesia, and cognitive impairment. It occurs in up to 13% of patients receiving long-term antipsychotic therapy. Treatment of drug-induced parkinsonism may involve lowering the dosage of a typical antipsychotic, changing to an atypical agent, adding an anticholinergic agent such as diphenhydramine or benztropine, or adding an agent that enhances dopaminergic activity (e.g., amantadine).

Perioral lip tremor, termed the *rabbit syndrome*, is an uncommon late-onset extrapyramidal adverse effect of antipsychotics. **Tardive dyskinesia** is a late-onset extrapyramidal syndrome that can range from reversible to partially reversible to irreversible. Clinical observation suggests that if patients take these drugs long enough, the majority develop the disorder. Tardive dyskinesia is characterized by painless, stereotyped, repetitive movements of the orofacial structures. There can be occasional tongue protrusion, lip smacking, facial grimacing, and choreoathetosis of the trunk and limbs. Although tardive dyskinesia can occur with any antipsychotic agent, it is more common with the typical agents. In young patients, the observed annual occurrence rate of tardive dyskinesia is about 3% to 5% with the typical antipsychotics. In elderly patients, tardive dyskinesia can develop in up to 25% during the first year of haloperidol therapy. The occurrence rate for tardive dyskinesia with the atypical agents is about one tenth that with the first-generation antipsychotics.

Because the symptoms of tardive dyskinesia may be irreversible, the best treatment is the use of steps to minimize its occurrence.[19] Early detection and prompt withdrawal of the antipsychotic increase the likelihood of complete recovery. Unlike with drug-induced parkinsonism, anticholinergic agents exacerbate tardive dyskinesia and should not be used.

OTHER ADVERSE EFFECTS

Therapeutic use of atypical antipsychotics is linked with the development of type 2 diabetes mellitus and diabetic ketoacidosis.[19,23-26] There is some suggestion that the risk is greatest with olanzapine.[27] Atypical antipsychotics are associated with weight gain and intra-abdominal obesity, abnormal glucose regulation, and insulin resistance.[28] Nonalcoholic steatohepatitis has been reported with the therapeutic use of risperidone and olanzapine, and pancreatitis has been associated with the use of clozapine. Hyperprolactinemia is more common with the typical antipsychotics, but can occur with the atypical antipsychotics as well, manifesting as menstrual disturbances and galactorrhea in females and gynecomastia in males.[29] Amisulpride, paliperidone, and risperidone are the most likely of the atypical antipsychotics to induce hyperprolactinemia.

Phenothiazines are associated with leukopenia in up to 0.8% and agranulocytosis in 0.05% of patients.[30] Several atypical antipsychotics have also been associated with agranulocytosis, with the highest incidence in patients taking clozapine, in whom leukopenia occurs in 3% and agranulocytosis in 0.8%. Due to these adverse effects, clozapine can only be prescribed within a strictly monitored program.

Seizures have been associated with several antipsychotics, primarily chlorpromazine, loxapine, and clozapine.[31-33] The risk of seizure appears to be dose dependent.

NEUROLEPTIC MALIGNANT SYNDROME

Neuroleptic malignant syndrome is a rare but potentially fatal idiosyncratic complication of antipsychotic drug therapy.[34,35] Neuroleptic malignant syndrome is not the result of overdose. It most often occurs shortly after the start of therapy or after a dosage adjustment, and the antipsychotic serum concentration is usually within the therapeutic range. Neuroleptic malignant syndrome is associated with all the typical antipsychotics and most of the commonly available atypical antipsychotics, including aripiprazole, clozapine, olanzapine, risperidone, and ziprasidone.[36,37] The incidence is about 1 to 2 cases per 10,000 patients treated.[35]

Neuroleptic malignant syndrome typically develops over a period of 1 to 3 days and is characterized by the tetrad of fever, muscular rigidity, autonomic dysfunction, and altered mental status (including lethargy, agitation, mutism, or coma). The rigidity is typically described as lead-pipe and cogwheel rigidity, similar to that observed with parkinsonism.

Major diagnostic criteria for neuroleptic malignant syndrome are fever and muscle rigidity (**Table 180-3**). An international consensus panel includes two criteria that embody important concepts about this syndrome: (1) recent dopamine antagonist exposure or dopamine agonist withdrawal, and (2) negative evaluation for other causes.[38] Common

TABLE 180-3 Diagnostic Criteria for Neuroleptic Malignant Syndrome

	Caroff and Mann*	Levenson†	American Psychiatric Association‡
Major criteria	Fever >38°C (100.4°F)	Fever	Fever
	Muscle rigidity	Muscle rigidity	Muscle rigidity
		Elevated CK level	
Minor criteria	Change in mental status	Tachycardia	Diaphoresis
	Tachycardia	Abnormal blood pressure	Dysphagia
	Hypertension or hypotension	Tachypnea	Tremor
	Tachypnea or hypoxia	Leukocytosis	Incontinence
	Diaphoresis or sialorrhea	Diaphoresis	Altered mental status
	Tremor	Altered mental status	Mutism
	Incontinence		Tachycardia
	Increased CK level or myoglobinuria		Labile blood pressure
	Leukocytosis		Leukocytosis
	Metabolic acidosis		Elevated CK level
Diagnostic requirement	Both major and at least 5 minor criteria must be present, and treatment with an antipsychotic must have been within 7 d of symptom onset (or 2–4 wk with a depot agent).	All 3 major criteria or 2 major and 4 minor criteria must be present.	Both major and at least 2 minor criteria must be present.

Abbreviation: CK = creatine kinase.

*Caroff SN, Mann SC: Neuroleptic malignant syndrome. *Med Clin North Am* 77: 185, 1993.

†Levenson JL: Neuroleptic malignant syndrome. *Am J Psychiatry* 142: 1137, 1985.

‡American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed, text revision. Washington, DC: American Psychiatric Association, 2000:795.

laboratory abnormalities include elevated creatine kinase level, leukocytosis, elevated levels of hepatic transaminases, hypernatremia or hyponatremia, metabolic acidosis, myoglobinuria, elevated BUN and creatinine levels, and decreased serum iron level.[39]

Treatment is primarily supportive.[34,35,40,41] Withdraw any antipsychotics and potentiating drugs, such as anticholinergics, antihistamines, or lithium. Consider and evaluate for other medical conditions that can present in a similar manner, including CNS infection, other drug-induced hyperthermic syndromes, serotonin syndrome, anticholinergic poisoning, and sympathomimetic toxicity.[40,41] Reduce the patient's temperature with external cooling measures; pharmacologic antipyretics such as acetaminophen are not beneficial in lowering the temperature associated with this syndrome. Sedation is very important to decrease agitation and sympathetic activity; a benzodiazepine, such as lorazepam, is recommended.[34,40,41]

Airway and breathing difficulties should be anticipated, and patients with excessive secretions, dysphagia, decreased airway reflexes, acidosis, or hypoxia should be intubated. In addition, strongly consider intubating patients with fever and rigidity, because muscular paralysis reduces the muscle contraction and thereby reduces the fever. **When patients with neuroleptic malignant syndrome are intubated, nondepolarizing agents (e.g., rocuronium) are preferred over depolarizing agents (e.g., succinylcholine)**.

Complications from profound muscle rigidity are responsible for most deaths in neuroleptic malignant syndrome. Prompt reduction in muscle rigidity can be expected to minimize the occurrence of complications such as rhabdomyolysis, renal failure, respiratory failure, disseminated intravascular coagulation, and cardiovascular collapse. The role of specific pharmacotherapy is unclear. For each therapy reported effective, none has clearly been shown to be superior to supportive care alone.[34,40,41]

Pharmacologic therapies described in case reports and series include amantadine, bromocriptine, and dantrolene. **Dantrolene** (1.0 to 2.5 milligrams/kg IV load, followed by 1 milligram/kg IV every 6 hours) should primarily be used for more severe cases of neuroleptic malignant syndrome in which the rigidity is pronounced. Dantrolene should not be used concurrently with calcium, because this increases the risk of cardiovascular collapse.[6] **Bromocriptine**, a centrally acting dopamine agonist, can reduce fever and muscle rigidity in neuroleptic malignant syndrome and possibly shorten the duration.[42] This drug is only available in an oral preparation and may require administration by a nasogastric tube. Adverse sides effects of hypotension, vomiting, and worsening of psychosis are limiting factors to the routine use of bromocriptine.[41]

CHAPTER 181

Lithium

Sandra M. Schneider
Daniel J. Cobaugh
Benjamin D. Kessler

INTRODUCTION

Lithium is one of the most effective medications for the continuous treatment of bipolar disorder. It is particularly useful for the treatment of acute manic episodes and reduces rates of suicide associated with affective disorders.[1-3] Off-label uses for lithium include augmentation of the action of other antidepressant drugs and treatment of aggression, posttraumatic stress disorder, and pediatric conduct disorders. Lithium for the treatment of Alzheimer's disease is under investigation.[4] Lithium toxicity most often results from accidental or intentional overdose, increased dose, or reduction in renal clearance of lithium.

PHARMACOLOGY

The specific pharmacologic effect responsible for the therapeutic benefit in bipolar disorder and mania is unknown.[5] Lithium competes with other similar cations, including sodium, potassium, magnesium, and

calcium, and displaces them from intracellular and extracellular sites. Interference with sodium ions at the sodium channel and the sodium-potassium pump on the cell membrane is responsible for lithium's adverse effect on myocardial electrical activity. Lithium inhibits arginine vasopressin, an effect that is responsible for polyuria and nephrogenic diabetes insipidus seen during lithium therapy. Some toxic effects of lithium may be due to inhibition of 3-glycogen synthase kinase, which is present in high quantities in the brain.[5] Other pharmacologic effects include inhibition of inositol monophosphatase and reduction of the concentration of inositol in the cytoplasm, inhibition of adenylate cyclase and reduction of intracellular cyclic adenosine monophosphate and possibly cyclic guanosine monophosphate, and interference with the release and reuptake of norepinephrine at the nerve terminal site. Lithium may enhance serotonin release, particularly from the hippocampus, and has been implicated in serotonin syndrome when combined with other medications that alter serotonin metabolism.

Lithium is excreted by the kidneys, so medications that reduce glomerular function have the potential to contribute to lithium toxicity, particularly thiazide diuretics.[6] **Neuromuscular blocking agents such as succinylcholine, vecuronium, and pancuronium may result in a prolonged neuromuscular blockade when given to patients receiving long-term lithium therapy.**

PHARMACOKINETICS

After oral ingestion of therapeutic doses, lithium is rapidly and almost completely absorbed, although delayed absorption may occur with sustained-release products and after ingestion of a large number of tablets.[7] Lithium is not bound to plasma proteins and has an initial volume of distribution of 0.6 L/kg, which is similar to that of body water, but over time this can increase to 0.9 L/kg as the ion distributes throughout the body. Ingestion of a single tablet of lithium carbonate 300 milligrams containing 8.12 mEq of lithium ion will acutely raise serum lithium levels by about 0.2 mEq/L (0.2 mmol/L) in a 70-kg adult.

Lithium distribution into and out of the brain is slower, resulting in neurologic effects that do not correlate with serum levels. The lithium concentrations in the brain and in the serum may differ by twofold to threefold.[8] Continuation of toxic effects, even after hemodialysis, can be due to the drug's slow movement out of the CNS. Therefore, **serum levels do not predict CNS levels and only roughly correlate with clinical symptoms**.

The elimination half-life after a single dose of lithium is about 18 to 24 hours in young adults and almost twice that in the elderly.[7] After continued therapy of longer than a year, the lithium elimination half-life increases, up to almost 60 hours in all ages. Lithium is not metabolized and is excreted unchanged, primarily in the urine. Like other cations of similar size, lithium is reabsorbed in the proximal tubule.

Renal insufficiency is a critical factor in the development of lithium toxicity. Changes in fluid and electrolyte status can impact lithium clearance; sodium and water loss due to heat or exercise may lead to lithium retention. The elderly are particularly prone to toxicity because of their decreased volume of distribution and reduced renal clearance. Elderly patients are at risk for lithium toxicity when concomitantly treated with either loop diuretics or angiotensin-converting enzyme inhibitors.[9]

CLINICAL FEATURES

ADVERSE EFFECTS OF CHRONIC LITHIUM THERAPY

Adverse effects during therapeutic lithium use are common, occurring in up to 90% of treated patients. **The most frequent adverse effects include fine postural hand tremor, fatigue, polyuria due to loss of urinary concentration ability, hypothyroidism, and hyperparathyroidism with hypercalcemia.**[10-12] Worsening of a baseline tremor and development of ataxia or dysarthria are important signals of developing toxicity and may signal a need to decrease the dose of lithium. Long-term lithium treatment can lead to electroencephalographic changes, including diffuse slowing, an increase in theta and delta waves, and a decrease in alpha activity.

Lithium is a common cause of drug-induced nephrogenic diabetes insipidus, which is prevalent in up to 40% of patients receiving long-term lithium treatment and occurs through decreased expression of aquaporin-2 in the distal tubule of the nephron.[13,14] This leads to decreased urinary concentrating ability, which is usually compensated in patients by increased thirst. The defect in the distal nephron can also result in an inability to acidify the urine, causing an incomplete distal renal tubular acidosis without acidemia. Long-term lithium treatment can lead to a progressive nephropathy, with a mild reduction in glomerular filtration[12,15] and about a 1% absolute risk of requiring renal replacement therapy.[15,16] Maintaining serum lithium levels below 0.8 mEq/L (0.8 mmol/L) may reduce long-term renal damage.[17]

GI side effects, including nausea, vomiting, and diarrhea, are common at initiation of treatment, are generally transient, and can be decreased by giving the lithium dose with food or dividing the dose over the day. Development of these symptoms during the course of treatment, on the other hand, may signal toxicity or may cause volume depletion and induce toxicity.

ECG abnormalities commonly reported with lithium use include QT interval prolongation, T-wave flattening or inversion, and significant bradycardia.[18]

Hypothyroidism is the most prevalent endocrine dysfunction, occurring at a rate almost six times that in the general populace.[12,19] Hyperparathyroidism and hypercalcemia are frequently reported and can be associated with stimulation of hyperplasia or adenomas.[20]

TOXIC EFFECTS

Lithium toxicity can be divided into three main categories: acute toxicity in naïve patients, acute-on-chronic toxicity in those who take lithium long term and take an acute intentional overdose, and chronic toxicity developing in patients receiving long-term lithium therapy who experience a change in lithium dosage or decreased renal clearance.[21-24] Decreases in glomerular filtration or intravascular volume depletion are a precipitating cause in nearly all cases of chronic toxicity. Other factors may also contribute to the development of lithium toxicity (**Table 181-1**).[25]

Recognizing lithium toxicity may be challenging, particularly in patients with chronic toxicity.[26,27] There is only an approximate correlation between serum levels and clinical symptoms.[24] Common symptoms are increased tremor, muscle fasciculations, clonus, choreoathetosis, ataxia, muscle weakness, dysarthria, agitation, and lethargy (**Table 181-2**).[25,27,28] It may be difficult to distinguish between lithium toxicity and organic delirium.[29] Although most patients present with a slowing of cognitive function, cases of lithium toxicity presenting with mania or auditory, visual, and tactile hallucinations have been reported. As toxicity worsens, confusion, lethargy, stupor, seizures, and finally coma develop.

TABLE 181-1 Factors Precipitating the Development of Lithium Toxicity

Decreased glomerular filtration: renal injury or failure, heart failure, sepsis
Volume depletion: diuretic use, vomiting, diarrhea, diaphoresis, decreased oral intake
Drug–drug interaction, including polypharmacy

TABLE 181-2 Lithium Toxicity

Toxicity	Clinical Features	Typical Lithium Level (mEq/L or mmol/L)*
Mild	Nausea, vomiting, fatigue, lethargy, fine tremor	1.5–2.5
Moderate	Confusion, agitation, dysarthria, ataxia, hypertonia, hyperreflexia, nystagmus, muscular weakness	2.5–3.5
Severe	Coma, seizures, myoclonus, hyperthermia, cardiovascular collapse	>3.5

*Lithium levels have only an approximate correlation with severity.

Lithium toxicity commonly produces distal renal tubule dysfunction, with decreased response to arginine vasopressin, so that patients may develop significant polyuria compensated by polydipsia. Alteration of this balance can lead to electrolyte disturbances such as hypernatremia, volume depletion, and renal insufficiency.

GI symptoms such as nausea, vomiting, diarrhea, bloating, or generalized abdominal pain are common in both acute and chronic toxicity. Cardiac abnormalities are more common in acute toxicity and can cause hypotension, bradycardia, and ventricular dysrhythmias, presenting as syncope.[30,31] Chronic lithium toxicity may be associated with rare cases of ventricular tachycardia.[32] ECG changes with a prolonged QT interval, transient ST-segment depression, or T-wave inversion are seen in some patients. Less common toxic effects include hyperthermia, hypothermia, peripheral neuropathy, and severe leukopenia. Rare cases of adult respiratory distress syndrome have been associated with acute lithium toxicity.[33]

Up to 10% of patients with severe lithium toxicity die, generally of respiratory failure or cardiovascular collapse. Most patients recover, with toxic effects resolving as the body burden of lithium decreases. Permanent cerebellar and basal ganglia damage may develop. A syndrome of irreversible lithium-effectuated neurotoxicity has been described after lithium toxicity and involves various degrees of neurologic dysfunction after cessation of lithium use for at least 2 months. These patients have truncal ataxia, ataxic gait, scanning speech, and diffuse incoordination.[28] Short-term memory loss, dementia, and a tremor of the hands and head accompany the cerebellar signs.

DIAGNOSIS

Acute lithium overdoses present with more GI toxicity and less neurologic toxicity because of the slower accumulation into the brain after ingestion and distribution in body water. With time, as CNS lithium levels rise, neurologic findings increase after GI symptoms abate. Patients with acute overdose may have markedly elevated serum concentrations that do not correlate well with either symptom severity or prognosis.

Patients with chronic toxicity display earlier and more prominent neurologic effects in association with lower serum concentrations. Serum lithium levels in such patients correlate better with degree of toxicity, but the clinical condition of the patient is the most important factor.[34] Lithium toxicity has even been reported at therapeutic levels.

Acute-on-chronic ingestions occur in patients who are undergoing treatment with lithium and ingest an additional amount. These patients can have both GI and neurologic symptoms and signs.

Monitor lithium serum concentrations and obtain serial serum measurements during observation and treatment. Collect blood samples for measurement of serum lithium concentration in the appropriate tube to avoid falsely increased levels; collection in tubes containing lithium-heparin may cause false elevation in lithium level.[18] Therapeutic lithium levels are considered to be 0.6 to 1.2 mEq/L (0.6 to 1.2 mmol/L). The toxic range varies according to the clinical circumstance, with most patients manifesting toxic effects at levels >2 mEq/L (>2 mmol/L).

A 12-lead ECG may be helpful in identifying a level >1.2 mEq/L (>1.2 mmol/L); QT_c interval >440 milliseconds and diffuse T-wave inversions have positive likelihood ratios of 7 and 4, respectively.[35]

Lithium-induced hypothyroidism can be severe, precipitating myxedema crisis, so check thyroid-stimulating hormone and thyroid hormone levels in patients with altered level of consciousness.[36]

TREATMENT

Initial stabilization of the patient's condition includes protection of the airway and provision of ventilatory and hemodynamic support. Establish IV access, initiate cardiac rhythm monitoring, obtain an ECG, and order renal function tests, fluid and electrolyte levels, calcium levels, magnesium levels, CBC, thyroid-stimulating hormone and thyroid hormone levels if altered level of consciousness, pregnancy test where applicable, and serum levels of lithium and other possible co-ingestions. Subsequent treatment depends on clinical severity (**Table 181-3**).

TABLE 181-3 Management of Lithium Toxicity

IV saline infusion	Used in essentially all patients with toxicity Reestablishes euvolemia and normal lithium renal elimination
Whole-bowel irrigation	Used in awake patients who ingest sustained-release lithium preparations
Sodium polystyrene sulfonate	Consider in awake patients with mild to moderate toxicity
Hemodialysis	Used for patients with severe toxicity Also used for patients with renal failure, patients who cannot tolerate IV saline infusion, and patients with high elevated serum lithium levels (>4.0 mEq/L in any type of overdose and >2.5 mEq/L in chronic toxicity)
IV benzodiazepines	Used for seizures seen in severe toxicity

Treat seizures with IV benzodiazepines, such as lorazepam. Obtain toxicology and neurology consultation for refractory seizures. Phenytoin is ineffective in controlling drug-induced seizures.

Gastric lavage has no role in most cases of lithium overdose because the sustained-release preparations are often too large and the immediate-release preparations are too rapidly absorbed.[37] Ipecac syrup is no longer recommended.[38] Whole-bowel irrigation with polyethylene glycol solution at 2 L/h is effective in removing lithium from the body after an acute ingestion of sustained-release preparations, as long as there is no alteration of mental status.[39,40] **GI decontamination is useless in patients with chronic toxicity.**

IV administration of normal saline is critical, because nearly all patients with significant toxicity have some sodium and volume deficit.[41] Typical adult dosing is an IV bolus of normal saline, 20 mL/kg, followed by continuous infusion at 1.5 to 2 times the maintenance rate. Volume repletion reestablishes normal renal elimination kinetics of lithium. Diuretic-induced diuresis does not enhance lithium elimination, and in fact, loop and thiazide diuretics promote water loss, which is followed by lithium retention.

Sodium polystyrene sulfonate (Kayexalate®), an exchange resin, binds lithium, relieves a modest amount of the body burden of lithium, and shortens elimination half-life.[42,43] Doses used in observational studies, mostly in patients with chronic toxicity, are 30 grams dissolved in 120 mL of water, orally, every 4 to 6 hours. This approach is not widely used because oral drugs are to be avoided in patients with impaired mental status due to the risk of aspiration, the potential for hypokalemia and constipation, and the effectiveness of other therapies.

Anecdotal treatment with sodium bicarbonate and acetazolamide (both for urinary alkalinization) and aminophylline has no proven benefit.

Lithium can be removed by hemodialysis, but there is much debate over the threshold for initiating this treatment.[44] Hemodialysis is indicated in patients with symptoms of severe toxicity, those who cannot tolerate treatment with IV fluids, or those whose renal function is impaired and who lack the ability to eliminate lithium. Extracorporeal treatment is recommended for severe toxicity (coma, seizures, life-threatening dysrhythmias) or a serum lithium level > 4.0 mEq/L (> 4 mmol/L) in the presence of renal insufficiency. Consult with a medical toxicologist or nephrologist for patients who have little decrease or increase in serum lithium level after 6 hours of IV saline administration or for patients who have ingested sustained-release preparations.

The goal of hemodialysis is to reduce the body burden of lithium. Because of the intracellular concentration of lithium, redistribution after hemodialysis is expected and an increase in serum levels after hemodialysis is common. Therefore, monitor serum lithium levels for up to 8 hours after hemodialysis. If symptoms of toxicity recur or worsen or if the levels rise significantly, consider repeat hemodialysis. Peritoneal dialysis has been used for treatment of lithium toxicity in the past, but the clearance rates are approximately the same as through normal renal clearance (**Table 181-4**).

TABLE 181-4 Reported Lithium Clearance in Normal Adults with Acute Toxicity

Therapy	Elimination Half-Life (h)	Clearance (mL/min)
No treatment	18–42*	10–40*
IV saline	13–20	–
Sodium polystyrene sulfonate	12–20	–
Peritoneal dialysis	12–16	10–15
Hemodialysis	4–6	70–170

*Longer elimination half-lives and reduced clearance rates are seen in older adults and in patients with acute-on-chronic toxicity.

DISPOSITION

Admission decisions are made by considering such issues as the presence and persistence of factors predisposing the patient to toxicity, the acuity of the toxicity, and the circumstances that led to the toxicity.[45] Asymptomatic patients with acute ingestions should be monitored for 4 to 6 hours, with serial serum lithium levels measured. Admit patients with serum lithium levels of >1.5 mEq/L (>1.5 mmol/L) after an acute ingestion. **Any patient with an *acute* ingestion of a sustained-release preparation should be admitted regardless of serum lithium level.**

Patients with mild toxicity who have no additional risk factors may be managed with IV saline treatment for 6 to 12 hours, often in an observation unit. Once repeated serum lithium levels decrease to <1.5 mEq (<1.5 mmol/L), such patients can be discharged after psychiatric evaluation, if needed. Patients with moderate toxicity require admission, and patients with severe toxicity require intensive care.

Patients taking lithium may seek care in the ED for conditions not related to mental health or lithium toxicity. Take care to avoid prescribing any drugs that negatively impact glomerular filtration and renal function. Thiazide diuretics, nonsteroidal anti-inflammatory drugs, angiotensin-converting enzyme inhibitors, and angiotensin receptor blockers are some common agents that have the potential for lithium interaction promoting toxicity.[6,46]

CHAPTER 182

Barbiturates

Chip Gresham
Frank LoVecchio

INTRODUCTION

Barbiturate toxicity has historically been associated with the highest risk of morbidity and mortality among all sedative-hypnotics. Barbiturates are still the most common class of antiepileptic drugs used in developing countries, but their use is declining due to the introduction of safer, less toxic sedative-hypnotics, such as benzodiazepines, and second-generation anticonvulsants.[1] Status epilepticus,[2] severe ethanol and sedative withdrawal syndromes,[3-5] and toxicologic seizures[6] are typically managed with benzodiazepines, but barbiturates have a useful role as a second-line agent. They are still used in combination drugs (i.e., butalbital) and alone (i.e., secobarbital) for the treatment of tension and migraine headaches,[7,8] although the efficacy of either is controversial.[9] Barbiturates are used in the pharmacologic management of refractory intracranial hypertension from focal and diffuse brain injury, but evidence of improved outcomes has been modest.[10]

PHARMACOLOGY

Barbiturates are generally classified according to their duration of action, which is primarily dependent on lipid solubility and tissue distribution rather than the elimination half-life (**Table 182-1**).

Barbiturates readily distribute throughout the body to most tissues, crossing the blood–brain barrier and placenta, and are excreted in breast milk. Fetal blood barbiturate concentrations closely reflect maternal plasma levels, creating the potential for fetal withdrawal syndrome.[11] Most barbiturates are metabolized in the liver to inactive metabolites primarily through routes involving the cytochrome P450 system. The elimination half-life of barbiturates can be greatly shortened in infants and children and very prolonged in the elderly and in patients with liver or renal disease. Chronic barbiturate use induces activity of the cytochrome P450 enzymes and may accelerate the metabolism of other therapeutic drugs, such as oral contraceptives, anticoagulants, and corticosteroids, when taken concurrently.

Barbiturates' main action is the depression of activity in the CNS and musculoskeletal system. In the CNS, this is accomplished by enhancing the action of the primary inhibitory neurotransmitter γ-aminobutyric acid at its receptor.[12] When γ-aminobutyric acid binds to its chloride channel receptor, it causes it to open, resulting in depolarization, which temporarily stabilizes the resting membrane potential and inhibits the firing of new action potentials. Barbiturates bind to the α subunit of the γ-aminobutyric acid receptor, causing an increase in the duration of time that the cell membrane chloride channel is open, resulting in prolonged depolarization and prolonged inactivity.

Benzodiazepines bind to a different site on the α subunit of the γ-aminobutyric acid receptor and increase the frequency with which the chloride channel opens. Increased duration, as opposed to increased frequency, is one of the reasons cited for increased morbidity and mortality with barbiturate overdoses compared to benzodiazepines.

Barbiturates inhibit both the activity of the excitatory neurotransmitter, glutamate, at the glutamate receptor and calcium-mediated excitatory neurotransmitter release at the presynaptic terminal. Blockade of the calcium channel may contribute to the cardiac contractility impairment seen with barbiturate overdoses. Barbiturates also have effects on voltage-dependent sodium and potassium channels, but in concentrations typically far above the therapeutic range.[13] These effects may contribute to the toxicity or paradoxical actions seen with some barbiturate drugs in overdoses.

CLINICAL FEATURES

Mild to moderate barbiturate intoxication closely resembles alcohol intoxication and toxicity of other sedative-hypnotics; drowsiness, disinhibition, ataxia, slurred speech, and mental confusion are common features that escalate with increasing dose. The progressive neurologic depression seen with *severe* barbiturate intoxication predictably manifests as a range from stupor to coma to complete neurologic unresponsiveness, including the absence of a corneal reflex and deep tendon reflexes.

The most common vital sign abnormalities seen in overdose are respiratory depression, hypothermia, and hypotension, with respiratory depression usually occurring first. Abnormal temperature control and respiratory depression are centrally mediated phenomena, whereas hypotension is primarily a result of decreased vascular tone. Pulse rate, pupil size, light reactivity, and nystagmus are variable. GI tract motility is slowed, resulting in delayed gastric emptying and ileus. Skin bullae, sometimes referred to as "barb blisters" or "coma blisters," are uncommon and may indicate nothing more than the effects of local skin pressure, although hypoxia has been implicated as well.[14] Coma blisters are not specific to sedative-induced coma; they have been reported after surgery,[15] from other causes of coma,[16] and even without coma.[17]

Early deaths in barbiturate overdose result from respiratory arrest and cardiovascular collapse. Common complications include hypoglycemia (perhaps due to starvation), pulmonary edema, aspiration pneumonia, and acute lung injury. Current mortality rates range between 1% and 3%; death usually results from multiple organ system failure. Lethal doses are estimates (Table 182-1), but severe poisoning can be assumed if more

TABLE 182-1 Selected Properties of Commonly Used Barbiturates

	Long Acting*		Intermediate Acting*		Short Acting*		Ultrashort Acting*	
Agent	Barbital†	Phenobarbital†	Amobarbital	Butalbital	Pentobarbital	Secobarbital	Thiopental	Methohexital

Abbreviation: ND = no data.

*This classification scheme is a convention only; it preceded the discovery that the elimination half-lives do not conform to the apparent duration of action.

†Only drugs responsive to alkaline diuresis.

‡In nontolerant individuals.

than 10 times the hypnotic dose has been ingested in a single exposure in an intolerant patient.[18] As with other sedative-hypnotics, the toxic properties of barbiturates may be enhanced in the presence of benzodiazepines or alcohol. Conversely, the depressive effects may be protective in a mixed-stimulant overdose.[19]

DIAGNOSIS

Laboratory evaluation in barbiturate overdose should include determination of glucose levels, blood chemistries, CBC, arterial blood gas (if indicated), toxicology screen, chest radiograph, and an electrocardiogram. Urine drug screens most commonly use the immunoassay methodology, and a false-positive result on the barbiturate screen has been reported with ibuprofen and naproxen.[20] If important, confirm a positive urine screen using a more accurate method, such as gas chromatography–mass spectrometry.

Barbiturate serum levels are useful in establishing the diagnosis of a comatose patient; however, acute treatment decisions should be clinically based. Serum barbiturate levels reported in lethal overdoses vary widely, and measurements are not reliable in predicting clinical course after an overdose because they do not reflect brain barbiturate concentrations and may underestimate the clinical condition of a patient in the setting of polydrug exposure.[21] Barbiturate levels are also invalid in chronic barbiturate abusers who have developed physiologic tolerance and in patients with renal or hepatic disease who have decreased clearance.[18]

TREATMENT

In a barbiturate overdose, the initial priorities are airway management and supportive care. Once pulmonary and cardiovascular function has been stabilized, options for increasing drug clearance are considered.

AIRWAY ASSESSMENT AND INITIAL STABILIZATION

Assess the patient's mental status and airway stability. Intubation with mechanical ventilation in severe sedative-hypnotic overdose is often required. Barbiturate toxicity results in decreased cardiac output and vascular tone, often resulting in profound hypotension. Volume expansion with intravenous crystalloids is the mainstay for circulatory support in the absence of cardiac failure. If fluid resuscitation fails to correct hypotension, administer vasopressors such as dopamine or norepinephrine. Hypothermia between 30°C (86°F) and 36°C (96.8°F) is common and should be monitored via continuous core temperature and treated with rewarming measures.

ACTIVATED CHARCOAL

A single dose of activated charcoal should be given to cooperative, clinically stable patients who present within 1 hour of acute oral overdose.[22] Multidose activated charcoal is beneficial in reducing serum phenobarbital concentrations; however, no significant difference in clinical outcome has ever been demonstrated. Current consensus guidelines are to consider multidose activated charcoal if a patient has ingested a life-threatening amount of phenobarbital.[23] A typical adult regimen for multidose activated charcoal is an initial dose of 50 to 100 grams PO followed by 12.5 to 25 grams PO every 4 hours. Concurrent administration of cathartic agents remains unproven and is discouraged (see chapter 176, General Management of Poisoned Patients). Careful attention to and monitoring of the patient's airway is important to decrease the risk of aspiration or bowel obstruction.

FORCED DIURESIS

Forced diuresis is not recommended because of the risks of sodium and fluid overload and lack of proven efficacy.

URINARY ALKALIZATION

Urinary alkalization (see chapter 176) does enhance the clearance of phenobarbital and primidone (which is metabolized to phenobarbital). The treatment is less effective than multidose activated charcoal in reducing serum levels, does not improve clinical outcomes, and **is not effective for shorter-acting barbiturates.**[24] In barbiturate poisoning, urinary alkalization is not a first-line treatment and has only a minor, if any, role.[25,26]

EXTRACORPOREAL ELIMINATION

Hemodialysis, hemoperfusion, and hemodiafiltration can enhance elimination of phenobarbital but are reserved for patients who are deteriorating despite aggressive supportive care.[26-28] **These modalities are not useful for poisoning from barbiturates other than phenobarbital.** Exchange transfusion has also been reported to be useful in neonatal phenobarbital toxicity.[29]

DISPOSITION AND FOLLOW-UP

Mild to moderate barbiturate intoxication responds well to general supportive care, including a single dose of activated charcoal, if appropriate. Improvement in neurologic status and vital signs over 6 to 8 hours signals eventual patient discharge or transfer. When indicated, obtain

mental health assessment. For a long-acting agent such as phenobarbital, serial serum levels should be obtained during the initial 6 hours after an overdose before concluding the patient can be safely discharged or transferred. Evidence of toxicity after 6 hours will require hospital admission, and patients with severe toxicity should go to the intensive care unit. Consult with a medical toxicologist or local poison center to assist in the care of barbiturate-poisoned patients.

SPECIAL CONSIDERATIONS

BARBITURATE WITHDRAWAL SYNDROME

Barbiturates are notorious for their rapid development of tolerance, high liability for physical dependence and abuse, and multiple drug interactions. Abrupt discontinuation of barbiturates in a chronically dependent user will produce minor withdrawal symptoms within 24 hours and major life-threatening symptoms within 2 to 8 days. The severity of the withdrawal reflects the degree of physical dependence and drug half-life. Cessation of short-acting barbiturates results in more severe abstinence symptoms than stopping long-acting barbiturates. Such effects are consistent with the clinical observation that the brain has more time to adapt to gradually declining drug concentrations.

Clinical manifestations of barbiturate withdrawal mimic those described for alcohol withdrawal. *Minor symptoms* include anxiety, restlessness, depression, insomnia, anorexia, nausea, vomiting, muscle twitching, abdominal cramping, and sweating. *Major symptoms* include psychosis, hallucinations, delirium, generalized seizures, hyperthermia, and cardiovascular collapse.

Priorities in the treatment of major withdrawal symptoms are cardiovascular stabilization and seizure control. Seizures may be treated with benzodiazepines but are more effectively treated with barbiturates. Due to the associated mortality, gradual in-hospital detoxification is needed.

NEONATAL WITHDRAWAL

Infants born to mothers physically dependent on barbiturates are at risk for dependence and subsequently withdrawal. Withdrawal may manifest within the first to third days of life.[11] Signs and symptoms include high-pitched crying, vomiting, diarrhea, tremors, and, possibly, seizures. Withdrawal is treated with gradually decreasing doses of phenobarbital.[11]

CHAPTER 183

Benzodiazepines

Dan Quan

INTRODUCTION

Benzodiazepines, to varying degrees, have in common six major pharmacologic effects: sedative, hypnotic, anxiolytic, amnestic, anticonvulsant, and muscle relaxant.[1] Benzodiazepines are commonly used for the short-term treatment of anxiety, insomnia, seizures, and alcohol and sedative-hypnotic withdrawal.[2-5] The long-term benefits of benzodiazepines for psychiatric disorders are controversial.[6,7] Midazolam, a benzodiazepine with a short duration of action, is also used for procedural sedation and general anesthesia (**Table 183-1**).

Isolated benzodiazepine overdose has low mortality, and death is rare.[8] However, increased rates of morbidity do result from mixed overdose, especially in combination with opioids. **Isolated overdose with high-potency short-acting agents, such as alprazolam, temazepam, and triazolam, is associated with higher incidences of intensive care unit admissions, coma, and mechanical ventilation with toxicity compared to other benzodiazepines, such as diazepam.**[9] In the ED, parenteral administration of benzodiazepines may result in significant complications, particularly respiratory depression and hypotension, especially when combined with opioids or other sedatives.

PHARMACOLOGY

Benzodiazepines stimulate the α subunit of the postsynaptic γ-aminobutyric acid ($GABA_A$) receptor in the CNS. Stimulation of this receptor affects the ligand-gated chloride channel on the cell membrane, altering the transmembrane resting potential to below stimulation threshold and rendering the postsynaptic neuron less excitable. Stimulation of this $GABA_A$ receptor leads to inhibitory effects throughout the neuraxis, producing the typical clinical effects of sedation, anxiolysis, anticonvulsant activity, and striated muscle relaxation.

In general, benzodiazepines are well absorbed from the GI tract. The onset of action after oral ingestion is limited more by the rate of absorption from the GI tract than by the relatively rapid passage from the bloodstream into the brain. With the exception of lorazepam and midazolam, IM injection of benzodiazepines results in unpredictable absorption. IV administration of midazolam and lorazepam has an onset of action in 1 to 5 minutes. Diazepam may be administered rectally, and midazolam may be administered intranasally or intrabuccally, with variable rates of absorption by those routes.

Benzodiazepines are relatively lipid-soluble, with some variation among the agents. Increased lipid solubility is associated with more rapid diffusion across the blood–brain barrier. After single doses, the more highly lipophilic benzodiazepines have a shorter onset of action but also a shorter duration of activity. This short duration of activity occurs because of rapid egress of the drug from the brain and bloodstream into inactive tissue storage sites. For this reason, the serum half-life is not a good indicator of the duration of action in an acute ingestion.

Benzodiazepine derivatives undergo hepatic metabolism through different pathways depending on the agent. Hepatic biotransformation occurs through either oxidation or conjugation; both pathways may be used by some derivatives. Oxidation often produces active metabolites that prolong the pharmacologic effects of the parent compounds. Oxidation is more susceptible to impairment by such factors as disease states (chronic liver disease), demographic characteristics (advanced age), and concurrent treatment with drugs that affect metabolism (estrogen, isoniazid, ethanol, ketoconazole, cimetidine, and phenytoin). Conjugation is a rapid process that generally produces inactive metabolites. Examples of agents that undergo conjugation primarily include lorazepam, oxazepam, and temazepam. These agents may be safer in these susceptible groups such as those patients with hepatic dysfunction.

There is conflicting evidence on how benzodiazepines affect fetal development.[10-12] In general, the cohort studies did not find an increase in congenital malformations, but the case-control studies did show a small increase, especially for cleft lip and palate. This difference is ascribed to the higher sensitivity of case-control studies in identifying an association with specific conditions. The effect on fetal outcome of large doses of benzodiazepines taken for suicide attempts by pregnant women is not clear. Retrospective reviews of overdose with four different benzodiazepines, albeit with relatively small numbers, did not find an increased incidence of congenital abnormalities in the offspring.[13-16]

Chronic use of benzodiazepines during pregnancy can result in **withdrawal syndrome** in the infant after birth such as "floppy baby syndrome" (sedation, hypotonia, apnea, cyanosis, hypothermia) and neonatal withdrawal (restlessness, hypertonia, tremors).[17] Nearly all benzodiazepines enter breast milk, and therefore, caution should be exercised in patients taking benzodiazepines.[10,11]

Administration of benzodiazepines in patients with comorbid conditions such as hepatic dysfunction or the elderly may cause significant effects. Those with hepatic dysfunction may have impaired metabolism, causing increased clinical effects. Elderly patients taking benzodiazepines are at increased risk for falls, cognitive impairment, delirium, fractures, and motor vehicle accidents.[12,18]

TABLE 183-1 Benzodiazepines

Generic Name	Time to Peak Effect (hours)[†]	Elimination Half-Life (hours)[‡]	Duration of Action (hours)	Active Metabolite Half-Life (hours)	Oral Dose Equivalents in Milligrams to Diazepam 10 Milligrams

*Available in the United States.

[†]After oral ingestion, unless otherwise specified.

[‡]Parent compound.

Drug–drug interactions with benzodiazepines occur mainly with drugs that affect the **cytochrome P450 pathway**, specifically CYP3A4 and CYP2C19. For example, drugs such as ketoconazole or cimetidine are CYP3A4 inhibitors and may increase benzodiazepine blood levels, increasing their duration of action and/or clinical effect. Benzodiazepines themselves have not been implicated in affecting cytochrome P450 enzymes and, therefore, are unlikely to interfere with metabolism of other agents.

CLINICAL FEATURES

The clinical presentation of benzodiazepine intoxication is nonspecific and may be highly variable because of the frequent co-ingestion of other agents. Except for additive effects, drug interactions of benzodiazepines with other sedative-hypnotics are unusual.

The predominant manifestations of benzodiazepines are neurologic and are characterized by somnolence, dizziness, slurred speech,

confusion, ataxia, incoordination, and general impairment of intellectual function. Prolonged coma is atypical and should prompt suspicion of intoxication with other agents or a non–toxin-related medical condition. In the elderly, infants and children, protein-deficient persons, and those with hepatic disease, the neurologic effects of benzodiazepines may be prolonged or enhanced.

Paradoxical reactions, including excitement, anxiety, aggression, hostile behavior, rage, and delirium, have been reported but are quite uncommon. Paradoxical reactions may occur more with hyperactive children and in psychiatric patients. Benzodiazepines may have a disinhibiting effect, which, in the presence of various extrinsic factors, can lead to such actions as aggressive or hostile behavior. Other effects that have been reported and that have unclear etiologies include headache, nausea, vomiting, chest pain, joint pain, diarrhea, and incontinence.

Benzodiazepines may cause short-term anterograde amnesia; this effect may be desired, especially in procedural sedation.[12] Agents most often associated with anterograde amnesia are lorazepam, midazolam, and triazolam, although this may occur with the other benzodiazepines.

Uncommonly, respiratory depression and hypotension may occur, generally with either parenteral administration or in the presence of co-ingestants. IV administration is more likely to cause serious cardiorespiratory effects with rapid administration of large doses. In addition, the elderly and those with underlying cardiorespiratory disease are more susceptible to adverse effects of IV administration.

Propylene glycol as a diluent in parenteral preparations of diazepam and lorazepam may cause severe metabolic acidosis (lactic acidosis), nephrotoxicity, and hyperosmolar states when infused at doses >1 milligram/kg per day for an extended period of time.[19,20] During such treatment, an osmolar gap >10 is predictive of elevated propylene glycol concentrations.[20] Treatment of propylene toxicity is generally supportive but may require hemodialysis.[21]

Extrapyramidal reactions have been associated with the use of midazolam. Various allergic, hepatotoxic, and hematologic reactions also have been reported, but they are infrequent. In general, benzodiazepines have no long-term organ-system toxicity other than that which can be ascribed to indirect effects from neurologic or cardiorespiratory depression.

DIAGNOSIS

Toxicologic testing in benzodiazepine ingestion is of limited value. Serum benzodiazepine levels do not correlate well with the clinical state, so serum level measurement is not routinely indicated. Qualitative testing with urine drug screens is typically designed to identify major metabolites of most benzodiazepines, such as oxazepam, temazepam, or nordiazepam, and not the parent compound.[22] Depending on the antibody specificity used in the immunoassay, a false-negative test can occur and is commonly seen with midazolam and flunitrazepam. A urine benzodiazepine screen can usually detect a short-acting agent (e.g., lorazepam) up to 3 days and a long-acting agent (e.g., diazepam) up to 30 days after ingestion. Thus, detection of a benzodiazepine agent taken in the recent past may not correctly identify the toxicologic cause of the patient's current condition. False-positive benzodiazepine urine drug screens have been reported with oxaprozin and sertraline, although improved immunoassay techniques have reduced this potential interference.[23,24]

TREATMENT

GENERAL MEASURES

Benzodiazepines often are ingested with other agents, and the history is frequently inaccurate. Therefore, in patients with depressed or altered mental status, other metabolic and toxicologic possibilities should be considered (see chapter 176, General Management of Poisoned Patients). Do not induce emesis in benzodiazepine overdose because mental status depression may develop and increase the risk for pulmonary aspiration. Activated charcoal binds benzodiazepines effectively and may be considered. Gastric lavage, elimination enhancement by forced diuresis, hemodialysis, or hemoperfusion is not effective. Monitor neurologic and respiratory status and provide mechanical ventilation if necessary. Aspiration pneumonitis may be caused by severe respiratory and neurologic depression.

TABLE 183-2 Contraindications to Flumazenil

Overdose of unknown agents
Suspected or known physical dependence on benzodiazepines
Suspected cyclic antidepressant overdose
Co-ingestion of seizure-inducing agents
Known seizure disorder
Suspected increased intracranial pressure

BENZODIAZEPINE ANTAGONIST

Flumazenil is a unique selective antagonist of the central effects of benzodiazepines, although there have been inconclusive claims that it may be effective in reversing the neurologic toxicity from other drugs.[25] Potential clinical applications include the reversal of coma in benzodiazepine overdose and reversal of iatrogenic benzodiazepine-induced sedation during procedural sedation.[22,26] Its use in benzodiazepine toxicity may obviate the need for tracheal intubation and respiratory support.[27]

However, some toxicologists advocate that flumazenil has limited utility in the ED, noting it is useful mainly in reversing the effects of short-acting benzodiazepines administered for diagnostic and therapeutic procedures.[28] Even in such cases, management is usually accomplished safely and easily by allowing the effects of the benzodiazepine to subside without antidotal administration. Although the plasma elimination half-life of flumazenil is approximately 1 hour, its duration of action is variable and depends on the dose of flumazenil and the benzodiazepine administered. **Recurrent benzodiazepine toxicity may result once the effects of flumazenil have worn off.** This is less likely for a benzodiazepine with a short duration of action, such as midazolam. The dose **of flumazenil is 0.2 milligram IV**, which can be repeated every minute, titrated according to response or to a total dose of 3 milligrams.

Several considerations should limit the empiric administration of flumazenil to a poisoned patient (**Table 183-2**). There is a higher incidence of side effects, albeit generally minor, when flumazenil is administered to an unconscious patient presenting to the ED.[27] Of greater importance, generalized seizures have occurred in patients given flumazenil after co-ingestions of benzodiazepines and seizure-inducing agents, particularly cyclic antidepressants.[29] Seizure activity after flumazenil administration also has occurred in patients physically dependent on benzodiazepines and in patients receiving benzodiazepines for control of a seizure disorder. The putative explanation for this convulsive activity is either the reversal of the cerebroprotective and anticonvulsive effects of benzodiazepines or the precipitation of a benzodiazepine withdrawal syndrome.

Flumazenil-precipitated seizures in patients who are chronically taking benzodiazepines should be treated aggressively with another $GABA_A$ receptor agonist because the benzodiazepine site on the receptor is antagonized. **Anticonvulsants such as phenobarbital or propofol are recommended for flumazenil-induced seizures.** Careful monitoring of the patient's respiratory and mental status is necessary during treatment and may require securing the airway.

Another reason to avoid empiric administration of flumazenil in overdose patients is that the history is often unreliable or unavailable. The apparent overdose may be caused instead by an intracranial mass lesion. **Flumazenil is contraindicated in patients with a suspected elevation of intracranial pressure, such as in severe head injury, due to its adverse effect on cerebral hemodynamics.**

DISPOSITION AND FOLLOW-UP

Indications for observation or hospital admission include significant alterations in mental status, respiratory depression, and hypotension. If mental status depression persists or is profound, other agents or conditions must be considered. Although many clinicians use the 6-hour

principle for observation of stable patients after ingestion, there is insufficient literature to recommend a specific duration for appropriate ED observation to conclude the patient is safe for discharge or transfer after a benzodiazepine overdose.

BENZODIAZEPINE ABUSE AND WITHDRAWAL

Physiologic addiction to benzodiazepines may occur, particularly with prolonged use and high doses.[30] Benzodiazepines are usually abused by individuals who abuse other psychoactive drugs and use the benzodiazepine to augment the effects of the primary agent or to counter its adverse effects. In addition, those with alcohol addiction may abuse benzodiazepines.

Benzodiazepine withdrawal may occur on abrupt discontinuation and is more likely in patients with prolonged use and high doses. Because of the long biologic half-life of several derivatives, withdrawal manifestations may not occur for several days to more than 1 week after discontinuing the benzodiazepine. Unfortunately, it is often difficult to distinguish between withdrawal and underlying symptoms for which the drugs were prescribed initially.

Reported withdrawal manifestations include anxiety, irritability, insomnia, nausea, vomiting, tremor, sweating, and anorexia. Serious manifestations, including confusion, disorientation, psychosis, and seizures, also have been reported. For patients with an acute organic brain syndrome, a history of possible benzodiazepine withdrawal always should be pursued. Withdrawal reactions may be avoided by gradually tapering the medication, although there is no consensus benzodiazepine tapering method, including the length of time to taper.[31,32] It appears that slow tapering over weeks to months may be preferred. Treatment of acute withdrawal reactions may be accomplished by drug substitution or by reintroduction of a benzodiazepine with subsequent tapering.[33] Benzodiazepine equivalent dosing should be considered if treatment with benzodiazepine substitution is performed. Withdrawal from high-potency benzodiazepines, such as alprazolam, may require higher doses of traditional benzodiazepines (e.g., IV diazepam) to achieve the appropriate clinical response.

CHAPTER 184

Nonbenzodiazepine Sedatives

Michael Levine
Dan Quan

INTRODUCTION

The term *sedative-hypnotic* refers to any drug designed to produce sedation and sleepiness. These drugs can be divided into the benzodiazepines (see chapter 183, Benzodiazepines) and nonbenzodiazepines (**Table 184-1**).

One is most likely to encounter toxicity from these sedative drugs as part of accidental or nonaccidental overdose, as well as after an assault or trauma. Many nonbenzodiazepines were developed and are marketed for the treatment of insomnia.[1] The sedative effect of other agents, including antihistamines (e.g., diphenhydramine, doxylamine), antidepressants (e.g., amitriptyline, trazodone, and mirtazapine), and antipsychotics (e.g., quetiapine), are also used to promote sleep.

Three sedative agents used in the past have been removed from the legal U.S. and Canadian markets: ethchlorvynol, glutethimide, and methaqualone. However, comments on the Internet suggest these drugs might be available to North American customers from locations in Eastern Europe, Africa, Asia, and South America.[2]

TABLE 184-1 Sedative-Hypnotics

Name	Time to Peak Plasma Levels	Oral Bioavailability	Elimination Half-Life
Buspirone	40–90 min	<5%	2–3 h
Carisoprodol	1.5 h	Unknown	2 h
Chloral hydrate	30 min	Unknown	4 min for chloral hydrate and 6–10 h for trichloroethanol
γ-Hydroxybutyrate	30–60 min	25%	0.3–1 h
Melatonin	30–60 min	15%	40–50 min
Meprobamate	3.6 h	Unknown	10 h
Ramelteon	45 min	2%	1–2.6 h
Tasimelteon	0.5–3 h	Unknown	1.3 h
Zaleplon	0.7–1.4 h	30%	0.9–1.2 h
Zolpidem	1–2 h	65%–70%	1.4–4.5 h
Zopiclone	1.5–2 h	75%–80%	5–6 h
Eszopiclone	1–1.5 h	75%–80%	6–7 h

BUSPIRONE

Buspirone is approved by the U.S. Food and Drug Administration for treatment of anxiety disorders.[3] Other off-label uses include treatment of depression and nicotine dependence. Buspirone is a partial agonist at the serotonin-1A receptor and an antagonist of the dopamine-2 receptor. The resultant effect on serotonin and dopamine neurotransmitter levels is complex, depending on the concentration of the drug and specific brain location, but overall effects are primarily suppression of CNS serotoninergic activity and enhancement of dopaminergic and, possibly, noradrenergic activity.

The typical starting dose for buspirone is 5 milligrams PO three times daily, and the maximum recommended total daily dose is 60 milligrams. Following ingestion, absorption is rapid and nearly complete, with significant first-pass metabolism in the liver, primarily via oxidation, resulting in a low bioavailability. Metabolism of buspirone, by cytochrome P3A4, produces several metabolites, including one active metabolite. Primary elimination is renal, with additional substantial fecal elimination.

Common adverse effects with buspirone use include sedation, GI discomfort, vomiting, and dizziness. In therapeutic dosing, buspirone does not appear to cause psychomotor depression and has not been associated with any potential for abuse or withdrawal.[4]

The effects observed with a buspirone overdose would likely be an exaggeration of adverse effects observed during therapeutic dosing. In general, the drug is well tolerated in overdose, and the treatment is largely supportive.[5] Animal toxicity studies indicate the potential for buspirone to provoke seizures, and one human case report noted the occurrence of a generalized tonic-clonic convulsion approximately 36 hours after a buspirone overdose (**Table 184-2**).[6] **Because of its serotoninergic properties, buspirone has been associated with serotonin syndrome.**[7]

CARISOPRODOL AND MEPROBAMATE

Carisoprodol and its primary active metabolite meprobamate have been used since the 1950s. Carisoprodol is marketed as a centrally acting muscle relaxant, whereas meprobamate is marketed as an anxiolytic drug.

The exact mechanism of action of carisoprodol is not known; animal data demonstrate its ability to block interneuronal activity within the spinal cord and descending reticular formation. Other evidence suggests that the primary mechanism of action is simply related to sedation.[8] Carisoprodol may also have direct γ-aminobutyric acid activity, independent of its metabolite meprobamate.[9]

The recommended dose of carisoprodol is 200 to 350 milligrams PO up to four times daily. Following ingestion, carisoprodol is rapidly

TABLE 184-2 Selected Aspects of Nonbenzodiazepine Overdose

Agent	Features Commonly Seen with Overdose	Unique Toxicologic Effects
Buspirone	Sedation	Generalized seizures (rare) Serotonin syndrome (possible)
Carisoprodol	Sedation, coma, cardiovascular collapse, pulmonary edema	Myoclonic jerks
Meprobamate	Sedation, coma, cardiopulmonary depression	Gastric bezoar with prolonged coma
Chloral hydrate	Coma	Cardiac instability, ventricular dysrhythmias, sensitivity to catecholamines, GI distress, hemorrhagic gastritis
γ-Hydroxybutyrate	Amnesia, sedation, seizure, coma, cardiac and respiratory depression	Steep dose–response curve Sudden awakening
Melatonin	Sedation, disorientation	None observed
Ramelteon	Sedation	None observed
Tasimelteon	Unknown	Limited experience, headache (possible)
Zolpidem	Sedation, coma possible	Limited experience, vomiting
Zaleplon	Sedation, incoordination	Limited experience, headache (possible)
Zopiclone and eszopiclone	Sedation	Limited experience, methemoglobinemia and hemolytic anemia (large overdoses)

absorbed, with an onset of action within 30 minutes and a duration of action between 2 and 6 hours. Several formulations are marketed, sometimes combined with aspirin, caffeine, or codeine. Following metabolism in the liver, the carisoprodol metabolites are renally excreted.

The recommended dose of meprobamate is 400 milligrams PO three or four times daily, with a maximum total daily dose of 2400 milligrams. Following ingestion, meprobamate is rapidly absorbed, with a duration of action of 6 to 10 hours. Following metabolism in the liver, the metabolites and 10% to 20% of the unchanged drug are eliminated by the kidneys.

With a carisoprodol overdose, sedation, coma, cardiovascular collapse, and pulmonary edema have been reported. **Myoclonic jerks are commonly observed and appear somewhat unique to carisoprodol; occasional jerking movements of the extremities in a sedated or comatose patient suggest carisoprodol toxicity.** Serotoninergic features of carisoprodol intoxication have been noted, but the mechanism by which these symptoms and signs are produced is not understood.[10] Treatment of carisoprodol overdose and toxicity is supportive.

With meprobamate overdose, sedation, coma, and cardiopulmonary depression are seen, but the myoclonic jerks described above are not. **Ingestion of a large number of meprobamate tablets has been reported to form a gastric bezoar, and prolonged coma has been attributed to such retained drug within the stomach.** If this occurs, endoscopic removal of the mass or multidose activated charcoal would appear useful.

Carisoprodol and meprobamate have significant potential for abuse and dependence.[11] A withdrawal syndrome has been described in which patients can develop tremor, anxiety, insomnia, and anorexia, usually within 12 to 48 hours of abstinence. Visual and auditory hallucinations and seizures have been described during withdrawal, although these later effects are observed less consistently.

CHLORAL HYDRATE

Chloral hydrate was first marketed as a sedative in 1869, making it the oldest sedative hypnotic agent still available. It remained quite popular until the early 1900s, when barbiturates largely supplanted its use. Chloral hydrate is primarily used for procedural sedation in young children because of its relatively wide therapeutic index, the lack of significant respiratory depression, and the ability for oral administration,[12] although it is not without risk.[13]

The hypnotic dose in adults is 500 to 1000 milligrams PO. For children the hypnotic dose is 50 milligrams/kg PO and the sedation dose is 80 to 100 milligrams/kg PO.[12] Following ingestion, chloral hydrate is quickly absorbed and rapidly reduced to trichloroethanol, an active metabolite, via alcohol dehydrogenase. Trichloroethanol is further oxidized to trichloroacetic acid, which is an inactive compound. Renal excretion of chloral hydrate is minimal.

Co-ingested chloral hydrate and ethanol have a synergistic effect. The metabolism of ethanol results in increased amounts of the reduced form of nicotinamide adenine dinucleotide, which, in turn, promotes the conversion of chloral hydrate to trichloroethanol. In addition, because of competition by chloral hydrate for alcohol dehydrogenase, there is decreased metabolism of ethanol. These interactions result in more elevated levels of both trichloroethanol and ethanol than would be seen if either was ingested alone. The resultant profound sedation yields the terms "**knock-out drops**" or "**Mickey Finn**" for this combination.

At therapeutic doses, chloral hydrate results in mental status depression, but airway and respiratory reflexes are not impaired. Paradoxical hyperactivity occurs in 1% to 2% and vomiting is seen in 3% to 10% of children given doses of 50 to 100 milligrams/kg PO.

With an overdose, chloral hydrate can produce coma. **An important feature of chloral hydrate overdose is cardiovascular instability, manifested by decreased cardiac contractility, myocardial electrical instability, and increased sensitivity to catecholamines.**[14] Commonly encountered cardiac dysrhythmias include premature ventricular contractions, ventricular fibrillation, torsade de pointes, and asystole. GI irritation, including nausea, vomiting, and hemorrhagic gastritis, has been observed. A diagnostic clue is the common presence of a pear-like odor.

Treatment of chloral hydrate overdose and toxicity is largely supportive. With coma, endotracheal intubation may be necessary. **IV β-adrenergic blockers should be used to treat ventricular dysrhythmias seen with chloral hydrate overdose.**[15] Torsade de pointes should be managed with IV magnesium sulfate or ventricular overdrive pacing.

Chronic consumption of chloral hydrate can result in dependency and addiction. A withdrawal state, similar to ethanol, has been described.

γ-HYDROXYBUTYRATE

γ-Hydroxybutyrate (GHB) is an endogenous molecule as well as a drug. GHB was originally used as an IV anesthetic, primarily in several European countries. In recent years, it has been marketed as a drug for body builders to improve body mass and reduce fat, as well as for use as a hypnotic, antidepressant, anxiolytic, and cholesterol-lowering drug.[16] GHB has been found in drug-facilitated sexual assaults.[17] Sodium oxybate (the sodium salt of GHB) is currently approved only for use within a highly regulated setting for the treatment of narcolepsy.[18] In some European countries, GHB or sodium oxybate is used as a treatment for alcohol dependence and withdrawal.[19] GHB can be formulated as a clear liquid or in solid form as a capsule, tablet, or white powder. GHB has many vernacular names, including **"liquid ecstasy," "Georgia Home Boy," "G,"** and **"Grievous Bodily Harm."**

Sodium oxybate is categorized a Schedule III drug by the U.S. Food and Drug Administration when used to treat narcolepsy, but GHB used for any purpose is considered a Schedule I drug. To circumvent laws, GHB precursors, namely γ-butyrolactone and 1,4-butanediol, have been introduced into the drug scene.[20] Following ingestion, lactonase enzymes in the blood convert γ-butyrolactone into GHB. Depending on the level of lactonase enzyme activity, this conversion can be rapid and produce a faster onset of symptoms compared with GHB. The conversion of 1,4-butanediol to GHB is a two-step process: conversion via alcohol dehydrogenase to γ-hydroxybutyraldehyde with subsequent conversion via aldehyde dehydrogenase to GHB.

GHB undergoes metabolism via GHB dehydrogenase to succinic acid semialdehyde, which, in turn, can either get converted to succinic acid, to enter the Krebs cycle, yielding carbon dioxide and water, or be converted to γ-aminobutyric acid, a primary inhibitory neurotransmitter. A small percentage of GHB will be excreted unchanged in the urine.

Following ingestion, GHB is rapidly absorbed from the GI tract, with peak plasma concentration occurring within an hour.[20] GHB has a relatively low oral bioavailability due to significant first-pass metabolism. After absorption, GHB follows a two-compartment model, in which the initial serum levels decline due to redistribution. There is a subsequent slower decline in the serum concentrations following metabolic degradation. Because of its short half-life, GHB is difficult to detect in the urine >6 hours after ingestion and is virtually nondetectable >12 hours after ingestion.[21] GHB has minimal protein binding and readily crosses the blood–brain barrier and placenta.

The body produces some endogenous GHB, both as a precursor and a breakdown product of γ-aminobutyric acid. At physiologic concentrations, GHB binds to a unique receptor, which is distinct from γ-aminobutyric acid receptors. When the concentration of GHB in the brain exceeds the physiologic micromolar concentration, GHB can bind to (and activate) the γ-aminobutyric acid subunit B receptors.

GHB has a steep dose–response curve with a narrow therapeutic ratio; doses of 10 milligrams/kg result in short-term amnesia, doses of 20 to 30 milligrams/kg result in sedation and drowsiness, and doses exceeding 50 milligrams/kg result in seizure, coma, respiratory depression, and cardiac depression.[22] Bradycardia, hypothermia, and either miosis or mydriasis can occur.[20] During recovery, the patients often wake up surprisingly quickly as opposed to the more prolonged awakening phase seen after an overdose with other sedatives. Despite co-ingestants being commonly encountered, most patients fully regain consciousness within 6 hours. The co-ingestion of ethanol can worsen hypoxia and possibly result in a longer elimination half-life of GHB.[23]

Treatment is largely supportive.[20] Intubation is generally unnecessary, even in patients with severely depressed consciousness (Glasgow Coma Scale score ≤8) because patients are usually able to protect their airway and maintain ventilation.[24] Once the patient is awake and alert, assuming no co-ingestants or secondary complications such as aspiration, the patient can be medically discharged or transferred. **Physostigmine or neostigmine is not recommended for reversal of known or suspected GHB intoxication.**[25] Fomepizole (a competitive antagonist of alcohol dehydrogenase) has little benefit in 1,4-butanediol overdoses because preventing metabolism of the ingested drug into GHB is of little benefit due to the short expected duration of symptoms.

Chronic GHB use is associated with a withdrawal syndrome characterized by two often distinct phases.[20,26] The first phase is typified by insomnia, confusion, GI distress, anxiety, and tremor. This first stage can be observed as soon as 2 hours after the last dose in patients who habitually use GHB. The second stage, which can occur in 2 to 3 days after the last dose, is characterized by tachycardia, hypertension, diaphoresis, tremor, confusion, hallucinations, and paranoia. The withdrawal state can last anywhere from 3 days to 2 weeks. The short latency period between the last dose and the onset of symptoms is helpful in distinguishing ethanol withdrawal from GHB withdrawal.

Toxicologic detection of GHB can be difficult because of its short half-life, the complexity of assay methodology, and the presence of the endogenous compound. If needed, toxicologic confirmation should be performed with blood or urine collected as soon as the individual arrives in the ED.[21]

MELATONIN

Melatonin is an endogenous hormone that is normally secreted by the pineal gland and is believed to be involved with the circadian sleep–wake cycle.[27] Melatonin is available without prescription in tablets or capsules at doses ranging from a physiologic dose of 0.3 milligram up to a pharmacologic dose of 10 milligrams.

Two primary melatonin receptor subtypes are found in the human CNS.[27] The MT_1 receptor is located primarily in the hypothalamic suprachiasmatic nucleus and is involved in the effect melatonin has on circadian rhythm. The MT_2 receptor is found primarily in the retina, presumably involved in the interaction between incoming light, melatonin, and the circadian cycle. The MT_2 receptor is also found in the hypophysial pars tuberalis and is possibly responsible for the effects of melatonin on reproduction.

Following ingestion, peak plasma melatonin concentrations occur within 40 to 50 minutes. Melatonin has a short plasma half-life and a short duration of action in therapeutic doses. Melatonin is metabolized by initial conversion to O-desmethylmelatonin and 6-hydroxymelatonin. Both are subsequently conjugated as either a glucuronide or a sulfate and then excreted by the kidneys.

At therapeutic dosing, side effects from melatonin include fatigue, headache, dizziness, and irritability.[28] Data on melatonin overdoses are limited, but overdose would be expected to result in an exaggeration of therapeutic effects, primarily sedation and disorientation without any significant life-threatening effects.[29]

RAMELTEON

Ramelteon is a highly selective agonist at the melatonin MT_1 and MT_2 receptors, marketed for the treatment of insomnia.[30] Ramelteon has no significant activity at the γ-aminobutyric acid, dopamine, serotonin, norepinephrine, or opiate receptor sites. An active metabolite does have weak activity at the serotonin-2B receptor, but is thought to be clinically insignificant.

Ramelteon is rapidly absorbed following oral administration, but oral bioavailability is <2% due to extensive first-pass metabolism. Hepatic metabolism of ramelteon yields four metabolites, one of which is active. Metabolism is primarily through cytochrome P1A2 enzyme, with minor contributions via P2C and P3A4. The coadministration of P1A2 inhibitors such as fluoroquinolones and verapamil has been shown to increase ramelteon concentrations. Protein binding is extensive, the volume of distribution is large, and excretion is primarily renal.

In overdose, sedation would be expected and treatment is supportive.[31] Ramelteon has not been associated with any potential for abuse and has minimal risk for producing withdrawal symptoms or rebound insomnia.[30]

TASIMELTEON

Tasimelteon is an agonist at melatonin MT_1 and MT_2 receptors used for treatment of non–24-hour sleep–wake disorder, a syndrome characterized by insomnia or excessive sleepiness from abnormal synchronization between the 24-hour light–dark cycle and the endogenous circadian rhythms of sleep and wakefulness.[32] The majority of patients with this syndrome are totally blind. Ramelteon and tasimelteon may have benefit in sleep disorders associated with comorbid psychiatric, neurologic, and cardiovascular conditions.[33]

The recommended dose of tasimelteon is 20 milligrams taken on an empty stomach before bedtime, at the same time every night. After ingestion, peak concentrations occur within 0.5 to 3 hours. There is a large volume of distribution, high protein binding, and extensive metabolism with an elimination half-life of 1.3 hours.

There is no reported experience with tasimelteon overdose. Adverse effects reported during clinical trial suggest headache may occur. There has been no observed findings suggestive of abuse potential, physical dependence, or withdrawal during clinical trials.

ZOLPIDEM, ZALEPLON, AND ZOPICLONE

Zolpidem, zaleplon, and zopiclone are three nonbenzodiazepine sedative-hypnotics used to treat insomnia.[1,28] All three promote sleep by enhancing CNS γ-aminobutyric acid activity but differ in their pharmacodynamic and pharmacokinetic profiles.

All three drugs bind to the benzodiazepine binding site on the postsynaptic γ-aminobutyric acid subtype A1 receptor, although they have different binding affinities to the α-1 and α-2 subunits.[34] Zaleplon has a very short half-life (about 1 hour), as opposed to the somewhat longer half-lives of zolpidem and zopiclone (Table 184-1).

All three drugs were initially promoted as an improvement upon benzodiazepines for the treatment of insomnia. They were to be safer, produce less psychomotor impairment with therapeutic doses, and be not addictive and not associated with a withdrawal state. With experience, all

three drugs have been found to impair psychomotor function,[35,36] create tolerance and dependence, and be associated with withdrawal states characterized by insomnia, anxiety, agitation, and delirium.[34] **Zaleplon, presumably because of its shorter elimination half-life, appears to produce less tolerance and withdrawal symptoms than zolpidem or zopiclone.**[37]

Zolpidem undergoes hepatic metabolism into three inactive metabolites, so dosage restrictions are recommended for those with hepatic impairment and those with chronic renal insufficiency. Common adverse effects include somnolence and nausea. Because of occasional psychomotor impairment, individuals should not drive or engage in hazardous activity the day following use of zolpidem. There are numerous reports of sleep walking or vivid dreams after its consumption. Following overdose, sedation (including coma) and vomiting can occur. Fatalities usually occur with co-ingestants, rather than with zolpidem by itself.[38]

Zaleplon absorption occurs rapidly (Table 184-1) but can be delayed if zaleplon is co-ingested with a high-fat meal. Following absorption, zaleplon undergoes extensive first-pass metabolism in the form of oxidation via aldehyde oxidase to form inactive metabolites. Elimination is primarily renal, with some fecal elimination as well. In therapeutic doses, zaleplon is not associated with any dependence or withdrawal state when taken for up to 5 weeks.[39] At doses up to 10 milligrams, no psychomotor or memory impairment is observed, but a dose of 20 milligrams is associated with some impairment. Reports of overdose with zaleplon are limited, but one could expect sedation, incoordination, and, possibly, headache to occur.

Zopiclone is not currently available in the United States, but **eszopiclone**, the *S*-configuration and active isomer of zopiclone, is marketed. Zopiclone is rapidly absorbed and hepatically metabolized into active (*N*-oxide metabolite) and inactive (*N*-dimethyl metabolite) compounds. Nearly half of the parent drug is excreted in the lungs following decarboxylation. Reports of zopiclone or eszopiclone overdose indicate sedation to be the primary observed effect.[40] Prolonged coma was reported in an elderly patient who ingested a large amount of eszopiclone.[41] Rare cases of methemoglobinemia and mild hemolytic anemia have been reported after large zopiclone overdoses.[42]

HISTORICAL SEDATIVES

Ethchlorvynol was marketed during the 1950s as an alternative to barbiturates. In 1999, the remaining U.S. manufacturer stopped production and sales of the drug, but availability elsewhere in the world is suggested by mention on Internet sites. Following ingestion, ethchlorvynol is rapidly absorbed from the GI tract with a biphasic distribution process, characterized by an initial phase of adipose tissue deposition followed by a redistribution out of adipose stores and back into the plasma. Ethchlorvynol has a plasma half-life of 10 to 25 hours, undergoes hepatic metabolism, and is renally excreted. At therapeutic dosing, sedation and nystagmus can occur. Overdose can be characterized by prolonged deep coma, hypothermia, hypotension, bradycardia, and cardiovascular collapse. Similar to other severe coma states, bullous lesions have been seen with ethchlorvynol overdose. Abusers have been reported to inject the drug, sometimes producing acute pulmonary edema. Ethchlorvynol overdose may produce a vinyl-like odor that can be a useful diagnostic clue. Treatment is largely supportive, but charcoal hemoperfusion has been used in massive overdoses. Ethchlorvynol is associated with both tolerance and physical dependence, and a withdrawal state has been described.

Glutethimide was withdrawn from the market in 1999 when the remaining U.S. manufacturer stopped production and sales. Availability overseas is suggested by listings on the Internet for sales of this drug. A unique aspect of this drug was that the combination of oral glutethimide with codeine produced a euphoria considered similar to that induced by heroin. A characteristic of glutethimide overdose is the ability to produce a deep coma with periods of cyclic responsiveness. The cause of these cycles has been ascribed to an active metabolite, but evidence is not convincing. Following ingestion, absorption is variable and plasma half-life is 10 to 12 hours. Glutethimide possesses antimuscarinic properties, so toxic patients may have tachycardia, hypertension, mydriasis, urinary retention, and intestinal ileus. Treatment is primarily supportive. Chronic glutethimide abuse is associated with the development of psychosis and seizures.

Methaqualone was withdrawn from the U.S. market in 1984 when the remaining manufacturer stopped production. Continued use and abuse of methaqualone in South Africa is a significant problem, with the drug often mixed with cannabis and smoked. As with the other two sedatives of historical interest, availability in other countries is suggested by Internet sites. A unique feature of a methaqualone overdose is muscular hyperactivity, with hyperreflexia and clonus and a lower rate of respiratory depression and hypotension compared with other sedatives. In severe overdoses, prolonged supportive treatment is often required. Chronic methaqualone abuse can produce both tolerance and habituation, and abstinence can provoke seizures.

CHAPTER 185

Alcohols

Jennifer P. Cohen
Dan Quan

INTRODUCTION

All alcohols cause clinical inebriation, with the strength of the inebriating effects directly proportional to the alcohol's molecular weight; hence, at the same concentration, isopropanol is more intoxicating than ethanol (**Figure 185-1**).

Primary toxicity can be due to the parent compound (ethanol and isopropanol) or to toxic metabolites (ethylene glycol and methanol). **Ethanol** and **isopropanol** are the most common alcohols ingested; their principal effects are GI irritation and intoxication; and they do not in themselves produce metabolic acidosis. **Methanol** and **ethylene glycol** are toxic alcohols because they cause serious physiologic morbidity.

ETHANOL

INTRODUCTION

Ethanol (CH_3CH_2OH, molecular weight 46.07) is a colorless, volatile liquid that is the most frequently used and abused drug in the world. Morbidity from acute ethanol intoxication is usually related to secondary injuries rather than direct toxic effects. Toxicity most commonly occurs from ingestion, but ethanol may also be absorbed via inhalation or percutaneous exposure.

Ethanol is readily available in many different forms. A standard alcoholic beverage, such as 12 oz (355 mL) of beer (2% to 6% ethanol by volume), 5 oz (148 mL) of wine (10% to 20% ethanol by volume), or 1.5 oz (44 mL) of 80-proof spirits (40% ethanol by volume), contains about 15 grams of ethanol. Ethanol may be found in high concentrations in many other common household products such as mouthwash (may contain up to 75% ethanol by volume), colognes and perfumes (up to 40% to 60%), and as a diluent or solvent for medications (concentration varies widely between 0.4% and 65%). Such products are often flavored or brightly colored and may be attractive to children.

PATHOPHYSIOLOGY

Ethanol is rapidly absorbed after oral administration, and blood levels peak about 30 to 60 minutes after ingestion. The presence of food in the stomach prolongs absorption and delays the peak blood level. High

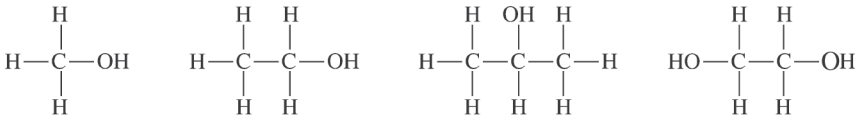

FIGURE 185-1. Chemical structures of the common alcohols.

concentrations of ethanol in the stomach may cause pylorospasm delaying gastric emptying. Some ethanol is broken down in the stomach by gastric alcohol dehydrogenase, which lowers the amount available for absorption. This enzyme is present at higher levels in men than in women, which may account for the fact that women usually develop a higher blood ethanol level than men after consuming the same dose per kilogram of body weight. The volume of distribution of ethanol is also gender dependent due to difference in body fat percentages: 0.6 L/kg in men and 0.7 L/kg in women.

Ethanol is a CNS depressant[1] that enhances the inhibitory neurotransmitter γ-aminobutyric acid receptors and blockade of excitatory *N*-methyl-D-aspartic acid receptors. Modulation of these systems leads to the development of tolerance, dependence, and a withdrawal syndrome when ethanol intake ceases in dependent individuals.

Because of the phenomenon of tolerance, blood ethanol levels correlate poorly with degree of intoxication. Although death from respiratory depression may occur in nonhabituated individuals at concentrations of 400 to 500 milligrams/dL (87 to 109 mmol/L), some alcoholic individuals can appear minimally intoxicated at blood concentrations as high as 400 milligrams/dL (87 mmol/L).[2] Although Canada, Mexico, and the United States have adopted 80 milligrams/dL (17 mmol/L) as the legal definition of intoxication for the purposes of driving a motor vehicle, impairment may occur with levels as low as 50 milligrams/dL (11 mmol/L), especially in nonhabituated individuals.[3]

Ethanol is predominantly eliminated by hepatic metabolism, with about 10% excreted in the urine, exhaled breath, and sweat. **Alcohol dehydrogenase** (**Figure 185-2A**) is the major enzyme involved in the metabolism of ethanol, producing acetaldehyde. At low ethanol concentrations, this process follows first-order kinetics,[4] but as concentrations rise, alcohol dehydrogenase becomes saturated and metabolism switches to zero-order kinetics—a fixed amount is metabolized per unit of time. Also, as ethanol concentrations rise, the hepatic microsomal oxidizing system (specifically, cytochrome P-450 2E1 [CYP2E1]) plays a more important role in metabolism.

Both alcohol dehydrogenase and CYP2E1 are inducible and thus are more active in chronic ethanol users. Therefore, rates of ethanol elimination from the blood vary from about 20 milligrams/dL per h (4 mmol/L per h) in nonhabituated individuals[5] to up to 30 milligrams/dL per h (6 mmol/L per h) in individuals with chronic alcoholism.

CLINICAL FEATURES

The hallmark of ethanol toxicity is clinical inebriation.[6] Behavioral disinhibition may initially appear as euphoria or agitation and combativeness. As intoxication becomes more severe, slurred speech, nystagmus, ataxia, and decreased motor coordination develop. Severe intoxication may cause respiratory depression and coma. Nausea and vomiting often occur in conjunction with neurologic depression.

Ethanol causes peripheral vasodilation and flushed, warm skin. Vasodilation causes heat loss to the environment promoting hypothermia. Vasodilation may also lead to orthostatic hypotension and reflex tachycardia. Ethanol-induced hypotension is usually mild and transient, so significant or persistent hypotension warrants investigation for alternative causes.

Ethanol ingestion may cause hypoglycemia, usually in children and malnourished individuals due to low glycogen stores and reduced gluconeogenesis. The metabolism of ethanol by alcohol dehydrogenase requires the presence of the oxidized form of nicotinamide adenine dinucleotide (NAD^+), which is then converted into its reduced form (NADH). The metabolism of a significant amount of ethanol increases the NADH/NAD^+ ratio, which then promotes the conversion of pyruvate to lactate, diverting pyruvate away from the gluconeogenesis pathway (**Figure 185-2B**).

When a chronic alcoholic suddenly stops consuming calories in the form of either ethanol or food, the body uses alternative fuel sources and begins to break down adipose tissue. This metabolism of fatty acids results in ketoacidosis (see chapter 226, Alcoholic Ketoacidosis).

DIAGNOSIS

Ethanol-intoxicated patients often have other disease processes, such as infections and traumatic injuries, so perform a detailed physical examination, looking especially for evidence of trauma, and obtain as much history as possible. Uncomplicated ethanol intoxication improves over a few hours. **If depressed mental status fails to improve or deteriorates, consider other causes of altered mental status and evaluate aggressively.**[7,8]

The clinical assessment guides the selection of laboratory tests. For altered levels of consciousness, obtain a point-of-care glucose level. Ethanol levels are not necessarily required in cases of mild or moderate intoxication when no other abnormality is suspected, but measure serum alcohol levels in patients with altered mental status of unclear cause. Clinical judgment of ethanol intoxication is unreliable, and self-reported drinking is also unreliable, particularly around levels of 100 milligrams/dL (22 mmol/L)[9,10] or in alcohol-tolerant patients.[11] In isolated ethanol intoxication, the presence of horizontal gaze nystagmus has a sensitivity of 70% to 80% for a blood ethanol level of 80 milligrams/dL (17 mmol/L) and a sensitivity of 80% to 90% for blood ethanol levels >100 milligrams/dL (22 mmol/L).[12-14]

Ask about concomitant drug use, especially cocaine. The attraction of abusing these drugs together may relate to the formation of the cocaine metabolite cocaethylene that, although less potent than the parent compound, has a half-life that is three to five times longer.[15] The risk of sudden death among users of both drugs simultaneously is higher than that among cocaine users alone.

Ethanol ingestion is the most common cause of an osmolar gap on serum electrolyte analysis (see chapter 17, Fluids and Electrolytes) and

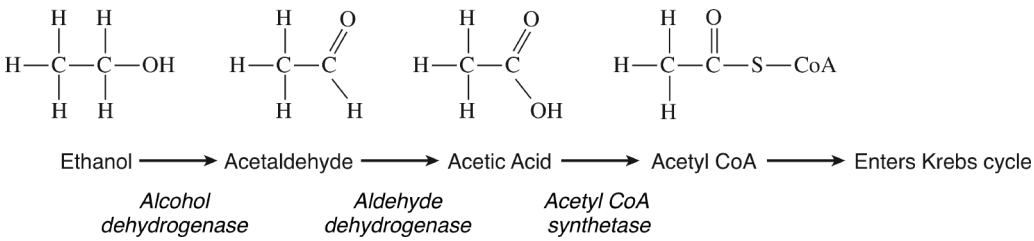

FIGURE 185-2A. Metabolism of ethanol. CoA = coenzyme A.

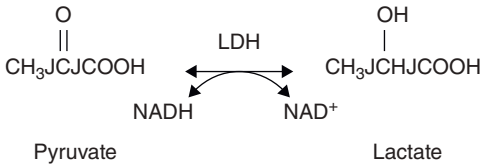

FIGURE 185-2B. Conversion of pyruvate to lactate. LDH = lactate dehydrogenase; NAD^+ = oxidized form of nicotinamide adenine dinucleotide; NADH = reduced form of nicotinamide adenine dinucleotide.

may be associated with a mild metabolic acidosis,[16] but a significant anion gap metabolic acidosis suggests the presence of lactic acidosis, ketoacidosis, or methanol or ethylene glycol toxicity.

TREATMENT

Management is observation until sobriety.[6] Activated charcoal is not useful since ethanol is rapidly absorbed; consider activated charcoal only if toxic adsorbable substances have been coingested.

Treat hypoglycemia with IV glucose 0.5 to 1 grams/kg. Although acute **Wernicke's encephalopathy** can be precipitated by prolonged sustained administration of IV carbohydrate, there is no evidence that a single dose of IV glucose can cause this syndrome.[17,18] The prevalence of vitamin deficiencies in acutely intoxicated ED patients is low and does not justify the routine use of IV vitamin-containing fluids.[19] However, long-term drinkers are sometimes treated with IV fluids containing magnesium, folate, thiamine, and multivitamins, termed a ***banana bag*** because of the yellow color imparted by the multivitamin mixture. Wernicke's encephalopathy is characterized by abnormal mental status, ataxia, and nystagmus, and requires daily treatment with thiamine, 100 milligrams, until normal diet is resumed. **Fluid administration does not hasten alcohol elimination**, so establishment of IV access for fluid administration alone is unnecessary in uncomplicated mild to moderate intoxication.[20,21]

Metadoxine, which is not currently available in the United States but is available in Latin America, Mexico, Asia, Africa, and Eastern Europe, enhances the metabolism of ethanol and accelerates recovery.[6,22] Metadoxine is an ion pair between pyrrolidone carboxylate and pyridoxine. A dose of 900 milligrams IV is reported to double the rate at which ethanol blood levels decrease with time compared with the patient's own metabolism.[23,24]

DISPOSITION AND FOLLOW-UP

Patients with acute ethanol intoxication as the only clinical problem require ED observation until sober. Prior to discharge, reassess for an underlying mental health disorder, such as suicidal or homicidal ideation, that requires further care or hospital admission. Clinical judgment, rather than a serum ethanol level, determines the appropriateness of discharge. Discharge the patient in the care of a responsible companion. Patients treated for alcohol intoxication should not be responsible for their own transportation home.

ISOPROPANOL

INTRODUCTION

Isopropanol (CH_3CHOCH_3, molecular weight 60.10), also known as ***isopropyl alcohol*** and ***2-propanol***, is a colorless, volatile liquid with a bitter, burning taste and an aromatic odor. It is found in many common, inexpensive household products, such as **rubbing alcohol** (usually 70% isopropanol). Isopropanol is widely used in industry as a solvent and disinfectant and is a component of a variety of skin and hair products, jewelry cleaners, detergents, paint thinners, and deicers.

Poisoning usually results from ingestion[25] but may also occur after inhalation or dermal exposure in poorly ventilated areas or during alcohol sponge bathing. **Isopropanol is approximately twice as potent as ethanol in causing CNS depression, and its duration of action is two to four times that of ethanol.** As a result, it is often used as a substitute intoxicant by alcoholics as well as in suicide attempts.

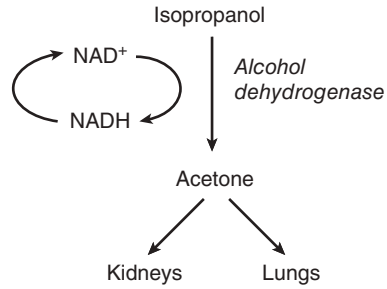

FIGURE 185-3. Metabolism of isopropanol. NAD^+ = oxidized form of nicotinamide adenine dinucleotide; NADH = reduced form of nicotinamide adenine dinucleotide.

PATHOPHYSIOLOGY

Isopropanol is rapidly absorbed from the GI tract. Its peak blood levels occur 30 to 120 minutes after ingestion, and its volume of distribution is similar to that of ethanol. The major pathway for the metabolism of isopropanol is in the liver by alcohol dehydrogenase (50% to 80%), with the remainder excreted unchanged in the urine. Isopropanol is metabolized to a ketone, not an acid (**Figure 185-3**).

Ketosis and an osmolar gap without acidosis are the hallmarks of isopropanol toxicity.[25,26] The principal metabolite, acetone, does not cause eye, kidney, cardiac, or metabolic toxicity, although high levels of acetone may contribute to CNS depression. Acetone is excreted primarily by the kidneys, with some excretion through the lungs. It takes about 30 to 60 minutes after isopropanol ingestion for acetone to appear in the serum and about 3 hours for it to be detectable in the urine.[27]

Isopropanol metabolism most closely follows concentration-dependent (first-order) kinetics. The elimination half-life of isopropanol in the absence of ethanol is 6 to 7 hours, whereas the elimination half-life of acetone is 17 to 27 hours.[28] The long half-life of acetone may contribute to the prolonged mental status depression often associated with isopropanol poisoning. The toxic dose of 70% isopropanol is approximately 1 mL/kg, although as little as 0.5 mL/kg may cause symptoms. The minimum lethal dose for an adult has been reported as approximately 2 to 4 mL/kg, but survival has been reported following ingestions of up to 1 L. **Children are especially susceptible to toxic effects and may develop symptoms after as little as three swallows of 70% isopropanol.**[29]

CLINICAL FEATURES

The primary clinical toxicities of isopropanol are CNS depression caused by both the parent compound and acetone, and gastric irritation from isopropanol itself.[25,26] Onset of symptoms occurs within 30 to 60 minutes after ingestion, with peak effects in a few hours and duration of symptoms for many hours longer, possibly due to the contribution of acetone. As with the metabolism of any alcohol by alcohol dehydrogenase, the increased NADH/NAD^+ ratio may produce hypoglycemia.

Gastric irritation appears early and is a striking feature of isopropanol ingestions. GI symptoms range from nausea, vomiting, abdominal pain, and acute pancreatitis to hemorrhagic gastritis and upper GI bleeding. Severe poisoning is marked by early onset of coma, respiratory depression, and hypotension; rhabdomyolysis and renal failure have also been reported.

Massive ingestion may cause hypotension secondary to peripheral vasodilation. In infants and small children, if isopropanol is used to clean the skin, chemical burns can result and systemic symptoms can occur from dermal absorption.

DIAGNOSIS

Obtain point-of-care glucose testing and other testing as directed by the history and physical examination. Assess for upper and lower GI bleeding. Suspect isopropanol poisoning if the fruity odor of acetone or the

smell of rubbing alcohol is present on the breath. Other signs are elevated osmolar gap, ketonuria, and ketonemia without acidosis. An increased anion gap or metabolic acidosis is not due to isopropanol intoxication, so if either is present, investigate for another cause.

A spurious increase in serum creatinine level as a result of acetone's interference with the colorimetric creatinine assay is sometimes seen.[30,31]

Serum isopropanol and acetone levels may be assessed, although isopropanol levels may not be readily available from hospital laboratories. Isopropanol levels of 50 milligrams/dL (8 mmol/L) are often associated with intoxication in individuals who are not habituated to ethanol, but alcoholic patients may be considerably more resistant to the CNS effects of isopropanol.

TREATMENT

Treatment is supportive. Do not administer activated charcoal or perform gastric lavage unless indicated by coingestion of an additional toxic substance. **Do not administer fomepizole or ethanol**, because the metabolite (acetone) is no more toxic than isopropanol itself, and preventing isopropanol metabolism may prolong CNS toxicity.

Monitor for respiratory depression, and intubate and ventilate as needed. Hypotension usually responds to IV fluids. Obtain blood for type and cross-match if needed to treat GI bleeding.

Consider hemodialysis if hypotension is refractory to conventional therapy or when the isopropanol level is >400 milligrams/dL (>66 mmol/L).[25] However, there is no consensus regarding the need for hemodialysis even in life-threatening situations.[31] Hemodialysis eliminates both isopropanol and acetone.

DISPOSITION AND FOLLOW-UP

Patients with lethargy or prolonged CNS depression should be admitted to the hospital. Those who remain asymptomatic for 4 to 6 hours after ingestion may be discharged with referral for substance abuse counseling or mental health evaluation as indicated.

METHANOL AND ETHYLENE GLYCOL

INTRODUCTION

Methanol and **ethylene glycol** are similar in that the parent compounds possess minor toxicity (both causing inebriation and some direct gastric irritation) but the major toxicity occurs when the liver metabolizes these compounds to substances that cause metabolic acidosis and end-organ damage.[25,32-34] Treatment is primarily directed toward halting the formation of these toxic metabolites. **Table 185-1** provides a summary comparison of methanol and ethylene glycol metabolism, clinical features, and treatment.

Methanol **Methanol**, the simplest alcohol (CH_3OH, molecular weight 32.05), is a colorless, volatile liquid with a distinctive "alcohol" odor. Methanol is used in the synthesis of other chemicals and may be found in automotive windshield cleaning solution, solid fuel for stoves and chafing dishes, model airplane fuel, carburetor cleaner, gas line antifreeze, photocopying fluid, and solvents. Trivial amounts are found in fruits and vegetables, aspartame-containing products, and fermented spirits.

Most cases of methanol poisoning occur by ingestion, and most contemporary exposures in the United States occur from unintentional ingestion of windshield washer fluid and other automotive cleaning products.[35,36] Worldwide, there are outbreaks of poisoning from contaminated alcoholic beverages.[37,38] Persons who wish to consume ethanol but have no access to it for financial or other reasons may consume methanol as an alternative, either intentionally or unintentionally (due to improper or confusing labeling containing the word *alcohol*). Methanol may be systemically absorbed after inhalation or dermal exposure, but this rarely causes significant clinical toxicity. **Hence, extensive evaluation or observation is not required after minor skin or inhalational exposures.**

Ethylene Glycol Ethylene glycol [$CH_2CH_2(OH)_2$, molecular weight 62.07] is a colorless, odorless, sweet-tasting liquid. It was considered

TABLE 185-1 Features of Methanol and Ethylene Glycol Toxicity and Treatment

	Methanol	Ethylene Glycol
Sources	Windshield cleaners; gas line antifreeze, solvents, solid fuel for stoves, adulterated alcoholic beverages, moonshine	Glycerin substitute, hydraulic fluid, antifreeze, adulterated alcoholic beverages, adulterated toothpaste (diethylene glycol)
Absorption	30–60 min	1–4 h
Metabolism (untreated)	Decreases 8.5 milligrams/dL per h (2.7 mmol/L per h)	Elimination half-life ≈ 3–8 h
Minimum lethal dose	1 gram/kg or about 100 mL in an adult	1.1 to 1.7 grams/kg or about 100 mL in an adult
Metabolism	Methanol → formaldehyde → formic acid	Ethylene glycol → glycoaldehyde → glycolic acid → glyoxylic acid → oxalic acid
Toxic effects	Formic acid blocks oxidative phosphorylation; metabolic acidosis from formic and lactic acids	Metabolic acidosis and tissue toxicity from glycolic acid and calcium oxalate tissue damage
Clinical features	Inebriation from parent compound, then 12–14 h later: metabolic acidosis; blurred or snow field vision; nausea, vomiting, abdominal pain	Inebriation from parent compound, then 4–12 h: CNS effects, hypocalcemia, metabolic acidosis; 12–24 h: multisystem organ failure; 24–72 h: renal failure
Diagnosis	Methanol level >20 milligrams/dL (>6 mmol/L) Early: unexplained osmolal gap >10 mOsm/kg H_2O Later: elevated anion gap metabolic acidosis	Ethylene glycol level >20 milligrams/dL (>3.2 mmol/L) Early: unexplained osmolal gap >10 mOsm/kg H_2O Later: elevated anion gap metabolic acidosis and calcium oxalate crystals in urine
Treatment	Fomepizole 15 milligrams/kg IV over 30 min and then 10 milligrams/kg IV over 30 min every 12 h OR Ethanol 10 mL/kg of 10% IV ethanol @ 100 milligrams/kg per h to keep ethanol level >150 milligrams/dL Folic acid 1 milligram/kg IV every 4–6 h (up to 50 milligrams per dose), continue until toxicity resolved IV sodium bicarbonate to maintain serum pH >7.30 See text for indications for hemodialysis	Fomepizole 15 milligrams/kg IV over 30 min and then 10 milligrams/kg IV over 30 min every 12 h OR Ethanol 10 mL/kg of 10% IV ethanol @ 100 milligrams/kg per h to keep ethanol level >150 milligrams/dL Pyridoxine 50–100 milligrams IV every 6 h for 24–48 h Thiamine 100 milligrams IV every 6 h for 24–48 h Magnesium sulfate 2 grams IV (once) IV sodium bicarbonate to maintain serum pH >7.20 See text for indications for hemodialysis

nontoxic in the early 1900s until the first case of toxicity was reported in 1930.[39] Ethylene glycol has many contemporary uses as a glycerin substitute, preservative, component of hydraulic brake fluid, foam stabilizer, component for chemical synthesis, and most commonly an automotive coolant (antifreeze).

Virtually all ethylene glycol toxicity results from ingestion, because the chemical has a low vapor pressure and does not penetrate skin well.[40] Its sweet taste renders ethylene glycol an attractive ingestant for children and pets. Other common exposure scenarios include ingestion as an ethanol substitute when ethanol is unavailable, and intentional suicidal ingestions.[36]

PATHOPHYSIOLOGY

Methanol After ingestion, methanol is rapidly absorbed, with peak blood levels achieved within 30 to 60 minutes, although there has been a case report of delayed peak at 8 hours after a large ingestion.[41] Methanol is rapidly distributed among body water with a volume of distribution of 0.6 to 0.77 L/kg. Without treatment, the minimum lethal dose in humans is thought to be approximately 1 gram/kg or 1.25 mL/kg. With treatment, survival has been reported after much larger ingestions. **The dose required to cause permanent visual impairment in an adult is estimated to be about a mouthful (24 grams or 30 mL).**

Methanol is metabolized in the liver by alcohol dehydrogenase to formaldehyde, and then by aldehyde dehydrogenase to formic acid (**Figure 185-4**). First-order kinetics is present at very low methanol concentrations, with an elimination half-life of 1.8 to 3.0 hours.[42] At higher methanol concentrations, metabolism switches to zero-order kinetics, and blood methanol level decreases at a fixed rate, roughly 8.5 milligrams/dL per h (2.7 mmol/L per h).[43] Very small amounts of the unchanged parent compound may also be exhaled in vapor form.

Formic acid is the metabolite responsible for the toxicity and metabolic acidosis that occurs with methanol poisoning. Acidosis correlates well with formic acid levels both in its magnitude and in the timing of its development. Formic acid's main mechanism of toxicity is its binding to cytochrome oxidase and blockade of oxidative phosphorylation. This leads to anaerobic metabolism and development of lactic acidosis.[20] In addition, metabolism of methanol increases the NADH/NAD^+ ratio, which favors the conversion of pyruvate to lactate and thereby worsens lactic acidosis. Early in the course of methanol poisoning, more of the acidosis is due to formic acid itself, whereas later on, as cellular aerobic respiration is blocked and more lactate builds up, the contribution of lactate becomes more significant.[44]

Formic acid's inhibition of cytochrome oxidase increases with decreasing pH, so acidemia worsens the blockade of aerobic metabolism. Falling pH also favors the undissociated form of formic acid (as opposed to formate ion), which moves more readily across tissue barriers. Therefore, at lower pH, more formic acid can enter the brain and ocular tissues, worsening CNS depression as well as retinal and optic nerve injury. Lower pH may also prolong formic acid elimination by increasing tubular reabsorption.[45]

Ethylene Glycol Ethylene glycol is rapidly absorbed from the GI tract, and blood levels generally peak 1 to 4 hours after ingestion. Ethylene glycol distributes rapidly with a volume of distribution of 0.5 to 0.8 L/kg. Based on animal studies and a limited number of case reports, the minimum lethal dose in humans is estimated to be 1.0 to 1.5 mL/kg or 1.1 to 1.7 grams/kg (approximately 100 mL in an adult).[39]

Like methanol, ethylene glycol itself has minor toxicity (it is a stronger inebriant than both methanol and ethanol and causes gastric irritation), and it is the hepatic oxidation of ethylene glycol that creates the toxic metabolites responsible for metabolic acidosis and end-organ damage. The liver metabolizes about 80% of an ingested dose, whereas the other 20% is excreted unchanged in the urine. When metabolism is unblocked, ethylene glycol has first-order metabolic kinetics with an elimination half-life of roughly 3 to 8 hours.

Like the other alcohols, ethylene glycol is metabolized sequentially by alcohol dehydrogenase to glycoaldehyde, followed by metabolism with aldehyde dehydrogenase to glycolic acid (**Figure 185-5**). The subsequent conversion of glycolic acid to glyoxylic acid is the rate-limiting step for the elimination of ethylene glycol. Glycolic acid is the toxic metabolite, and its buildup is responsible for most of the metabolic acidosis. Once glycolic acid is converted to glyoxylic acid, it can be metabolized by one of several pathways. The major pathway is the conversion of glyoxylic acid to oxalic acid. Oxalic acid can complex with calcium, which leads to hypocalcemia and precipitation of calcium oxalate crystals in tissues and urine.[46] **End-organ damage from ethylene glycol poisoning is thought to be due to direct cytotoxicity of glycolic acid (although the exact mechanism of this is unclear) and tissue damage from precipitation of calcium oxalate crystals.**[46,47]

CLINICAL FEATURES

Methanol **Methanol poisoning is characterized by CNS depression, metabolic acidosis, and visual changes.**[25] However, multiple other organ systems are also affected.[25] Coma, seizure, and severe metabolic acidosis on presentation predict a poor outcome in methanol poisoning.[48,49] Severity of poisoning correlates more with the level of acidosis than with the methanol level.

Because methanol itself is not toxic, but requires metabolism to formic acid before tissue damage occurs, clinical signs and symptoms may be significantly delayed after exposure, often by 12 to 24 hours. Because ethanol competes for alcohol dehydrogenase, formation of the toxic

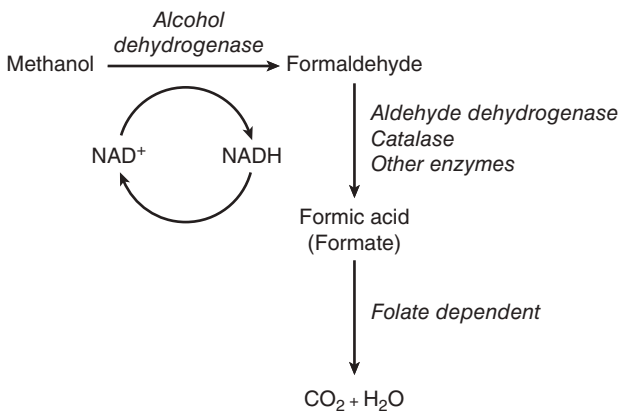

FIGURE 185-4. Metabolism of methanol. NAD^+ = oxidized form of nicotinamide adenine dinucleotide; NADH = reduced form of nicotinamide adenine dinucleotide.

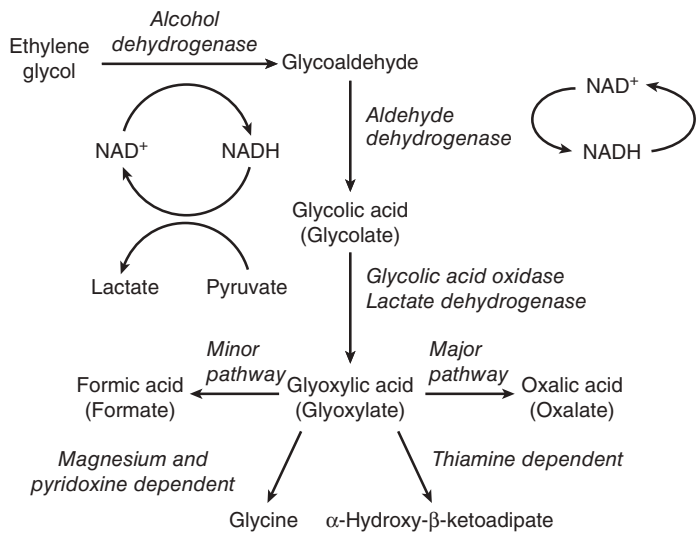

FIGURE 185-5. Metabolism of ethylene glycol. NAD^+ = oxidized form of nicotinamide adenine dinucleotide; NADH = reduced form of nicotinamide adenine dinucleotide.

metabolites from methanol will be delayed if ethanol has also been ingested.

Methanol is only a mild inebriant, and patients with tolerance to ethanol also demonstrate tolerance to methanol's intoxicating effects. Neurologic symptoms seen with methanol toxicity include headache, vertigo, dizziness, and seizures. Retinal and optic nerve tissue seem to be especially sensitive to the toxic effects of formic acid. **Ocular toxicity may present as photophobia or blurred or "snow field" vision**, with clinical findings including papilledema, nystagmus (rare), and nonreactive mydriasis once permanent damage has occurred.[50]

Head CT may demonstrate bilateral putamen necrosis, subcortical white matter damage, and other patterns of brain injury from methanol poisoning.[51,52] Intracranial hemorrhages may occur in rare cases, so obtain a noncontrast head CT first when considering heparin for hemodialysis or for other reasons.[53] **Delayed parkinsonism and polyneuropathies can occur.**[54]

Cardiovascular toxicity includes tachycardia and hypotension, which may progress to shock. Initially, patients often demonstrate tachypnea and shortness of breath while attempting to compensate for the metabolic acidosis, but over time, this may progress to respiratory failure.

Methanol is irritating to the GI tract and may cause abdominal pain, anorexia, nausea, vomiting, pancreatitis or gastritis. Transaminitis is usually mild and transient.[44] Rhabdomyolysis, renal failure, coma, and shock can occur in severe cases.[55]

Ethylene Glycol **Ethylene glycol poisoning is characterized by CNS depression, metabolic acidosis, and renal failure.**[25,56] However, multiple other organ systems may be affected.[25,56] Clinical poisoning has historically been divided into three stages, although timing may vary and stages may overlap.

The first or "neurologic" stage typically begins 30 minutes to 12 hours after ingestion due to the intoxicating effects of the ethylene glycol parent compound, and may range from mild depression to seizure and coma. Patients with tolerance to the depressant effects of ethanol may also exhibit relative tolerance to the inebriating effects of ethylene glycol. Patients are often described as appearing intoxicated (with ataxia, confusion, and slurred speech) but without an ethanol odor on the breath. Ethylene glycol is directly irritating to the GI tract, so abdominal pain, nausea, and vomiting may be present.

The generation of toxic metabolites generally takes 4 to 12 hours, or more if ethanol was coingested. CNS tissue effects of glycolic acid and calcium oxalate crystals include cerebral edema, basal ganglia hemorrhagic infarction, and meningoencephalitis.[57] Hypocalcemia, which occurs when calcium combines with oxalate, may contribute to seizures. Metabolic acidosis appears as toxic metabolites are generated.

The second or "cardiopulmonary" stage begins 12 to 24 hours after ingestion and is characterized by tachycardia and possibly hypertension. Tachypnea compensates for metabolic acidosis. Glycolate and oxalate crystal deposition in tissues leads to multiorgan system failure, including heart failure, acute lung injury, and myositis. Hypocalcemia, if present during any stage, may cause prolongation of the QT interval, myocardial depression, and arrhythmias. Most deaths occur during this stage.

The third or "renal" stage is often delayed 24 to 72 hours after ingestion and is characterized by renal failure due to calcium oxalate crystal deposition in the proximal tubules, the most common major complication of serious ethylene glycol poisoning. Short-term hemodialysis is often required, and it may take weeks to months for the kidneys to recover. Delayed neuropathies may occur 5 to 20 days after ethylene glycol poisoning.[54,58,59]

DIAGNOSIS OF METHANOL OR ETHYLENE GLYCOL POISONING

Laboratory tests for a patient with suspected methanol or ethylene glycol poisoning should include blood ethanol levels, arterial blood gas analysis, chemistry panel, calculation of anion and osmolar gaps, serum osmolarity, and creatine kinase level. Serum ketone, β-hydroxybutyrate (if available), and lactate levels are helpful if a metabolic acidosis or an osmolar gap is present. Falsely elevated lactate results have been seen with some point-of-care analyzers in patients with severe ethylene glycol poisoning.[60,61] Check point-of-care glucose level. Measure serum acetaminophen and salicylate levels in patients with an intentional overdose. **Consider methanol or ethylene glycol poisoning in a patient with an unexplained acidosis** (see chapter 15, Acid-Base Disorders).

Acidosis will not be present immediately after exposure. The parent compounds must be converted to toxic metabolites before the acidosis develops; this may be delayed by hours to over a day, especially if ethanol is coingested.

Methanol and Ethylene Glycol Levels **The best laboratory test for diagnosing methanol or ethylene glycol poisoning is measurement of the specific serum level of the alcohol.**[34]

Asymptomatic individuals following methanol ingestion usually have levels of <20 milligrams/dL (<6 mmol/L), and CNS symptoms may appear as levels rise above that. Ocular problems are associated with methanol levels of >50 milligrams/dL (>16 mmol/L), and the risk of fatality rises with levels >150 to 200 milligrams/dL (>47 to 62 mmol/L). However, toxicity associated with a given level depends greatly on how long after ingestion the level was measured. A level of 50 milligrams/dL (16 mmol/L) obtained 3 hours after ingestion implies a much smaller ingestion and less toxicity than if the same value was obtained 12 hours after ingestion.[62]

Asymptomatic individuals following ethylene glycol ingestion usually have peak levels <20 milligrams/dL (<3.2 mmol/L). As with methanol, toxicity associated with a given level depends greatly on how long after ingestion the level was measured. More useful are factors indicating metabolic dysfunction such as acidosis.

Osmolar Gap In many hospital and clinical laboratories, methanol and ethylene glycol levels are not available in a timely manner to assist with initial medical decision making. In such circumstances, the **osmolar gap** may be used as a surrogate marker for toxic alcohol levels (**Table 185-2**).[63] This calculation determines the difference between the measured serum osmoles and the calculated osmoles. Methanol and ethylene glycol, but not their metabolites, are osmotically active and will contribute to the measured serum osmolarity.

For accurate calculation of the osmolar gap, obtain blood samples for a basic serum chemistry panel (including blood urea nitrogen, glucose, and sodium levels), measurement of ethanol level, and measurement of serum osmolarity simultaneously. **Using a previously obtained specimen to measure serum osmolarity ("add-on" tests) is not acceptable, because any toxic alcohols present may have volatilized since the sample was obtained.** In addition, the freezing point depression method must be used to measure serum osmolarity, rather than the vapor pressure method, which can miss volatile substances such as toxic alcohols. There is considerable variation in baseline osmolar gap in healthy subjects depending on the formula used for calculation,[64] so the range of "normal" values is −14 to +10 mOsm/kg H_2O, and ranges may differ among clinical laboratories. In general, an osmolar gap of more than 10 to 15 mOsm/kg H_2O raises concern for toxicity. An osmolar gap of >50 mOsm/kg H_2O is highly suggestive of either methanol or ethylene glycol poisoning and is associated with increased mortality.[65]

The osmolar gap is highest when the parent toxic alcohol level is at its peak (roughly 30 to 60 minutes after ingestion), before significant metabolism has occurred (**Figure 185-6**). As the time since ingestion increases and the parent compound is metabolized, the osmolar gap will

TABLE 185-2 Substances That Contribute to the Osmolar Gap

Substance	Molecular Weight	mOsm/kg H_2O with a Serum Concentration of 100 milligrams/dL	Conversion Factor
Ethanol	46	22	4.6
Isopropanol	60	17	6.0
Methanol	32	31	3.2
Ethylene glycol	62	16	6.2

Notes: Calculated serum osmolarity = 2 × sodium + (blood urea nitrogen/2.8) + (glucose/18) + (ethanol/4.6) + (isopropanol/6.0) + (methanol/3.2) + (ethylene glycol/6.2)

Osmolar gap = measured serum osmolarity − calculated serum osmolarity

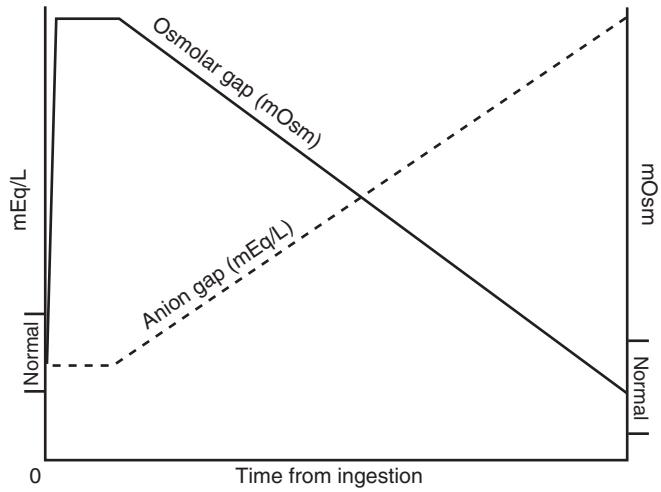

FIGURE 185-6. Relative changes in anion and osmolar gaps over time from ingestion of a toxic alcohol.

decrease. Hence, later-presenting patients may not have significant osmolar gaps. As metabolism occurs, acid metabolites build up and an anion gap metabolic acidosis develops as the osmolar gap narrows. There may be a time period in the middle range when the patient has both an osmolar gap and an anion gap.[66]

Although the osmolar gap may be helpful in conjunction with the rest of the clinical picture, it has many shortcomings and cannot be relied on to definitively diagnose or exclude a toxic alcohol poisoning.[63,67,68] Other conditions such as ketoacidosis, shock, and sepsis may cause an elevated osmolar gap.[69] Also, forgetting to account for ethanol is a common error when calculating the osmolar gap.

As noted, the range of normal variation in osmolar gap is wide and dependent on the formula used for calculation, so a toxic concentration of methanol or ethylene glycol may be present with an osmolar gap in the normal range.[67-69] For example, 1 milligram/dL (0.3 mmol/L) of methanol will raise serum osmolarity by 0.34 mOsm/kg H_2O.[20] Therefore, a methanol concentration of 50 milligrams/dL (15 mmol/L)—generally accepted to be toxic—will raise serum osmolarity 17 mOsm/kg H_2O. If a given patient's baseline was low to begin with, this methanol concentration would not create an abnormal osmolar gap.

Anion Gap The positively charged cations in the serum are electrically balanced by the negatively charged anions. In the clinical laboratory, not all cations and anions are routinely measured, and the level of measured cations is usually greater than that of measured anions; the difference is termed **unmeasured anions**. The predominant serum cation measured is sodium, which is almost completely balanced by the measured charged chloride and bicarbonate anions; the difference is termed the **anion gap**, consisting mostly of serum proteins, phosphate, sulfate, organic acids, and conjugate bases of ketoacids (see chapter 15, Acid-Base Disorders).

$$\text{Anion gap} = Na^+ - (Cl^- + HCO_3^-)$$

The normal anion gap varies according to the methodology used, and the physician should use the values established by the clinical laboratory. **In most clinical settings, an anion gap >15 mEq/L should be considered abnormal.** As noted, it takes time for the acidotic metabolites to become present, as much as 12 to 16 hours following methanol ingestion, so a normal anion gap does not exclude the diagnosis.

Urinary Fluorescence Urinary fluorescence under an ultraviolet or Wood's lamp has been anecdotally taught to be a helpful sign of ethylene glycol poisoning because most antifreeze products contain sodium fluorescein as an additive to aid in the detection of radiator leaks. Not all ethylene glycol products contain fluorescein; the fluorescence may be short-lived (lasting about 4 hours after ingestion); and the ability of the physician to detect fluorescence is affected by many technical factors.[70] Thus, the absence of urinary fluorescence cannot exclude an ethylene glycol ingestion. In addition, false-positive results occur, because many types of glass or plastic containers fluoresce on their own, and numerous foods, medications, toxins, and endogenous substances may cause urinary fluorescence.[71,72]

Calcium Oxalate Crystals for Ethylene Glycol Approximately half of patients poisoned with ethylene glycol demonstrate either monohydrate or dihydrate calcium oxalate crystals on urinalysis.[73] These are often misread as hippurate crystals. If present, they start to appear 4 to 6 hours after ingestion and may persist for days, especially in patients with renal failure. The monohydrate form is more common, and the dihydrate form is more specific for ethylene glycol poisoning.

TREATMENT

Because toxic alcohols are absorbed so rapidly, gastric decontamination is unlikely to be of benefit, and there is no evidence to support its routine use.[39,44,74] Activated charcoal may be used if there is a coingestant known to adsorb to charcoal.

The basic principles of treatment for both methanol and ethylene glycol poisoning are performing initial resuscitation, providing cardiopulmonary support, correcting acidosis, preventing formation of toxic metabolites, and enhancing the clearance of the parent compound and toxic metabolites.

Correct Acidosis Correcting acidosis may improve the outcome in patients poisoned with methanol because acidosis worsens the toxicity of formate; rapid improvement in visual and other systemic symptoms has been reported with correction of acidosis. In addition, alkalinization may help increase formic acid clearance by decreasing reabsorption in the proximal renal tubules.[45] However, the benefits of alkalinization may be equivocal if the patient is treated with metabolic blockade and hemodialysis. When used in methanol poisoning, give IV sodium bicarbonate infusions to maintain a serum pH of >7.30.[44] There is no evidence that alkalinization is specifically beneficial in ethylene glycol poisoning, but it seems reasonable to use sodium bicarbonate IV if there is a severe metabolic acidosis with pH <7.20.

Metabolic Blockade Because laboratory confirmation may take time and because prompt treatment is important to prevent the formation of toxic metabolites, the decision to block metabolism often must be made before the diagnosis is secure (**Table 185-3**).[75] Start treatment while sorting out the clinical picture to protect the patient from serious toxicity, such as blindness or renal failure. Treatment with either ethanol or fomepizole greatly slows the elimination of methanol and ethylene glycol. Because hepatic oxidation is inhibited, elimination is determined by first-order renal excretion, and the elimination half-life averages 52 hours (range 22 to 87 hours) for methanol (compared to an elimination

TABLE 185-3 Indications for Metabolic Blockade with Fomepizole or Ethanol

1. Elevated plasma levels: methanol >20 milligrams/dL (>6 mmol/L) or ethylene glycol >20 milligrams/dL (>3 mmol/L)
2. If methanol or ethylene glycol level not available:
   - A. Documented or suspected significant methanol or ethylene glycol ingestion with ethanol level lower than approximately 100 milligrams/dL (22 mmol/L)*
   - B. Coma or altered mental status in patient with unclear history and:
     - (1) Unexplained serum osmolar gap of >10 mOsm/L
     - *or*
     - (2) Unexplained metabolic acidosis *and* ethanol level of <100 milligrams/dL (<22 mmol/L)*

*If serum ethanol level is >100 milligrams/dL (>22 mmol/L), patient will be protected from the formation of toxic metabolites by coingestion of ethanol, and specific metabolic blockade treatment can be delayed until toxic alcohol level is available. If the ethanol level is likely to fall to <100 milligrams/dL before the toxic alcohol results are back, then initiate metabolic blockade.

half-life without metabolic blockade of 1.8 to 3 hours) and 13 to 20 hours for ethylene glycol (compared to an elimination half-life without metabolic blockade of 3 to 8 hours).[39,45,76,77]

Metabolic Blockade with Fomepizole The initial step in the metabolism of methanol (see **Figure 185-4**) or ethylene glycol (see **Figure 185-5**) is performed by alcohol dehydrogenase. This enzyme is competitively inhibited by either ethanol or **fomepizole** (4-methyl-1H-pyrazole).[76] Both ethanol and fomepizole have a much higher affinity for alcohol dehydrogenase than does methanol or ethylene glycol. Although ethanol was traditionally administered for metabolic blockade in methanol and ethylene glycol poisonings, fomepizole has supplanted ethanol for this purpose in many institutions. The primary advantage of fomepizole is the lack of side effects such as CNS depression, GI irritation, and hypoglycemia caused by ethanol therapy.[78-80] Fomepizole is less susceptible to dosing errors than ethanol.[81] The primary limiting factor to fomepizole use is the increased cost of the drug relative to ethanol, which may reduce availability in resource-poor locations.

Fomepizole is dosed with an initial loading dose of 15 milligrams/kg IV administered over 30 minutes, followed by additional doses of 10 milligrams/kg IV (also infused over 30 minutes) every 12 hours. Fomepizole is continued until the toxic alcohol level is <20 milligrams/dL (methanol <6 mmol/L or ethylene glycol <3 mmol/L) and the metabolic acidosis has resolved. Fomepizole is believed to induce its own metabolism, so it is recommended that the dose be increased to 15 milligrams/kg every 12 hours if treatment lasts >48 hours.[44,82] More frequent dosing (every 4 hours) is required during hemodialysis because fomepizole is removed during this procedure. Fomepizole does not require frequent monitoring of serum levels or dosage adjustments necessary with ethanol treatment.

Adverse effects from fomepizole are rare; mild and transient nausea, headache, dizziness, and injection site irritation are most commonly reported.[76] The safety of fomepizole in pregnancy is unknown, so the risks and benefits to fetus and mother of fomepizole therapy should be weighed against those of the alternative treatments. Reports show good efficacy of fomepizole therapy in children.[83]

Metabolic Blockade with Ethanol If fomepizole is not available or its use is contraindicated (i.e., the patient has a known allergy), ethanol may be used to inhibit toxic alcohol metabolism. Ethanol may be administered PO or IV.[84] Although ethanol may prevent toxic alcohol metabolism at blood levels as low as 30 milligrams/dL (7 mmol/L), the general recommendation is to maintain a target ethanol level of 100 to 150 milligrams/dL (22 to 33 mmol/L).[44] Extremely elevated toxic alcohol levels may reduce the effectiveness of alcohol dehydrogenase inhibition by ethanol, and ethanol levels of >150 milligrams/dL (>33 mmol/L) may be required to effectively block production of the toxic metabolites. Achieving the desired ethanol level may be difficult because individual response to ethanol administration varies considerably depending on baseline ethanol consumption.

The loading dose of IV ethanol is 800 milligrams/kg (10 mL/kg of 10% IV solution). Maintenance dosing varies depending on the patient's baseline ethanol use but generally averages 100 milligrams/kg per h (1.2 mL/kg per h of 10% IV solution) with ranges between 70 and 150 milligrams/kg per h (0.8 to 2 mL/kg per h of 10% IV solution). The oral loading dose (PO or via nasogastric tube) using 80-proof liquor is 1.5 to 2 mL/kg followed by maintenance dosing of 0.2 to 0.5 mL/kg per h. **Do not use oral ethanol preparations IV.** Serum ethanol concentrations should be monitored every 1 to 2 hours. All maintenance doses need to be doubled for patients undergoing hemodialysis.

With severe adult poisoning and when fomepizole therapy may be delayed or transport time to the hospital may be long, administration of three or four 1-oz (30-mL) "shots" of 80-proof liquor should raise blood ethanol concentrations sufficiently to block toxic alcohol metabolism in a 70-kg adult.[20] Maintenance dosages are approximately one to two shots per hour.

Ethanol treatment is continued until the toxic alcohol level is <20 milligrams/dL (methanol <6 mmol/L or ethylene glycol <3 mmol/L) and the metabolic acidosis has resolved. The disadvantage of using ethanol is the induction of a state of inebriation, so patients require close monitoring for neurologic and respiratory depression. Individual metabolic variations make dosing complicated, and frequent serum level monitoring and dosage adjustments are required. Children and malnourished individuals are particularly at risk for the development of hypoglycemia, although with careful monitoring, this complication is rare.[79] Administration of the 10% IV ethanol solution requires central venous access, because it is hyperosmolar and irritating to peripheral veins. Use of less concentrated solutions, such as 5% IV ethanol solutions, may require administration of large fluid volumes.

TABLE 185-4 Indications for Hemodialysis after Methanol or Ethylene Glycol Ingestion

Refractory metabolic acidosis: pH <7.25 with anion gap >30 mEq/L and/or base deficit less than −15
Visual abnormalities*
Renal insufficiency
Deteriorating vital signs despite aggressive supportive care
Electrolyte abnormalities refractory to conventional therapy
Serum methanol or ethylene glycol level of >50 milligrams/dL†

*Applies only to methanol; visual abnormalities may not resolve immediately, so their persistence in the absence of other indications once hemodialysis is started is *not* an indication for continued hemodialysis.

†Although previously considered an indication for hemodialysis, there are reports of patients with levels of ≥50 milligrams/dL (methanol ≥15 mmol/L or ethylene glycol ≥7.5 mmol/L) being successfully treated with fomepizole with or without bicarbonate and no hemodialysis.

Hemodialysis Hemodialysis can rapidly clear the toxic alcohols and metabolites, as well as correct acid-base disorders, thereby shortening the duration of metabolic blockade treatment.[39,44,85-87] Conversely, with fomepizole, patients can receive prolonged treatment with few side effects and without the need for hemodialysis and attendant risks.[88]

Hemodialysis may be required emergently for patients with severe acidosis, visual changes, hemodynamic instability, or renal failure (**Table 185-4**).[39,44,89,90] A serum level of ≥50 milligrams/dL (methanol ≥15 mmol/L or ethylene glycol ≥7.5 mmol/L) is considered an indication for hemodialysis, but this criterion has been questioned because many patients with high methanol or ethylene glycol levels have been effectively treated without hemodialysis.[56,88,91,92] Consider the entire clinical picture, rather than making a decision based only on a serum level. Some rebound in toxic alcohol levels may occur after hemodialysis is stopped, so it is recommended that metabolic blockade therapy be continued for several hours after cessation of dialysis, with blood level rechecked to ensure that the toxic alcohol level remains low.[39,44]

Vitamin Therapy Adjunctive treatment with B vitamins (including folate) is recommended to help clear the toxic metabolites of methanol and ethylene glycol more quickly, although no solid evidence exists to indicate that this treatment is necessary or even helpful.[93]

In methanol poisoning, high doses of folate or folinic acid may facilitate breakdown of formic acid into carbon dioxide and water (see **Figure 185-4**). Experimental animals with very large folate stores do not develop acidosis and toxicity from methanol poisoning unless they are artificially depleted of folate. Theoretically, increasing folate stores should hasten the detoxification of formate and prevent it from accumulating and causing end-organ damage. Folinic acid, the activated form of folic acid, is preferred, but folic acid may be used if the former is not available. Recommended dosing is 1 milligram/kg (up to 50 milligrams) IV every 4 to 6 hours.[44]

In ethylene glycol poisoning, adjunctive therapy with pyridoxine, thiamine, and magnesium may be used to facilitate metabolism of glyoxylate to nontoxic glycine and α-hydroxy-β-ketoadipoic acid (see **Figure 185-5**). Magnesium can be given as a one-time dose of magnesium sulfate 2 grams IV. The two B vitamins are given in large doses: thiamine, 100 milligrams IV, and pyridoxine, 50 to 100 milligrams IV, both every 6 hours for 2 days.[94]

Visual impairment can be a permanent complication of methanol poisoning.[95,96] Although treatment with fomepizole or ethanol and bicarbonate can prevent ocular toxicity, there is no other proven therapy to prevent or restore established visual damage.[95]

DISPOSITION AND FOLLOW-UP

Because of the complex management decisions required with methanol or ethylene glycol poisoning, consultation with a medical toxicologist or a regional poison control center is strongly recommended. Symptoms of methanol or ethylene glycol intoxication may be delayed, particularly if ethanol has been coingested. A patient with suspected ethylene glycol ingestion should be observed and monitored for 6 hours. If no ethanol is present, the patient remains completely asymptomatic, there is no osmolar gap, and no metabolic acidosis develops, the patient can be discharged. Methanol toxicity may be delayed longer, so a patient with suspected methanol ingestion should be observed for 12 hours using the same criteria. A patient with significant signs and symptoms should be admitted to an intensive care setting. Patients seen at facilities unable to provide hemodialysis or intensive care should be transferred as soon as possible, if in sufficiently stable condition, to institutions capable of providing such care. Suicidal patients should receive a psychiatric evaluation when their condition improves and prior to discharge.

CHAPTER 186

Opioids

Guillermo Burillo-Putze
Oscar Miro

INTRODUCTION

Opioids refers broadly to all compounds related to opium that possess analgesic and sedative properties. **Opiate** describes the opioid alkaloids found naturally in the opium poppy plant, *Papaver somniferum*. The term **narcotic** refers to a broader group of agents, predominantly used by law enforcement to designate a variety of controlled substances with abuse or addictive potential; use of this term in medical practice is discouraged.

Opioid abuse is a significant public health issue in the United States with a dramatic increase in prescription opioid use and abuse in the past 10 years.[1,2] Opioids most frequently involved in reported toxic drug exposures were, in order of number of cases recorded, tramadol, oxycodone, methadone, morphine, buprenorphine, and hydrocodone.[3] Deaths were primarily associated with exposure to methadone, oxycodone, and morphine. The majority of prescription opioid overdose deaths were associated with diversion, doctor shopping, and nonmedical use.

PHARMACOLOGY

Opioids modulate nociception in the terminals of afferent nerves in the CNS, peripheral nervous system, and GI tract. Opioids are agonists at the three primary opioid receptors: μ (mu), κ (kappa), and δ (delta). Opioid receptors are similar to other G protein–coupled receptors; they are transmembrane proteins that undergo conformational change when activated by external molecules, and this change then alters some aspect of intracellular function. Opioid receptors vary widely in morphology and distribution. Also, the specificity and affinity of an opioid for a particular receptor are variable. For example, tramadol possesses 1/6000 the affinity of morphine at the μ-receptor site.

Stimulation of the μ-receptors results in analgesia, sedation, miosis, respiratory depression, cough suppression, euphoria, and decreased GI motility. Stimulation of κ-receptors results in weaker analgesia, sedation, miosis, decreased intestinal motility, dysphoria, and hallucinations. Stimulation of the δ-receptors results in some analgesia and antidepressant effect. **All currently available opioid agonists possess μ-receptor activity and result in some degree of respiratory depression.**

There is interplay between opioid receptors and other transmembrane receptors found in the nervous system. One example is that opioid binding to μ-receptors in the nucleus accumbens results in the localized release of dopamine (the "dopamine pleasure pathway"). A second example is that the analgesic effect of morphine is enhanced in the presence of *N*-methyl-D-aspartate receptor blockers such as amantadine. A third example is the induction of mast cell histamine release by morphine and meperidine.

Opioids can be categorized as naturally occurring compounds (termed *opiates*), chemical modifications of natural compounds (semisynthetic), and completely artificial compounds (synthetic) (**Table 186-1**). Some opioids are agonists at all opioid receptors (e.g., morphine and hydromorphone), whereas others are partial agonists–antagonists (e.g., pentazocine, butorphanol, and nalbuphine) at the opioid receptors.

PHARMACOKINETICS

Opioids are readily absorbed, achieving peak blood levels 30 to 60 minutes after ingestion of standard oral formulations. Sustained-release forms take longer after ingestion to achieve peak blood levels; for example, morphine sulfate controlled-release tablets take about 90 minutes to reach peak blood levels compared with 30 minutes for standard morphine tablets. After GI absorption, most opioids undergo first-pass hepatic metabolism, so bioavailability can vary from as low as 10% to as high as 80% after PO administration. Thus, at equal doses, most opioids are more potent given parenterally than PO. The opioids with good oral bioavailability are codeine, oxycodone, methadone, hydromorphone, and tapentadol.

The metabolism of codeine, meperidine, methadone, morphine, oxycodone, and propoxyphene is mostly hepatic and subject to drug interactions and genetic variations. For example, antiretroviral medications can enhance the metabolism of methadone, which results in lower plasma methadone concentrations. As another example, codeine is metabolized to morphine via cytochrome P-450 isoenzyme 2D6, an enzyme with genotypic and phenotypic variability. Patients with rapid cytochrome P-450 enzyme 2D6 metabolism produce more morphine after a fixed dose of codeine.[4] These interactions and genetic variations may influence the therapeutic effect of opioids (see chapter 35, "Acute Pain Management").

In drug misuse, unconventional routes of administration (insufflating or injecting ground opioid tablets, heating fentanyl patches or applying more than one patch to the skin) may alter the drug's pharmacokinetics and often increase the rate of opioid absorption. Similarly, in cases of opioid overdose resulting in high plasma levels, the pharmacokinetics are altered due to enzymatic saturation. This may increase the severity of poisoning, delay the onset, and prolong the duration of action, as compared with the expected therapeutic actions.[5]

CLINICAL FEATURES

The full opioid intoxication toxidrome includes respiratory and mental status depression, analgesia, miosis, orthostatic hypotension, nausea and vomiting (especially in opioid-naïve patients), histamine release resulting in localized urticaria (Figure 186-1) and bronchospasm, ileus secondary to decreased GI motility, and urinary retention secondary to increased vesical sphincter tone.[6] The depression in mental status can be profound. The respiratory depression is characterized by slow and shallow respirations that can produce hypercarbia, hypoxia, and cyanosis. Miosis is not universally present from intoxication with every opioid; normal or even enlarged pupils have been documented secondary to diphenoxylate, meperidine, morphine, pentazocine, and propoxyphene toxicity. Mydriasis may also signal severe cerebral hypoxia or result from co-ingestants. Other possible findings include pulmonary edema, hypothermia, rhabdomyolysis, compartment syndrome, myoglobinuric renal failure, and seizures associated with overdoses of tramadol, propoxyphene, and meperidine.

Opioid-induced acute lung injury, previously known as *noncardiogenic pulmonary edema*, is an uncommon complication associated with heroin overdose.[6,7] Acute lung injury can occur immediately or be delayed up to 24 hours after heroin overdose and presents with tachypnea, rales, decreased oxygen saturation, and bilateral pulmonary infiltrates with a normal cardiac silhouette on chest radiograph. The incidence of acute

lung injury is 10% in patients with severe heroin overdose requiring naloxone.[8] The pathophysiology of heroin-induced acute lung injury is poorly understood, but some degree of direct capillary injury is suspected. Treatment includes oxygen supplementation and ventilatory support, either noninvasive or invasive modalities, and positive end-expiratory pressure. Additional naloxone, diuretics, and digoxin are not indicated.

The combination of meperidine, tramadol, or dextromethorphan with monoamine oxidase inhibitors, selective serotonin reuptake inhibitors, or linezolid can result in **serotonin syndrome** (see chapter 178, Atypical and Serotonergic Antidepressants).[9] Serotonin syndrome is characterized by disorientation, hyperthermia, autonomic instability, hyperreflexia, and muscle rigidity, especially in the lower extremities. Although uncommon, deaths have been reported. Naloxone is not effective in treating opioid-induced serotonin syndrome.[9,10]

DIAGNOSIS

The combination of coma, miosis, and respiratory depression strongly suggests opioid intoxication, and in many clinical scenarios, evidence of opioid use is present. The combination of a respiratory rate of <12 breaths/min, miosis, and circumstantial evidence of opioid use (drug paraphernalia, needle marks, presence of a tourniquet, bystander corroboration) was highly sensitive for opioid overdose.[11]

Listen for auscultatory findings suggestive of pulmonary edema. Undress the patient completely and look for hidden opioids or drug-use paraphernalia, check for fentanyl patches on all parts of the body, including mucous cavities, and palpate muscle groups to detect signs of compartment syndrome.

The differential diagnosis of opioid intoxication includes toxicologic exposure to agents that produce similar findings, such as clonidine, organophosphates and carbamates, phenothiazines and atypical antipsychotic medications, sedative-hypnotic medications, and carbon monoxide. Clonidine overdoses are characterized by coma, bradycardia, hypotension, miosis, and periods of apnea that respond to tactile or auditory stimulation. Organophosphate and carbamate overdoses cause the cholinergic toxidrome: miosis, muscle fasciculations, profuse vomiting and diarrhea, and sweating. Phenothiazines, olanzapine, and risperidone cause

neurologic depression and miosis from decreased adrenergic tone.[12] γ-Hydroxybutyrate intoxication is associated with profound CNS depression, bradypnea, and, occasionally, miosis. Sedative-hypnotic agents and carbon monoxide cause profound neurologic depression but are not usually associated with miosis. Hypoglycemia, hypoxia, CNS infections, postictal states, and pontine and intracranial hemorrhages should also be considered in the differential diagnosis.

OPIOID SCREENS

A qualitative urine opioid screen may aid in the diagnosis, but available tests have limitations. The assay in most commercially available urine opioid screens recognizes morphine.[13] Therefore, morphine and those opioids that are metabolized to morphine, such as codeine and heroin, are readily detected. However, the semisynthetic opioids hydrocodone and oxycodone are usually not detected by urine opioid screens, and essentially all synthetic opioids also are not routinely detected. A specific urine assay is required to detect oxycodone or methadone.

Urine opioid screens can have false-positive results.[13] Depending on the threshold level, ingestion of poppy seeds contained in baked goods can lead to a false-positive test result. Rifampin, rifampicin, quinine, diphenhydramine, and fluoroquinolones have been reported to cause false-positive urine opioid screen results, presumably by interfering with the immunoassay technique. An opioid analogue, dextromethorphan, can produce a positive result on the urine opioid screen. Prescription drugs reported to cause a false-positive result with the methadone urine drug screen include chlorpromazine, clomipramine, diphenhydramine, doxylamine, ibuprofen, quetiapine, thioridazine, and verapamil.

A urine opioid screen can be positive up to 2 to 3 days after a single use of codeine, morphine, or heroin. The methadone-specific screen can be positive up to 3 days after ingestion. Thus, detection of an opioid agent taken in the recent past may not correctly identify the toxicologic cause of the patient's current condition. Plasma acetaminophen concentration should be obtained in all suicidal ingestions and all cases of combination opioid-acetaminophen overdoses.

TREATMENT

Airway protection and ventilatory maintenance are the most important treatment steps for opioid intoxications, because respiratory depression is the major morbidity and the cause of essentially all the mortality.[6] Use bag-valve mask ventilatory support as needed to initially maintain adequate oxygenation and ventilation. After adequate ventilation is ensured, administer naloxone (**Table 186-2**). In fully awake patients or after the airway is protected with an endotracheal tube in unresponsive patients, administer single-dose activated charcoal, 1 gram/kg PO, if an opioid ingestion occurred within the hour. Endotracheal intubation is a therapeutic option in some cases of opioid overdose with severe respiratory depression unresponsive or poorly responsive to naloxone or in cases in which acute lung injury is suspected.[6] Intubation offers the advantages of protection of the airway, easy access for suctioning, provision of an alternate route of administration for some medications, and total airway control. Rapid-sequence intubation, omitting anesthetic-sedative agents, is the preferred technique.

Under special circumstances, delayed and multiple doses of activated charcoal may be useful, as in diphenoxylate hydrochloride–atropine sulfate overdoses and in cases of large ingestions of sustained-release preparations.[14]

TABLE 186-2 Opioid Antagonists

Drug	Route	Initial Dose*	Onset of Action	Duration of Action†
Naloxone	IV	0.1–0.4 milligrams if breathing spontaneously	1–2 min	20–90 min
		2 milligrams if apneic		
	IM or SC	2 milligrams	5–6 min	
	Intranasal	2 milligrams (1 milligram in each nostril)	6–8 min	
	Nebulized	2 milligrams in 3 mL normal saline	5 min	
Nalmefene	IV	0.1–0.5 milligrams if breathing spontaneously	2–5 min	Up to 4 h
		2 milligrams if apneic	2–5 min	8 h
	IM or SC	1 milligram	5–15 min	4–6 h
Naltrexone	PO	50 milligrams	30–60 min	24 h
		100 milligrams	30–60 min	48 h
		150 milligrams	30–60 min	72 h

*See text regarding subsequent dosing.

†Duration dependent on amount of opioid agonist present.

NALOXONE

Naloxone, a derivative of oxymorphone, is a pure competitive antagonist at all opioid receptors, with particular affinity for μ-receptors. Naloxone therefore fully reverses all the effects of opioids, including respiratory depression, CNS depression, miosis, and analgesia. Naloxone also antagonizes opioid-induced seizures, except those induced by meperidine, propoxyphene, or tramadol. The elimination half-life of naloxone is 60 to 90 minutes, but the duration of action is as short as 20 minutes if a large amount of opioid agonist is present.

Naloxone has poor oral bioavailability but is well absorbed when given by injection (IV, SC, or IM), inhaled, or deposited on mucosa (intratracheally or intranasally, but not sublingual). Inhaled naloxone by nebulization is reasonably effective in reversing depressed mental status and respirations in opioid toxicity, with about 10% requiring additional rescue parenteral naloxone.[15-17] Intranasally administered naloxone provides a pharmacokinetic profile similar to that of IM or SC naloxone and is used by EMS personnel and in bystander naloxone administration programs.[18-20]

Naloxone effectiveness is dependent on the dose administered and the amount of opioid that needs to be reversed. A small starting dose of naloxone, 0.1 milligram IV, is recommended in opioid-dependent patients who present with mental status depression but with minimal respiratory depression, because larger doses can induce opioid withdrawal symptoms in opioid-dependent patients. An initial dose of naloxone, 0.4 milligram IV, is recommended in non–opioid-dependent patients who present with mental status depression but with minimal respiratory depression. Subsequent doses of naloxone of 0.1 to 0.4 milligram IV are administered until the desired effect is reached. Incremental dosing of naloxone mitigates the precipitation of acute opioid withdrawal.[21]

An initial dose of naloxone, 2 milligrams IV, should be administered to patients presenting with apnea or near-apnea and cyanosis, regardless of drug use history. Repeated doses of 2 milligrams IV every 3 minutes are recommended until a maximum of 10 milligrams IV is reached or respiratory depression is reversed. Exposures to synthetic opioids, such as propoxyphene, fentanyl, pentazocine, or dextromethorphan, and to sustained-release preparations may require these larger-than-ordinary doses. Toxicity from leaking opioid-containing packets in the intestinal tract (i.e., in "body packers") can be extremely severe, and such patients require large and sustained naloxone doses until the drug-containing packets are expelled or removed.

The duration of action of naloxone is often shorter than that of the offending opioid, so naloxone infusions are occasionally required to support respiration over several hours as the opioid is metabolized. This is especially true for certain long-acting opioids, such as buprenorphine, methadone, and propoxyphene; for exposures to sustained-release preparations; and for ingestions of dermal patches. A continuous infusion should be considered only if the patient responded to the initial naloxone bolus and subsequently required repeat administration. **To calculate the naloxone continuous infusion dose, determine the "wake-up dose" and administer two thirds of that dose per hour by IV infusion.** Adjustments may be required if the patient develops respiratory depression (by repeating a bolus and increasing infusion rates) or withdrawal symptoms (by decreasing infusion rates). It is

recommended that patients on naloxone infusions be admitted to a monitored unit.

Naloxone has a remarkable safety profile. Although adverse effects are seen in about one third of patients who receive it for a suspected opioid overdose, serious complications are rare.[22] The most common adverse effects associated with naloxone are anxiety, nausea, vomiting, diarrhea, abdominal cramps, piloerection, yawning, and rhinorrhea, related to the precipitation of the opioid withdrawal syndrome. Careful dosing of naloxone can prevent the precipitation of opioid withdrawal symptoms.[21,23]

Naltrexone, an oral opioid antagonist, is primarily used to maintain opioid abstinence after detoxification. Naltrexone may be useful in preventing delayed respiratory depression in opioid-naïve methadone-intoxicated patients in resource-limited locations.[24] The elimination half-life for the two major active metabolites of naltrexone is 10 to 13 hours, but the duration of action is dose-dependent and longer.

Nalmefene, both an oral and parenteral opioid antagonist, has not been available in the United States since August 2008. The elimination half-life is about 11 hours. In the suspected opioid-dependent adult with mental status and respiratory depression, the initial nalmefene dose is 0.1 milligram IV. If no withdrawal occurs, a dose of 0.5 milligram is given, followed by 1 milligram in 2 to 5 minutes if mental status or respirations are still depressed.

DISPOSITION AND FOLLOW-UP

The optimal observation period after an opioid intoxication is determined by the history and clinical picture. Naloxone-responsive injection drug users with presumed heroin intoxication can be safely discharged 1 to 2 hours after administration of naloxone if they have independent mobility, oxygen saturation on room air >92%, respiratory rate >10 breaths/min, pulse rate >50 beats/min, normal temperature, and a Glasgow coma scale score of 15.[25]

In cases of exposure to opioids other than heroin, an observation period of 4 to 6 hours in the ED is recommended after the last naloxone administration. In long-acting opioid overdose, observation should be extended for a minimum of 8 hours.[4] Moderate to severely symptomatic patients usually require hospital admission to monitored settings and may require continued administration of naloxone. A behavioral health evaluation is needed in cases with suicidal intent.

SPECIAL CONSIDERATIONS

BUPRENORPHINE

Buprenorphine is a partial agonist at μ-receptors, with decreased intrinsic activity that causes its clinical effects to plateau at higher dosages.[26] Buprenorphine has high affinity for and slow dissociation from the μ-receptor, which results in a long duration of action. Furthermore, other opioid agonists (such as heroin) or antagonists (such as naloxone) cannot easily displace buprenorphine from the μ-receptor. Buprenorphine has poor oral bioavailability because of extensive first-pass metabolism and is therefore administered SL or parenterally. The most frequently prescribed SL buprenorphine formulation is in combination with naloxone in a 4:1 ratio. Because naloxone has poor bioavailability from PO or SL administration, it was introduced into the preparation to discourage and limit parenteral abuse of the buprenorphine portion while not interfering with therapeutic use in the form of the SL tablet.

Buprenorphine can be associated with three distinct clinical scenarios. First, the opioid-naïve patient who overdoses on buprenorphine will experience mental status depression, nausea, vomiting, miosis, and respiratory depression (usually with a plateau). In this situation, naloxone may not be fully effective in reversing mental status and respiratory depression.[27] **Because of the long duration of action of buprenorphine, readministration of naloxone and naloxone infusions is frequent, and admission to the hospital is necessary in symptomatic patients.** The second possible scenario is buprenorphine exposure in the opioid-dependent patient still under the influence of the opioid agonist. In this case, buprenorphine will precipitate opioid withdrawal symptoms, because the partial agonist buprenorphine behaves like an antagonist in the presence of an agonist. Buprenorphine-induced withdrawal is best managed with symptom-driven therapy, including antiemetics, nonopioid analgesics, antidiarrheals, and nonbenzodiazepine sedatives for insomnia. The third possible clinical scenario is buprenorphine exposure in the opioid-dependent patient undergoing withdrawal, in whom buprenorphine will act as a partial agonist and alleviate the symptoms of opioid withdrawal. This forms the basis for buprenorphine detoxification and maintenance therapy. Thus, **buprenorphine is unique in that it can both induce and treat opioid withdrawal, depending on the timing of its administration.**

METHADONE

Methadone is synthetic opioid used as replacement therapy in opioid-dependence and for chronic pain. The initial analgesic duration is 4 to 8 hours with an elimination half-life of 12 to 18 hours. With repetitive dosing, analgesic action duration and elimination half-life increase to about 22 to 36 hours and up to 59 hours, respectively. The long duration of activity enables once-a-day dosing during chronic therapy. Methadone has a higher risk for overdose-related deaths than other opioids, often with co-ingestants.[28,29]

Methadone has several drug–drug interactions that can precipitate toxicity or withdrawal in patients on chronic therapy.[30] Interactions between methadone and human immunodeficiency virus medications are common and complex, creating potential for both increased toxicity and withdrawal. The relevant interactions for emergency physicians include ciprofloxacin, fluconazole, ketoconazole, and omeprazole, which can increase toxicity. Drug–methadone interactions that have potential to precipitate withdrawal include macrolide (especially clarithromycin), phenobarbital, phenytoin, spironolactone, and verapamil.

Methadone prolongs the QT interval prolongation in acute overdose or during long-term methadone treatment, providing the substrate for cardiac dysrhythmias, such as torsade de pointes.[31] In patients with acute methadone overdose resulting in QT interval prolongation, serum electrolyte imbalances should be corrected and the patient should be admitted to a monitored bed until the condition resolves. Patients on long-term methadone therapy who develop a QT_c interval of >450 milliseconds but <500 milliseconds do not require a dosage adjustment, but electrolyte imbalances should be corrected if present, and patients should be followed on an outpatient basis with frequent ECGs. In patients on long-term methadone therapy who develop a QT_c interval of >500 milliseconds, any electrolyte imbalances should be corrected, methadone dosage reduction or discontinuation should be considered, and other contributing factors should be eliminated.[32]

Acute methadone overdoses present similar to other opioid intoxications, but the duration can be much longer.[33] Naloxone infusions are often required with close neurologic and respiratory monitoring, or oral naltrexone can be used in resource-limited circumstances.[24]

PROPOXYPHENE

Propoxyphene and its metabolite, norpropoxyphene, are cardiotoxic and neurotoxic.[34] Propoxyphene overdoses produce sodium channel blockade, causing QRS interval prolongation, atrioventricular conduction block with bradycardia, prolonged QT interval, and ventricular bigeminy. Seizures have been reported in about 10% of overdoses. Propoxyphene is usually combined with acetaminophen or salicylates, so levels of those drugs should be checked in an overdose.

As in other overdoses that involve sodium channel blockade, propoxyphene-induced QRS interval prolongation should be treated with sodium bicarbonate, 1 mEq/kg IV.[35] Seizures should be treated with benzodiazepine or phenobarbital. Naloxone will not reliably reverse the cardiotoxicity or terminate propoxyphene-induced seizures.[36]

TRAMADOL

Tramadol overdoses are associated with lethargy, nausea, tachycardia, and seizures.[37,38] At doses exceeding 500 milligrams, coma, hypertension, respiratory depression, and apnea are seen.[10,39] Features consistent with serotonin syndrome have been seen in isolated tramadol overdoses.[40] Tramadol-induced seizures are common, and naloxone is ineffective in preventing them. Fortunately, tramadol-induced seizures are usually single and anticonvulsants are not necessary.[41,42] Dependence during chronic therapy and withdrawal symptoms upon discontinuation have been reported with tramadol.[43]

MIXED AGONISTS-ANTAGONISTS

The mixed agonists-antagonists include pentazocine, butorphanol, and nalbuphine. These agents have variable but mostly antagonist activity at the μ-receptor. They may cause significant respiratory depression in overdose, and naloxone will reverse this respiratory depression. Mixed agonists-antagonists usually precipitate withdrawal when taken by an opioid-dependent individual, which reduces their potential for abuse. Pentazocine overdose can cause seizures.[44]

DIPHENOXYLATE HYDROCHLORIDE–ATROPINE SULFATE

Diphenoxylate hydrochloride–atropine sulfate is a frequently prescribed antidiarrheal agent. The medication is formulated as a combination tablet or liquid, containing diphenoxylate, 2.5 milligrams, and atropine, 0.025 milligram, in each tablet or 5 mL of liquid. In an overdose, initially the anticholinergic toxidrome dominates the clinical picture (see chapter 202, "Anticholinergics"). The second phase of intoxication is characterized by the opioid toxidrome. Children <6 years of age can be symptomatic after ingestion of a single tablet. In pediatric patients, absorption can be delayed up to 6 to 12 hours in some cases because of the effect of atropine on GI motility. Current recommendations are that all children <6 years of age be admitted to the hospital and be closely observed for 24 hours after ingestion of a combination tablet of diphenoxylate and atropine. Older children and adults should be observed in the ED for 6 hours. Administration of activated charcoal is recommended unless contraindicated.

MIXED DRUGS AND CONTAMINANTS

Illicitly obtained heroin is often mixed with other compounds, such as cocaine, scopolamine, clenbuterol, and fentanyl, which may contribute to heroin overdose toxicity. Adulterants found in illicit heroin may include strychnine, quinine, lactose, and talc. Scopolamine is an antimuscarinic agent that produces the anticholinergic toxidrome. Clenbuterol is a long-acting β-adrenergic agonist similar to albuterol and is used in veterinary medicine. Heroin-fentanyl mixtures (colloquially called **China-white**) resulted in hundreds of deaths among injection drug users in metropolitan areas of the United States during 2007.[45] A potent neurotoxin, 1-methyl-4-phenyl-1,2,3,-tetrahydropyridine, has been used as a meperidine adulterant, producing parkinsonism in users.[46]

Starting in Russia in 2010, episodes of deaths and gangrene were reported associated with intravenous desomorphine or **"Crokodile,"** a synthetic alternative to heroin crudely made from codeine tablets with a high concentration of tissue-toxic impurities. The colloquial name is derived from the appearance of the skin after it is injected.[47]

KRATOM

Kratom (*Mitragyna speciosa*) has mitragynine as its principal alkaloid, with stimulating effects at low doses (cocaine-like effect) and sedative effects (opioid-like effect) at high doses.[48] Regular kratom use can lead to dependence, craving, and withdrawal symptoms.[49,50] Kratom can produce serious toxicity or even death, often associated with interaction with other drugs, such as nasal decongestants, over-the-counter drugs, and benzodiazepines.[51] Krypton, a combination containing kratom, desmethyltramadol, and caffeine has been associated with fatalities.[52]

TABLE 186-3 Opioid Withdrawal

Onset: Within Hours	Onset: 12 h	Onset: 24–36 h
Peak effects: 36–72 h	Peak effects: 72 h	Peak effects: 72 h
Anxiety	Irritability	Insomnia
Yawning	Tremor	Muscle spasms
Drug craving	Piloerection	Abdominal pain
Lacrimation	Mydriasis	Nausea, vomiting, diarrhea
Rhinorrhea		
Diaphoresis		
Myalgias		

Kratom is available in smoke shops and on the Internet.[53] Kratom preparations are used as self-management of chronic pain, as replacement therapy for opioid analgesics, and for opioid and alcohol withdrawal symptoms.[54]

OPIOID WITHDRAWAL

Downregulation of endogenous endorphins, dynorphins, and opioid receptors occurs with long-term use of opioids. Abrupt cessation of opioid use does not allow time for upregulation of receptors and results in increased neuronal firing and the opioid withdrawal syndrome.

Opioid withdrawal usually starts with feelings of anxiety, yawning, lacrimation, diaphoresis, rhinorrhea, and diffuse myalgias (**Table 186-3**),[55] progressing to piloerection, mydriasis, nausea, profuse vomiting, diarrhea, and abdominal cramping. Opioid withdrawal reactions are very uncomfortable but are not life-threatening and rarely fatal. Vomiting and aspiration of gastric contents can cause pneumonitis and dehydration. Onset of withdrawal is usually within 6 to 12 hours of last heroin use and within 30 hours of last methadone exposure. It can be precipitated by the administration of antagonists such as naloxone or naltrexone or the administration of partial agonists such as buprenorphine. Opioid withdrawal symptoms usually peak on the third day of abstinence and resolve by the fifth or sixth day. Subjective and objective opiate withdrawal scales can be used to monitor the severity of symptoms and signs and guide therapy.[56]

Symptoms of opioid withdrawal can be rendered more tolerable by the administration of the central α_2-agonist clonidine, antiemetics, and antidiarrheal agents.[57] Clonidine may be used at a dose of 5 micrograms/kg PO if the blood pressure is >90 mm Hg systolic. Multidrug regimens are sometimes used in ambulatory detoxification programs to control withdrawal symptoms.[58,59]

The management of opioid-dependent individuals hospitalized for medical or surgical reasons remains controversial. Detoxification from opioids during the course of an acute medical illness is usually unsuccessful, and alleviation of withdrawal symptoms with opioid replacement is generally the goal. Daily administration of a verified dose of methadone PO (or half the verified dose IM if the patient cannot take oral medications) is recommended to inhibit withdrawal symptoms and reduce craving. This applies only to individuals who are enrolled in a methadone treatment program and in whom the dose can be verified. A habitual user who is not receiving methadone maintenance therapy can be given methadone 20 milligrams PO or 10 milligrams IM. These doses should inhibit withdrawal symptoms but not induce euphoria. Buprenorphine, 0.3 to 1.2 milligrams IV or IM every 6 hours, can safely be administered to a medically ill opioid-dependent patient experiencing withdrawal who will be admitted to the hospital.[60] **No methadone or buprenorphine should be administered to an opioid-dependent patient until withdrawal symptoms appear.**

CHAPTER 187

Cocaine and Amphetamines

Jane M. Prosser
Jeanmarie Perrone

INTRODUCTION

Historical records of indigenous cultures in South America describe early stimulant use by chewing leaves of the *Erythroxylum coca* plant, a practice that continues today. Cocaine was first used therapeutically in 1884 for ophthalmologic procedures. Amphetamines were first synthesized in 1887, and in 1932 they were first marketed medicinally in an inhaler form as a bronchodilator. Use of methamphetamine to enhance physical and intellectual performance began in the 1930s. These drugs have limited therapeutic roles but are widely used as drugs of abuse. Clinical effects and toxicity are due to sympathetic nervous system stimulation.

PHARMACOLOGY

COCAINE

Cocaine is the naturally occurring alkaloid found in *E. coca*, a plant indigenous to South America. The water-soluble hydrochloride salt is absorbed across all mucosal surfaces, including oral, nasal, GI, and vaginal epithelium; thus, cocaine can be topically applied, swallowed, or injected IV. The hydrochloride (salt) form is most often insufflated (snorted) or injected IV. The freebase form of cocaine can be prepared in several ways. A common method uses an alkali, such as sodium bicarbonate, to produce "crack cocaine," a freebase form that is stable to pyrolysis that, when smoked, produces the popping sound that characterizes its name. The onset and duration of action vary with the route of administration (**Table 187-1**).

When cocaine is insufflated nasally, the delayed and prolonged effect is a result of vasoconstrictive properties that limit mucosal absorption as well as the swallowing of a portion of the insufflated cocaine, which is then absorbed from the stomach. GI absorption is also delayed by vasoconstriction, producing delayed peak effect.

Cocaine is primarily metabolized to ecgonine methyl ester by plasma cholinesterase. Relative deficiency of this enzyme may predispose affected patients to life-threatening toxicity.[1] Benzoylecgonine is the other major metabolite excreted in the urine and is the target compound detected in routine urine toxicology screens. Cocaethylene is a long-acting metabolite formed when cocaine is used in combination with ethanol. Cocaethylene has vasoconstrictive properties similar to those of cocaine.

Cocaine is both a CNS stimulant and a local anesthetic.[2,3] Central effects are mediated by enhancement of excitatory amino acids and blockade of presynaptic reuptake of norepinephrine, dopamine, and serotonin. The excess of neurotransmitters at postsynaptic receptor sites leads to sympathetic activation, producing the characteristic physical findings of mydriasis, tachycardia, hypertension, and diaphoresis, and predisposing to dysrhythmias, seizures, and hyperthermia. Cocaine use produces a euphoria associated with enhanced alertness and a general sense of well-being. It is thought that the psychological addiction, drug craving, and withdrawal effects are mediated by interference with dopamine and serotonin balance in the CNS. Subsequent dopamine depletion at the nerve terminals may account for the dysphoria and depression associated with long-term abuse.

Like other local anesthetics, cocaine inhibits conduction of nerve impulses by blocking fast sodium channels in the cell membrane. Cocaine also has quinidine-like effects on conduction, causing QRS-complex widening and QT-interval prolongation. Thus, in large doses, cocaine may exert a direct toxic effect on the myocardium, resulting in negative inotropy and wide-complex dysrhythmia.

TABLE 187-1 Pharmacokinetics of Cocaine

Route of Exposure	Onset of Action	Peak Action	Duration of Action
IV	<1 min	3–5 min	30–60 min
Nasal insufflation (snorting)	1–5 min	20–30 min	60–120 min
Inhalation (smoking)	<1 min	3–5 min	30–60 min
GI	30–60 min	60–90 min	Unknown

AMPHETAMINES

Amphetamines comprise a broad class of structurally similar derivatives of phenylethylamine.[4] The derivative methamphetamine, also known as "ice," is abused by ingestion, IV injection, inhalation, or nasal insufflation. Absorption and peak effects vary with the route (**Table 187-2**). Modification of the basic amphetamine structure produces substances with additional psychoactive properties.[4] Over 50 such "designer" amphetamines have been created (**Table 187-3**), primarily for hallucinogenic effects (see chapter 188, "Hallucinogens"). Methamphetamine and the designer amphetamines may have effects that persist for up to 12 hours or longer.

Synthetic (or substituted) cathinones, often termed "**bath salts**," are designer drugs derived from naturally occurring amphetamine analogs found in the *Catha edulis* plant. Cathinones stimulate the release and block the reuptake of norepinephrine, dopamine, and serotonin at synapses in the brain, producing stimulant effects similar to cocaine and amphetamines.[5-7] Commonly abused substituted cathinones include mephedrone, methylenedioxypyrovalerone, and methylone, although the composition in bath salts sold for use by abusers varies widely. Stimulant medications for attention-deficit disorder, such as methylphenidate and dextroamphetamine, are available in both immediate- and extended-release formulations. Abusers may crush the extended-release tablet to separate the active agent from the extended-release matrix to achieve a rapid onset of action after insufflation or injection.[8]

Amphetamines enhance the release and block the reuptake of catecholamines at the presynaptic terminal and may also directly stimulate catecholamine presynaptic and postsynaptic receptors.[9] Some amphetamine metabolites inhibit monoamine oxidase, increasing cytoplasmic concentrations of norepinephrine. Certain amphetamine derivatives can also induce release of serotonin and affect central serotonin receptors.

TABLE 187-2 Pharmacokinetics of Methamphetamine

Route of Exposure	Onset of Action	Peak Action	Duration of Action
IV	15–30 s	30 min	10–12 h
Nasal insufflation (snorting)	3–5 min	1–2 h	10–12 h
Inhalation (smoking)	10–30 s	5–10 min	8–12 h
GI	15–20 min	2–3 h	10–12 h

TABLE 187-3 Commonly Abused Designer Amphetamines

Abbreviation	Chemical Name
MDMA	3,4-methylenedioxymethamphetamine
MDA	3,4-methylenedioxyamphetamine
MDEA	3,4-methylenedioxyethamphetamine
PMA	Paramethoxyamphetamine
DOB	4-bromo-2,5-dimethoxyamphetamine
2CB	4-bromo-2,5-dimethoxyphenylethylamine
STP or DOM	4-methyl-2,5-dimethoxyamphetamine

These serotonergic effects account for the hallucinogenic properties of some amphetamine derivatives such as MDMA (3,4-methylenedioxymethamphetamine) and mescaline (3,4,5-trimethoxyphenethylamine). Downregulation of dopamine receptor activity with long-term use may contribute to the withdrawal phenomenon. Mortality from amphetamine toxicity is a result of hyperthermia, dysrhythmias, seizures, hypertension (intracranial hemorrhage or infarction), and encephalopathy.

Stimulants such as methylphenidate, ephedrine, pseudoephedrine, and phenylpropanolamine produce toxic syndromes similar to those caused by cocaine and amphetamines.[10-15] Ephedrine is derived from ephedra or ma huang (*Ephedra sinica*) and is an indirect-acting sympathomimetic that was advertised as a "natural" stimulant in health food supplements and promoted for dieting, energy, and maintenance of alertness. Cardiovascular and neurologic toxicity associated with psychosis, severe hypertension, and several deaths prompted the U.S. Food and Drug Administration in 2004 to ban the sale of ephedra in dietary supplements.

CLINICAL FEATURES

The clinical features of cocaine and amphetamine toxicity are the result of their sympathomimetic, vasoconstrictive, psychoactive, and local anesthetic properties affecting a variety of organ systems.[2-4,9]

CARDIOVASCULAR

Cocaine induces dysrhythmias, myocarditis, cardiomyopathy, and acute coronary syndromes.[16] Other vascular complications include aortic rupture and aortic and coronary artery dissection. Even at relatively low doses, cocaine induces vasoconstriction in coronary arteries, contributing to cocaine-induced chest pain.[17] Coronary vasoconstriction is exacerbated by β-adrenergic blockade and antagonized by phentolamine, which suggests mediation through stimulation of α-adrenergic receptors.[18] This effect is further potentiated by cigarette smoking. In addition to promoting vasospasm, cocaine potentiates acute coronary syndrome by increasing atherogenesis through increased platelet aggregation, thrombogenesis, and accelerated atherosclerosis.

The patient most at risk for cocaine-associated acute coronary syndrome is a male between 20 and 40 years old, who is a cigarette smoker and who regularly uses cocaine.[19,20] All routes of cocaine administration are associated with chest pain, acute coronary syndrome, ST-elevation myocardial infarction, and non–ST-elevation myocardial infarction. Atypical chest pain is common.

Acute coronary syndromes and aortic dissection are also reported in association with ephedrine, phenylpropanolamine, and amphetamine use.[21] Mitral and aortic valve abnormalities associated with use of the amphetamine combination phentermine-fenfluramine prompted a voluntary recall of these drugs. Cardiopulmonary toxicity from other amphetamine diet aids has also been reported.

Dysrhythmias induced by cocaine can result from sympathomimetic stimulation, blockade of the sodium channel during depolarization, inhibition of the potassium channel during repolarization, and effects on calcium channel current.[16,22] Sympathomimetic-induced dysrhythmias are tachycardias, such as sinus tachycardia, reentrant supraventricular tachycardia, and atrial fibrillation and flutter. Sodium channel blockade produces a rightward shift of the terminal portion of the QRS complex as seen on the frontal plane ECG leads, a pattern similar to that of cyclic antidepressants.[23] Progressive toxicity may induce a complete right bundle-branch block or a prolonged QRS >120 ms that, when combined with sinus tachycardia, produces a wide-complex tachycardia. Cocaine can induce the ECG appearance of the **Brugada** pattern, although it is not clear whether this is strictly a toxic effect or if the sodium channel–blocking effect of cocaine unmasked an underlying genetic predisposition to the Brugada syndrome.[24]

Potassium channel blockade impairs repolarization, prolonging the QT interval on the ECG.[23] The effects of cocaine on calcium channel current are dose dependent and complex, but at concentrations associated with clinical toxicity, prolongation of both depolarization and repolarization is seen, as well as enhanced dispersion in repolarization.[22] Delayed repolarization and enhanced dispersion promote early afterpotentials that can trigger reentrant dysrhythmias, such as ventricular tachycardia and a variant, torsades de pointes.

Takotsubo syndrome, transient apical ballooning of the left ventricle, has been associated with cocaine use. The physiology is not clearly understood but has been attributed to the effects of a sympathomimetic surge on the myocardium after cocaine use.[25]

CNS

Neurologic syndromes associated with cocaine abuse include seizures, intracranial infarctions, and hemorrhages. Hyperadrenergic tone induces severe transient hypertension, hemorrhage, or focal vasospasm, and, sometimes, exacerbation of underlying abnormalities of cerebral blood vessels. Cerebral vasoconstriction following cocaine administration has been observed using magnetic resonance angiography.[26]

Other CNS manifestations reported after cocaine use include spinal cord infarctions, cerebral vasculitis, and intracranial abscesses. Choreoathetosis and repetitive movements (termed "crack dancing") are associated with cocaine and amphetamine intoxication and appear related to dopamine dysregulation. Acute dystonic reactions following cocaine use and withdrawal are also observed. Unilateral blindness has been reported secondary to central retinal artery occlusion, and bilateral blindness can be caused by diffuse vasospasm. A syndrome of corneal abrasions and ulcerations secondary to smoke and irritation is known as "crack eye." Keratitis caused by methamphetamine use has been described as well.

"Cocaine washout" is a syndrome that may occur in patients after a prolonged crack binge and results from depletion of neurotransmitters. Patients have a depressed level of consciousness but can be aroused to normal with stimulation. Resolution of lethargy can take up to 24 hours.

Amphetamine, phenylpropanolamine, and ephedrine use are associated with intracranial hemorrhage, infarction, encephalopathy, and seizures.[4,9] Amphetamines can also cause a CNS vasculitis resulting in focal neurologic deficits. A profound paranoid psychosis can be seen with long-term amphetamine abuse and withdrawal.

PULMONARY

Respiratory effects of cocaine use are more common in patients who smoke crack cocaine. Pulmonary hemorrhage, barotrauma, pneumonitis, asthma, and pulmonary edema have been observed.[27] Pneumomediastinum, pneumothorax, and pneumopericardium result from barotrauma secondary to performance of the Valsalva maneuver after inhalation or nasal insufflation in an attempt to enhance drug effect. Pneumonitis, asthma, and bronchiolitis may be an immunologic phenomenon or may result from numerous adulterants in illicit preparations.

Inhalation of crack cocaine is associated with new-onset bronchospasm, likely the result of local airway irritation.[28,29] Acute lung injury associated with cocaine use is multifactorial and may be catecholamine-mediated because a similar syndrome has been described in patients with adrenergic excess from pheochromocytoma and intracranial hemorrhage. Upper airway irritation and a "thermal" uvulitis can occur in patients smoking crack cocaine.

GI

Cocaine-induced mesenteric vasospasm may produce intestinal ischemia, bowel necrosis, ischemic colitis, and splenic infarctions. In addition, GI ulceration, bleeding, and perforation occur in association with cocaine use. Advanced tooth decay (termed "meth mouth") is common in habitual methamphetamine users. The reasons are presumably multifactorial and are related to poor oral hygiene, persistent dry mouth, consumption of high-carbohydrate carbonated beverages, jaw clenching, and tooth grinding. The belief that contamination with acidic or corrosive substances from the manufacturing process is responsible for this condition is not supported by analysis of illicitly produced methamphetamine.

ENDOCRINE

MDMA users may develop hyponatremia due to drug-induced secretion of vasopressin in the setting of overhydration with water. There is

limited evidence suggesting that synthetic cathinones may cause similar effects, and they have been associated with several deaths.

RENAL

Cocaine or amphetamine use may cause traumatic and nontraumatic rhabdomyolysis.[30,31] In cocaine-induced rhabdomyolysis, up to one-third of patients develop acute kidney failure.[31] Risk factors for rhabdomyolysis include altered mental status, seizures, dysrhythmias, and hemodynamic instability. Stimulants may further exacerbate renal injury by producing hyperthermia, vasoconstriction, hypotension, and hypovolemia. Renal infarction has been described following IV cocaine use.

PREGNANCY

Cocaine is a potent vasoconstrictor that affects uteroplacental blood flow. Cocaine abuse during pregnancy is associated with an increased incidence of spontaneous abortions, abruptio placentae, fetal prematurity, and intrauterine growth retardation.[32,33] Both spontaneous abortions and abruptio placentae appear to occur from placental vasoconstriction and increased uterine contractility, with concomitant maternal hypertension. A breastfed infant can become intoxicated secondary to maternal cocaine use. Methamphetamine abuse during pregnancy has detrimental effects on fetal growth.

DIAGNOSIS

Cocaine or amphetamine intoxication can usually be suspected based on the symptoms and signs of the sympathomimetic toxidrome: agitation, mydriasis, diaphoresis, tachycardia, tachypnea, hypertension, and possibly hyperthermia. Mental status can range from normal to severely agitated and paranoid. Lethargy or coma suggests a postictal state or intracranial hemorrhage. Symptoms such as chest pain, palpitations, dyspnea, headache, or focal neurologic complaints suggest end-organ toxicity. Without a history of cocaine or other stimulant use, it may be difficult to distinguish this presentation from other conditions with catecholamine excess, such as withdrawal from alcohol or sedative-hypnotic drugs (**Table 187-4**). Lactic acidosis may be present following seizures or as a result of vasoconstriction and hypoperfusion. As with all intoxicated patients, consider occult trauma and hypoglycemia.

TABLE 187-4 Differential Diagnosis of Cocaine or Amphetamine Toxicity

Toxicologic	Phencyclidine toxicity
	Hallucinogen toxicity
	Anticholinergic toxicity
	Sedative-hypnotic withdrawal
	Serotonin syndrome
	Neuroleptic malignant syndrome
Intracranial	Ischemic stoke
	Intracranial hemorrhage
	Traumatic brain injury
	Encephalitis or meningitis
	Cerebral vasculitis
	Neoplasm
Endocrine	Hypoglycemia
	Pheochromocytoma
	Hyponatremia
	Thyrotoxicosis
Psychiatric	Acute psychosis
Other	Heat stroke
	Hypoxia

Concomitant use of alcohol and other drugs frequently alters the clinical presentation. For example, a patient using both opioids and stimulants may present with a decreased level of consciousness and few if any other diagnostic features of catecholamine excess. When the opioid effects are reversed with naloxone, the stimulant effects are unmasked, often with impressive findings.

LABORATORY EVALUATION

Laboratory studies and imaging are directed by clinical findings. Obtain a chemistry panel and creatine kinase level in a patient with agitation or elevated temperature to evaluate for possible metabolic acidosis, renal failure, or rhabdomyolysis. Hyponatremia, often with altered mental status, occasionally occurs after the use of hallucinogenic amphetamines such as MDMA or mescaline. For chest pain, obtain an ECG and serum levels of cardiac biomarkers. If the patient is hyperthermic (>104°F or 40°C), coagulation and liver function studies should be performed. Altered mental status typically requires CT of the head.

Urine drug screens to confirm cocaine or amphetamine use are readily available, but interpretation requires knowledge of pharmacology and the testing method.[34] Most of the rapid urine screening tests for cocaine are highly specific for cocaine metabolites (such as benzoylecgonine) and exhibit little cross-reactivity to the parent compound or other metabolites. Commonly available urine drug screens for the cocaine metabolite benzoylecgonine are sensitive at very low levels, and cocaine use within the past 24 to 72 hours is typically detected, depending on dose. Cocaine can be detected in habitual users by more sensitive techniques (radioimmunoassay, gas chromatography) for up to 2 weeks after last use of the drug.

Most urine amphetamine screens detect amphetamine, dextroamphetamine, methamphetamine, and, with decreasing sensitivity, 3,4-methylenedioxyethamphetamine, MDMA, and 3,4-methylenedioxyamphetamine. Synthetic cathinones may be detected, but results are too variable to be clinically useful due to variation in both laboratory analyzers as well as "bath salt" preparations. Commercial urine drug screens for amphetamine are sensitive to 1000 nanograms/mL, and amphetamine use within the past 48 hours is usually detected. However, interfering substances and other phenylethylamine compounds cross-react with amphetamine immunoassays, which limits their specificity. For example, excessive use of certain nasal inhalers that contain cross-reacting stimulant-class drugs may lead to positive results on immunoassays. Patients who take the nonprescription decongestants pseudoephedrine or phenylephrine or use prescription stimulants for attention-deficit disorder or narcolepsy can have a positive urine amphetamine result. Many drugs, such as bupropion, chlorpromazine, promethazine, thioridazine, trazodone, desipramine, and doxepin, have metabolites that react with the amphetamine immunoassay. Other drugs, such as labetalol, isometheptene, ranitidine, ritodrine, and trimethobenzamide, possess enough structural similarity to the basic amphetamine form to react with the immunoassay as well.

TREATMENT

Follow the standard protocol for poisoned patients (see chapter 176, "General Management of Poisoned Patients"). Establish IV access, and provide oxygen administration for hypoxia. The cornerstone of therapy is monitoring of vital signs, treatment of medical complications, supportive care, and adequate sedation to prevent self-harm and allow for testing and imaging (**Table 187-5**).[35] Treat hyperthermia with cool-mist spray and fans or cooling blankets (see chapter 210, "Heat Emergencies").[36] Aggressive IV hydration is the primary treatment for rhabdomyolysis (see chapter 89, "Rhabdomyolysis"). Seizures are initially treated with benzodiazepines, and status epilepticus requires aggressive treatment (see chapter 171, "Seizures"). Obtain head CT to identify intracranial pathology as the cause of seizures.

SEDATION

Benzodiazepines are the cornerstone of therapy for sedation. Lorazepam, 2 milligrams IV, or diazepam, 5 milligrams IV, can be administered and titrated with repeated doses to decrease the excess autonomic

TABLE 187-5 Management of Sympathomimetic Toxicity

Vital sign monitoring
Supportive care and prevent self-harm
Benzodiazepines for sedation
Aggressive cooling for hyperthermia
IV fluid for rhabdomyolysis
Anticonvulsants for seizures
Evaluate chest pain and treat ACS
Phentolamine for uncontrolled hypertension
Targeted therapy for dysrhythmias
IV lipid emulsion for refractory dysrhythmias

Abbreviation: ACS = acute coronary syndrome.

and neural stimulation. Antipsychotics such as haloperidol, droperidol, and chlorpromazine are not first-line therapy because they may lower the seizure threshold, contribute to hyperthermia, and increase QT prolongation and the risk of ventricular dysrhythmias. However, if benzodiazepines are ineffective, antipsychotics are often necessary to control agitation and destructive and dangerous behavior.

CHEST PAIN

Chest pain characteristics in cocaine users are no different than in patients with atherosclerotic heart disease. Question chest pain patients about the use of cocaine.[37] Cocaine users with suspected acute coronary syndrome are managed with aspirin and nitroglycerin (see chapter 49, "Acute Coronary Syndromes").[37,38] Additional therapy is guided by the ECG. **Oral or intravenous calcium channel blockers (diltiazem, 20 milligrams IV) are recommended in patients with ST-segment elevation or depression.**[37]

Use of β-adrenergic antagonists ("β-blockers") in the management of cocaine-associated myocardial ischemia or infarction is controversial.[37-39] Case reports suggested that β-blockers may create the potential for unopposed stimulation of α-adrenergic receptors that worsens coronary and peripheral vasoconstriction, hypertension, and possibly ischemia.[37,38] Conversely, large observational studies of patients with cocaine-related chest pain did not find an increased incidence of adverse effects in patients who received a β-blocker in the ED.[40-42] Labetalol (a mixed α-adrenergic and β-adrenergic antagonist) has been suggested for use by some in cocaine-associated chest pain because it does not appear to induce coronary artery vasoconstriction, even though β-adrenergic blocking activity predominates over α-adrenergic blocking activity. **The 2014 AHA/ACC Guidelines recommend that β-blockers not be administered to patients with signs of acute intoxication unless they are also receiving coronary artery vasodilator therapy (e.g., IV nitroglycerin).**[38]

Emergent coronary angiography is recommended if ST segments remain elevated despite nitroglycerin and calcium channel blocker therapy.[37] Fibrinolytic therapy may be used for cocaine-induced ST segment elevation myocardial infarction, if no other contraindications exist and coronary angiography is not available.[37]

DYSRHYTHMIAS

Target antidysrhythmic therapy according to the probable pathogenesis of the dysrhythmia.[43] Sinus tachycardia is generally responsive to sedation, cooling, and intravenous fluid rehydration, and specific β-blocker therapy is rarely necessary. Use a calcium channel blocker to treat reentrant supraventricular tachycardia as well as to control the ventricular rate in atrial fibrillation or flutter.

A wide-complex tachycardia with clinical evidence of cocaine toxicity can be assumed to be due to sodium channel blockage and treated with sodium bicarbonate, a 1 to 2 mEq/L IV bolus followed by either intermittent boluses or an infusion.[43,44] The frequency of boluses or the rate of infusion is guided by clinical response and serum pH; do not alkalinize the serum above a pH of 7.55 with sodium bicarbonate. Lidocaine in standard doses can be used in refractory cases of wide-complex tachycardia; theory and animal models suggest harmful interaction, but clinical experience has documented safety.[43]

Magnesium, lidocaine, and overdrive pacing have all been reported to be successful in cocaine-induced torsades de pointes. It seems reasonable, although unproven, to administer magnesium in patients with a prolonged corrected QT interval to prevent torsades from occurring.

In cases of severe cocaine toxicity, with persistent cardiovascular instability and/or refractory wide-complex tachycardias, intravenous lipid emulsion therapy has been reported to rapidly terminate the dysrhythmia and stabilize the cardiovascular system,[45,46] although failure has been reported also.[47] No recommendations on dose can be made from such limited clinical experience, so it seems reasonable to use the standard IV 20% lipid protocol developed for local anesthetic systemic toxicity: 100 mL (1.5 mL/kg) IV bolus over 2 to 3 minutes followed by an infusion of 18 mL (0.25 mL/kg) per minute until clinical improvement is seen or a total dose of 10 mL/kg has been given.

HYPERTENSION

Treat severe hypertension not responding to sedation with a sodium nitroprusside infusion (initial dose, 0.3 microgram/kg per minute) or phentolamine (initial dose, 2.5 to 5.0 milligrams IV). Blood pressure may be lowered aggressively if the patient does not have chronic hypertension. Treatment for refractory hypertension is similar to that for hypertensive emergencies except that β-adrenergic blockers are not used (see chapter 57, "Systemic Hypertension").

BODY STUFFERS AND BODY PACKERS

Cocaine and other drugs can be internally concealed.[48] Patients who swallow cocaine following police pursuit to conceal the evidence are termed "body stuffers." The swallowed packets are often poorly wrapped and can leak or perforate.[49] "Body packers" swallow a large number of well-sealed packets in order to smuggle drugs across international borders. Both methods can result in severe toxicity and death.[35,49]

Management of an asymptomatic cocaine body packer brought in by police or customs officials is a treatment dilemma.[48] CT is the best imaging modality to identify the packets.[50] If the patient shows no signs of toxicity, give single-dose activated charcoal and institute whole-bowel irrigation with polyethylene glycol electrolyte solution to gently hasten packet elimination.[35,51] Continue whole-bowel irrigation until passage of the last packet, and then obtain a confirmatory CT to ensure that all containers have passed. For symptomatic patients, provide sedation and symptomatic care, and obtain immediate surgical consultation for operative removal of the packets. Do not consult for endoscopy or colonoscopy because endoscopic manipulation may rupture the packets.[48,49]

DRUG INTERACTIONS

Because cocaine is metabolized by plasma cholinesterase, co-administration of drugs such as succinylcholine and mivacurium that are also metabolized by plasma cholinesterase may lead to unpredictable rates of metabolism, leading to foreshortened or prolonged effects.

Both lidocaine and cocaine are local anesthetics and act as sodium channel antagonists. It is thought that the neurotoxic effects of both occur by similar mechanisms. Despite theoretical risk in treating cocaine-induced dysrhythmias with lidocaine, it has been used safely in patients with cocaine-associated myocardial infarction.

Monoamine oxidase inhibitors block the degradation of intracellular catecholamines, increasing adrenergic neurotransmitters in the presynaptic terminals. Amphetamines are indirect-acting sympathomimetic amines that induce the release of stored catecholamines and are also weak inhibitors of monoamine oxidase. Thus, patients taking monoamine oxidase inhibitors who subsequently use amphetamines or phenylpropanolamine (and to a lesser extent cocaine) may precipitate an acute syndrome of excessive catecholamine release that results in severe hypertension, tachycardia, hyperthermia, agitation, tremors, and possible severe neurotoxicity.

WITHDRAWAL

Cocaine withdrawal is characterized by irritability, paranoid ideation, and depression.[52] Although symptoms during cocaine withdrawal are generally milder than those during amphetamine withdrawal, psychological addiction may be particularly strong. Methamphetamine withdrawal is characterized by drowsiness, lethargy, hunger, tremor, and chills. There is considerable potential for long-term depression and suicide. Symptoms of withdrawal are strongest during the first 48 hours, but milder symptoms can last up to 2 weeks. Although pharmacologic adjuncts, such as antidepressants, adrenergic antagonists, or dopaminergic agents, are sometimes used during cocaine or amphetamine withdrawal, there are no data confirming efficacy.[52,53]

DISPOSITION AND FOLLOW-UP

Disposition depends on initial patient presentation, response to therapy, the nature of the stimulant involved, and expected duration of effect. Patients demonstrating resolution of toxicity and clear sensorium in the absence of focal complaints or end-organ damage should be advised of the medical risks of drug abuse and referred to appropriate detoxification, counseling, and social support services.

Patients who present with adrenergic excess following recent cocaine use and who respond to initial sedation may be expected to improve completely during a period of observation in the ED because of the relatively limited duration of cocaine effects. In contrast, amphetamines have a longer duration of effect and produce prolonged toxicity, which necessitates observation or hospitalization.

CHAPTER 188

Hallucinogens

Katherine M. Prybys
Karen N. Hansen

INTRODUCTION AND EPIDEMIOLOGY

The term *hallucinogen* is misleading. Hallucinogenic compounds rarely produce true hallucinations—but rather, users experience profound distortions in body image, sensory perception, and time perception, in addition to rapid, intense alterations in mood, increased intensity of any emotions, and heightened suggestibility. *Hallucinogen* is sometimes used interchangeably with the term *psychedelic*.

Hallucinogens are widely perceived as safe by the public. However, these substances can cause dangerous physiologic effects resulting in serious health consequences.[1-3] The identity, purity, and amount of hallucinogenic compound is usually uncertain, and individual response can be unpredictable.

Hallucinogens in current use consist of both natural and synthetic compounds.[4] The proliferation of "designer drugs"—chemical analogs or derivatives of illicit drugs marketed to circumvent existing drug laws—is a growing problem. Manufacturers of designer drugs try to circumvent U.S. federal drug laws by stamping their product with advisories such as "not intended for human consumption" or by identifying the products as plant food, bath salts, or potpourri. Prosecution through the Federal Analog Act, a section of the Controlled Substance Abuse Act, can occur only if the drug is "intended for human consumption." Because of this limitation in federal law, some states have moved to ban the sale of such drugs.

Conditions that mimic hallucinogen intoxication include alcohol or benzodiazepine withdrawal, anticholinergic poisoning, thyrotoxicosis, central nervous system infections, structural brain lesions, acute psychosis, hypoglycemia, and hypoxia.[5] Some prescription and nonprescription medications can cause hallucinations. The identity of street drugs is often misrepresented, and substitutions or adulteration of product is common.[6,7]

Drug-induced psychosis may be difficult to distinguish from primary psychotic disorders.[8,9] A patient with substance-induced psychosis is more likely to have a diagnosis of dependence on any drug, report visual hallucinations, and have a history of parental drug abuse.[9]

GENERAL APPROACH TO TREATMENT

Start by assessing the patient's general medical condition and stabilizing the vital signs. Identify and correct hypoxia and hypoglycemia. Obtain a core temperature to recognize hyperthermia. Obtain serum chemistries and if the patient is agitated, obtain creatine phosphokinase to identify rhabdomyolysis. Obtain an electrocardiogram to identify QT interval prolongation.

Gastric decontamination is not needed in most cases because most hallucinogens are rapidly absorbed and because most patients with adverse effects do not present until several hours after the drug was taken. However, consider administration of oral activated charcoal for ingestions occurring within the previous hour or longer when gastric emptying is delayed, such as with anticholinergic poisonings (e.g., nutmeg ingestion).

Reassurance and a calm, supportive environment can often sufficiently soothe the agitated patient. Pharmacologic sedation and possibly physical restraints may be necessary in order to ensure the safety of the patient and the ED staff and to facilitate evaluation and treatment. **Benzodiazepines** are the preferred agents for the treatment of hallucinogenic-induced agitation and delirium because they possess no significant drug interactions, have no dystonic or anticholinergic adverse effects, do not prolong the QT interval or promote arrhythmias, and are reversible by flumazenil if over sedation occurs. Start with diazepam 5 to 10 milligrams PO or IV, or lorazepam 1 to 2 milligrams PO, IM, or IV. Give repeated doses as needed, and monitor blood pressure and respiration. Tachycardia and hypertension often respond to sedation with benzodiazepines alone. Severe hypertension can be treated with IV nitroprusside. Correct electrolyte abnormalities and treat dehydration and hypovolemia with normal saline infusion. Treat symptomatic arrhythmias using standard antiarrhythmic protocols. Active cooling measures should be initiated for patients with significant hyperthermia. Treatment of severe agitation, hyperthermia, or seizures may require neuromuscular paralysis and endotracheal intubation. Seizures are treated with benzodiazepines or propofol. Patients with rhabdomyolysis require aggressive IV hydration to maintain urine output.

DISPOSITION AND FOLLOW-UP

Compared with other abused psychoactive agents, hallucinogens have some of the largest acute safety ratios when lethal doses are measured against the doses customarily used to produce the desired hallucinogenic effects.[10] Most patients seen in the ED due to adverse reactions from hallucinogen use can be discharged into the custody of family or friends if they are lucid and in medically stable condition after a period of observation. Patients with persistent psychotic symptoms or comorbid psychiatric illnesses require psychiatric evaluation.

COMMON HALLUCINOGENS

Common hallucinogens are listed in **Table 188-1**.

LYSERGIC ACID DIETHYLAMIDE

Lysergic acid diethylamide is a potent psychoactive drug. As little as 25 micrograms produces psychedelic effects. The hallucinogenic effects are believed to be mediated through agonism at the serotonin type 2 ($5\text{-}HT_2$) receptor.[11,12]

Lysergic acid diethylamide is a colorless, tasteless, odorless, water-soluble substance that is sold in various forms, but most commonly as small squares of dried blotter paper printed with colorful graphics and

TABLE 188-1 Common Hallucinogens

Drug	Typical Hallucinogenic Dose	Duration of Action	Clinical Features	Complications	Specific Treatment
Lysergic acid diethylamide	20–80 micrograms	8–12 h	Mydriasis Tachycardia Anxiety Muscle tension	Coma Hyperthermia Coagulopathy Persistent psychosis Hallucinogen persisting perception disorder	Reassurance Benzodiazepines
Psilocybin	5–100 mushrooms 4–6 milligrams of psilocybin	4–6 h	Mydriasis Tachycardia Muscle tension Nausea and vomiting	Seizures (rare) Hyperthermia (rare)	Reassurance Hydration Benzodiazepines
Mescaline	3–12 "buttons" 200–500 milligrams of mescaline	6–12 h	Mydriasis Abdominal pain Nausea/vomiting Dizziness Nystagmus Ataxia	Rare	Supportive Benzodiazepines
Methylenedioxymethamphetamine ("Ecstasy")	50–200 milligrams	4–6 h	Mydriasis Bruxism Jaw tension Ataxia Dry mouth Nausea	Hyponatremia Hypertension Seizures Hyperthermia Arrhythmias Rhabdomyolysis	Benzodiazepines Hydration Active cooling Dantrolene Specific serotonin antagonists
Synthetic cathinone derivatives ("bath salts")	50–300 milligrams of mephedrone	2–4 h	Agitation Tachycardia Hypertension Diaphoresis Mydriasis	Paranoia Panic reactions Hyperthermia Seizures Hyponatremia Rhabdomyolysis	Benzodiazepines Hydration Active cooling
Phencyclidine ("angel dust")	1–9 milligrams	4–6 h	Small or midsized pupils Nystagmus Muscle rigidity Hypersalivation Agitation Catatonia	Coma Seizures Hyperthermia Rhabdomyolysis Hypertension Hypoglycemia	Benzodiazepines Hydration Active cooling
Marijuana (cannabis)	5–15 milligrams of tetrahydrocannabinol	2–4 h	Tachycardia Conjunctival injection	Acute psychosis (rare) Panic reactions (rare)	Supportive Benzodiazepines
Synthetic cannabinoids ("K2," "Spice")	2–5 milligrams of JWH-018	3–4 h	Tachycardia Conjunctival injection	Acute psychosis Panic reactions Seizures (rare) Arrhythmias (rare)	Supportive Benzodiazepines
Bromo-benzodifuranyl-isopropylamine (Bromo-DragonFLY)	200–800 micrograms	10–14 h	Agitation Hallucinations	Seizures Vasoconstrictor with necrosis and gangrene	Supportive Benzodiazepines

cartoons that have been perforated and soaked in liquid lysergic acid diethylamide solution. Each square typically delivers a dose of 20 to 80 micrograms. Other forms include "microdots" (tiny tablets), "windowpane" (gelatin sheets), impregnated sugar cubes or candy, and small bottles of "breath drops" (the drug in solution).

The psychedelic effects begin within 30 minutes of ingestion, peak within 4 hours, and last between 8 to 12 hours.[13,14] Sympathomimetic stimulation with mydriasis and elevations of pulse, blood pressure, and temperature usually precede the psychedelic effects.[13,14] Marked facial flushing, mild gastric distress, piloerection, increased muscle tension, and hyperreflexia may occur. In massive overdoses, coagulopathy, hyperthermia, seizure, coma, and respiratory arrest have been reported.[15]

The psychedelic effects of lysergic acid diethylamide depend on the user's prevailing mood, expectations, and surrounding environment. Effects may be perceived as pleasurable or horrifying. Profound distortions in perception of sensory stimuli, time, emotions, and memories occur and may cause users to experience paranoia, depression, extreme panic, or an acute psychotic reaction known as a *dysphoric reaction* or "bad trip." Dangerous and impulsive behavior is possible, resulting in serious physical trauma or suicide. Prolonged and sometimes permanent psychosis, known as "flashbacks" or "hallucinogen persisting perception disorder," can result.[16]

The typical user is usually conscious, alert, and able to provide history of the drug ingestion.[13] Diagnosis is based on history of use, the presence

of sympathomimetic signs, and reported psychedelic effects. Lysergic acid diethylamide can be detected in the urine for several days after ingestion using specific radioimmunoassay and enzyme immunoassay techniques. Reassurance and observation in a quiet, safe environment are generally the only interventions required to manage a dysphoric reaction. Oral or parenteral benzodiazepines are indicated for patients with extreme agitation or signs of excessive sympathomimetic stimulation. Patients with paranoid or psychotic symptoms lasting longer than 8 to 12 hours may require hospital admission. Medical complications due to massive overdose are rare, and recovery is usually rapid and requires only supportive care.[13-15]

PSILOCYBIN

Psilocybin is a naturally occurring hallucinogenic compound found in at least six genera of mushrooms, but most notably the *Psilocybe* genus. Psilocybin is an indolalkylamine that is metabolized to the pharmacologically active compound psilocin. Both psilocybin and psilocin are believed to act as serotonin type 2 receptor agonists similar to lysergic acid diethylamide.

Psilocybin-containing mushrooms grow naturally in the southern United States and Europe but can also be grown from kits sold over the Internet.[17] Most species of psilocybin-containing mushrooms turn bluish when bruised, but this is not a definitive method of identification or determination of potency. Psilocybin-containing mushrooms may be dried or cooked without losing potency. Hallucinogenic mushrooms sold on the street are often nonpsychoactive mushrooms that have been adulterated with lysergic acid diethylamide or phencyclidine.[6] Because of the variation in mushroom size and concentration of psychoactive compounds, there is little correlation between the number of mushrooms ingested and the hallucinogenic effects. A user may ingest as few as five or as many as 100 mushrooms for a single "dose."

Hallucinogenic effects begin within 30 minutes of ingestion and last 4 to 6 hours.[18,19] The hallucinogenic effects are similar to, although less powerful than, those produced by lysergic acid diethylamide. Other common effects include mydriasis, tachycardia, nausea, and vomiting. Serious medical complications are extremely rare but include seizures, hyperthermia, rhabdomyolysis, and renal failure.[20] Mistaken identity and ingestion of highly toxic mushrooms is possible and can lead to serious outcomes.[21]

Management is supportive. There is no routinely available screening test for psilocybin or psilocin in the urine. If the patient's symptoms are not consistent with psilocybin ingestion, consider the possibility that a toxic mushroom (see Chapter 219, Mushroom Poisoning) or other psychoactive substances were ingested.[21]

MESCALINE AND PEYOTE

Mescaline is found in many cacti, most notably the Mexican Peyote cactus (*Lophophora williamsii*) and the Peruvian San Pedro cactus (*Trichocereus pachanoi*). Peyote is used in Native American religious ceremonies, and its legal use is restricted to the Native American Church. Mescaline is a phenylethylamine, structurally related to amphetamines, making it chemically distinct from lysergic acid diethylamide.[22] Mescaline is believed to act as a serotonin type 2 receptor agonist, but is much less potent than lysergic acid diethylamide.

Peyote is most commonly sold as raw cactus or "buttons," 2- to 3-cm discs sliced off of the top of the cactus. Each button contains approximately 45 milligrams of mescaline. A typical hallucinogenic dose is 200 to 500 milligrams. Pills or capsules sold on the street as "mescaline" are unlikely to be genuine and may instead contain lysergic acid diethylamide or phencyclidine.[6]

Peyote is bitter tasting and causes uncomfortable physical side effects within an hour of ingestion—including nausea, vomiting, abdominal discomfort, diaphoresis, dizziness, nystagmus, ataxia, and headache—that generally resolve after about 2 hours. Adrenergic stimulation causes mydriasis and mild elevations in pulse, blood pressure, and temperature. Hallucinogenic effects begin several hours after ingestion and persist for 6 to 12 hours. Significant morbidity or mortality caused by the physiologic effects of mescaline has not been observed, but death can result from aberrant behavior while under the influence of the drug.[23] Mescaline-intoxicated patients are managed supportively. Routine urine drug screens do not detect mescaline.

HALLUCINOGENIC AMPHETAMINES

More than 50 "designer" amphetamines have been created for their hallucinogenic properties. Best known is **methylenedioxymethamphetamine**, a synthetic phenylethylamine derivative structurally related to both amphetamines and mescaline and commonly known by the street name "**Ecstasy.**" Other designer amphetamines include methylenedioxyamphetamine and methylenedioxyethamphetamine ("**Eve**"). Methylenedioxymethamphetamine is known for both its psychedelic properties and unique effects on mood and intimacy, which has led to its reputation as a "love drug" popular in dance clubs.[24] Methylenedioxymethamphetamine has complex effects, interacting with dopamine, norepinephrine, acetylcholine, and β_2-adrenergic and serotonin type 2A receptors, and affecting the release of several hormones, including prolactin, oxytocin, adrenocorticotrophic hormone, dehydroepiandrosterone, and antidiuretic hormone.[25]

Methylenedioxymethamphetamine is usually ingested as tablets in doses of 50 to 200 milligrams. The drug is colorless and tasteless—properties lending to its use as a date-rape drug.[26] Symptoms occur within 30 minutes of ingestion and last about 4 to 6 hours. These include feelings of euphoria, inner peace, enhanced sociability, verbosity, and heightened sexual interest. The drug rarely causes actual hallucinations but can produce sensory effects such as alterations in the intensity of colors or sensation of textures. Other common effects include mydriasis, tachycardia, and elevated blood pressure, as well as nausea, jaw tension, bruxism, dry mouth, muscle aches, and ataxia. Current urinary amphetamine immunoassays incorporate a specific monoclonal antibody for methylenedioxymethamphetamine and should routinely detect this drug.

Methylenedioxymethamphetamine and related amphetamines can produce serious complications and death.[27-30] As with other amphetamines, large-quantity overdoses can cause severe hypertension, intracranial hemorrhage, and ischemia in the heart or brain.[27] Fatal arrhythmias and sudden cardiac death have been reported, both with and without underlying cardiac disease.[27,28] The most frequently cited causes of death are hyperthermia and hyponatremia.[31-34] A syndrome of methylenedioxymethamphetamine toxicity manifested by hyperthermia, seizures, disseminated intravascular coagulation, rhabdomyolysis, and hepatotoxicity has been described.[35] This pattern shares many features of the serotonin syndrome, and **combining methylenedioxymethamphetamine with selective serotonin reuptake inhibitors (see Chapter 178, Atypical and Serotonergic Antidepressants) or monoamine oxidase inhibitors (see Chapter 179, Monoamine Oxidase Inhibitors) can precipitate serotonin syndrome**.[36]

Hyponatremia is predominantly due to excessive water consumption and inappropriate antidiuretic hormone secretion.[31,32] Excessive water drinking from thirst can occur if the drug is taken at hot and crowded club venues, with vigorous dancing and profuse sweating.[31,33] Persistent neurotoxic effects are possible from chronic methylenedioxymethamphetamine use. Neuropsychiatric studies of habitual users demonstrate long-lasting cognitive impairment and mood dysfunction, including memory impairment, diminished learning ability, and depression.[37]

Gastrointestinal decontamination with activated charcoal may be useful if the drug was ingested within 60 minutes of ED arrival.[38] Hypertension and tachycardia often respond to benzodiazepines. Severe hypertension is treated with IV phentolamine or nitroprusside. Rapid IV titration with high doses of benzodiazepines or propofol may be required to control symptoms in patients with refractory agitation or seizures. Arrhythmias are managed with standard therapy.

Check serum electrolyte concentrations and anticipate and treat abnormalities, especially hyponatremia (see Chapter 17, Fluids and Electrolytes). Hyperthermia is managed with cooling measures and fluid resuscitation.[32,33] Patients with temperatures exceeding 40°C (104°F) have increased morbidity and mortality, so rapid cooling is important.[39] Although there is no evidence from controlled studies, expert opinion and case reports support the use of dantrolene when methylenedioxymethamphetamine-induced hyperthermia is refractory

to sedation and active cooling.[38,40-42] Specific serotonin antagonists, such as methysergide or cyproheptadine, have been suggested for patients with features of the serotonin syndrome following methylenedioxymethamphetamine use.[43]

SYNTHETIC CATHINONE DERIVATIVES

In the fall of 2010, U.S. Poison Control Centers began receiving calls regarding synthetic cathinone derivatives, and use has increased dramatically since then.[44,45] Cathinone is a naturally occurring alkaloid extracted from the leaves of the *Catha edulis* plant (khat) native to areas of Africa and the Middle East. Cathinone and synthetic derivatives, including mephedrone, methylenedioxypyrovalerone, and methylone, are chemically similar to amphetamines. These drugs likely stimulate the release and inhibit the uptake of biogenic amines such as norepinephrine, dopamine, and serotonin.

Synthetic cathinone derivatives are abused by individuals seeking a "legal" high with stimulatory effects similar to those of cocaine or methylenedioxymethamphetamine. These drugs are often labeled as "**bath salts**" or "**plant food**," with fanciful names such as "**Vanilla Sky**" or "**Ivory Wave**." They are often labeled as "not for human consumption" in an attempt to avoid federal regulations.

Synthetic cathinones can be nasally insufflated ("snorted"), ingested, or injected. Duration of effects depends on method of use—1 to 2 hours with nasal insufflation and up to 4 hours if ingested.[46] Approximately 20% of users report adverse effects including sweating, palpitations, nausea, headache, and dizziness.[46] Agitation is common, and paranoia, panic attacks, and aggression—including violent behavior—have been reported. Sympathomimetic toxicity, with dilated pupils, tachycardia, and hypertension, is common. Hyperthermia, seizures, hyponatremia, rhabdomyolysis, and deaths have been reported.[46-50] Synthetic cathinones are not detected on routine urine toxicology screens.

Treatment is primarily supportive, including cardiovascular monitoring; benzodiazepines as needed for agitation, sympathomimetic effects, or seizures; and cooling for hyperthermia. Admission to a monitored or intensive care unit setting is appropriate for patients with persistent symptoms.

In September 2011 the U.S. Drug Enforcement Administration issued an emergency order to place three synthetic cathinones (mephedrone, methylenedioxypyrovalerone, and methylone) temporarily into Schedule 1 under the Controlled Substances Act, making the manufacture, sale, or possession of these agents illegal.[51]

PHENCYCLIDINE

Phencyclidine is a synthetic piperidine derivative, structurally related to ketamine. Phencyclidine does not fit easily into a single classification, combining features of hallucinogens, depressants, and stimulants.[52] Unlike classic hallucinogens, phencyclidine causes a clouding of the sensorium rather than heightened sensory awareness. The primary pharmacologic action is blockade of *N*-methyl-D-aspartate receptor channels. At high concentrations, phencyclidine also interacts with other receptors and channels, including the opioid, acetylcholine receptor and voltage-gated electrolyte channels, and exhibits sympathomimetic effects by blocking reuptake of norepinephrine and dopamine.

Phencyclidine is easily and inexpensively synthesized. Powdered ("**angel dust**") or liquid ("**dippers**") drug is often combined with tobacco, marijuana, or other leafy materials and smoked. Phencyclidine can also be ingested orally, snorted, or intravenously injected.[53] Phencyclidine may be unknowingly ingested, because it is often sold as another drug or used to adulterate another illicit drug product.[17] The onset of action depends on the mode of administration. With smoking the onset is about 5 minutes and effects generally last 4 to 6 hours. With large doses, effects can persist for days due to its lipid solubility and accumulation in fat stores.[54,55]

Patients may experience CNS stimulation or depression, with clinical presentations ranging from physically violent to catatonic or comatose states.[53,56] A combination of cholinergic, anticholinergic, and sympathomimetic effects causes a confusing clinical toxidrome. Phencyclidine is often coadministered with other drugs such as crack cocaine ("**beam me up**"), marijuana ("**crystal supergrass**"), or ethanol, which also complicates the clinical picture.[54] The most common findings in phencyclidine-intoxicated patients are nystagmus and hypertension (generally mild), each occurring in almost 60% of cases.[54] Feelings of detachment (dissociation) from the environment and self may give the user feelings of strength, power, and invulnerability. Violent actions, agitation, bizarre and unpredictable behavior, and hallucinations or delusions are frequent. Diaphoresis, tachycardia, muscle rigidity, dystonic reactions, ataxia, and a decreased response to painful stimuli can occur. About 10% of patients are described as comatose.[55] Pupil size is variable, but widely dilated pupils are uncommon.[54]

Medical complications from phencyclidine toxicity are frequent.[52,56,57] Seizures occur in about 3% of patients, and rhabdomyolysis, occasionally producing acute renal failure, is reported in up to 70%.[55] Hypoglycemia, hypertension causing intracerebral hemorrhage, hyperthermia causing hepatic necrosis, and multiorgan failure can occur.[54,55,57,58] Violent behavior can result in self-injury.

Evaluate patients with suspected phencyclidine toxicity for occult injury, hypoglycemia, and rhabdomyolysis.[52,53,56] Phencyclidine can be detected by commercially available urine drug screens up to 8 days after single use and up to several weeks after long-term use.[59] Cough and cold medications (dextromethorphan, diphenhydramine, and doxylamine), analgesics (ibuprofen, meperidine, and tramadol), and psychotropics (imipramine, mesoridazine, thioridazine, and venlafaxine) cross-react with the drug screen and produce false-positive results.

Sedation and physical restraints are frequently required to control violent and aggressive behavior. Parenteral benzodiazepines are preferable to physical restraints because fighting against restraints may contribute to rhabdomyolysis.

Treatment is generally supportive. Treat seizures with benzodiazepines. Status epilepticus or seizures refractory to benzodiazepines may require intubation and treatment with propofol or barbiturates. Treat hyperthermia with active cooling measures. Hypertension usually responds to sedation, but severe hypertension can be treated with nitroprusside. Rhabdomyolysis is treated with aggressive hydration and close monitoring of urine output.

Patients exhibiting only minor clinical features of phencyclidine intoxication and no medical complications can be discharged when behavior normalizes.[52,53,55,56]

MARIJUANA OR CANNABIS

Marijuana or cannabis consists of the dried leaves and flowers of the hemp plant *Cannabis sativa*. **Hashish** is prepared from the dried resin from the flower tops of this plant. The psychoactive ingredient in marijuana is tetrahydrocannabinol.[60]

Marijuana is most often smoked[61] but can also be ingested. Symptoms persist for 2 to 4 hours after smoking, or longer if ingested. Clinical effects include drowsiness, euphoria, heightened sensory awareness, paranoia, and distortions of time and space. Hallucinations do not usually occur at usual doses. Common physiologic effects of marijuana are mild tachycardia, injected conjunctiva, bronchodilation, orthostatic hypotension, and impaired motor coordination.[62] Medical complications, such as panic reactions, brief toxic psychoses, pneumomediastinum, and pneumothorax, are rare. Acute cardiac events associated with marijuana use have been reported,[63,64] possibly the result of aging in the population of marijuana users and the increasing availability of medical marijuana.

Marijuana is used for treatment of medical conditions such as glaucoma and chemotherapy-related nausea and to promote weight gain in patients with HIV infection and AIDS.

Chronic cannabis use is associated with psychiatric, respiratory, cardiovascular, and bone effects.[65] Cyclic vomiting syndrome can be due to marijuana use.[66-68] Symptoms are often misdiagnosed as gastroparesis or opiate withdrawal, and cannabis cessation results in symptomatic recovery.

Acute psychiatric symptoms due to marijuana use can generally be managed with reassurance alone, but benzodiazepines can be used for severe symptoms. Standard urine drug screens are unreliable indicators of acute marijuana intoxication. High lipid solubility results in extensive deposition within body fat and slow excretion in the urine. After a single

use, tetrahydrocannabinol is detected by commercially available urine screens for up to 3 days. With long-term use, cannabinoids can be detected up to 30 days or longer after abstinence.[69] Ibuprofen, naproxen, pantoprazole, and efavirenz, a non-nucleoside reverse transcriptase inhibitor used to treat HIV infection, can produce false-positive results on the urine cannabinoid screen.

SYNTHETIC CANNABINOIDS

Synthetically produced cannabinoid-receptor agonists have been created for hallucinogenic use and are generally combined with herbal blends and labeled as "**Spice**" or "**K2**."[47] These products contain a variety of compounds that are active at the cannabinoid receptors but are not structurally related to tetrahydrocannabinol. One of the first synthetic cannabinoids (1-pentyl-1H-indol-3-yl)-1-naphthalenyl-methanone, goes by the term JWH-018 for the initials of J.W. Huffman, who developed this compound to investigate drug-receptor interactions.[70]

Products containing synthetic cannabinoids are sold in shops and on the Internet labeled as "incense" and "not for human consumption." The appeal of such products is driven by the desire for a legal "high" that is not detectable by current urine drug assays.

The product is usually rolled in paper and smoked in a manner similar to marijuana. Effects begin within minutes and may last for several hours, generally disappearing within 4 hours.[47] Most users will not seek or require medical attention, but some have experienced adverse reactions, with anxiety and tachycardia being the most common.[72] Other reported adverse effects include hypertension, diaphoresis, tremulousness, and agitation.[72,73] Synthetic cannabinoids can precipitate psychosis in patients with prior mental illness.[74] Symptoms are usually self-limited and short-lived, and treatment is supportive.

In March 2011 the U.S. Drug Enforcement Administration placed five synthetic cannabinoid compounds (JWH-018, JWH-073, JWH-200, CP-47,497, and cannabicyclohexanol) into Schedule 1, criminalizing their sale or use.[75] These will likely be replaced in the illegal hallucinogen marketplace by other related molecules in this class.

DESIGNER ALKALOIDS

Bromo-benzodifuranyl-isopropylamine, or **Bromo-DragonFLY**, is a phenethylamine hallucinogen.[76] Bromo-DragonFLY stimulates serotonin receptors in the brain, similar to lysergic acid diethylamide. Bromo-DragonFLY was developed as a research chemical to study the relationship between molecular structure and psychedelic activity. The name comes from its chemical structure, two furanyl rings with double bonds and a side amphetamine arm, which gives it the appearance of a dragonfly. In 2005, Bromo-DragonFLY became available in human experimental markets and was soon diverted to hallucinogenic use.

Bromo-DragonFLY is sold as white to pink powder that can be snorted, smoked, or injected. Bromo-DragonFLY may also be sold on blotter paper, similar to lysergic acid diethylamide, which has led to confusion in users mistakenly consuming Bromo-Dragon-FLY instead. The hallucinogenic dose of Bromo-DragonFLY ranges from 200 to 800 micrograms, with the onset of action within 20 to 90 minutes and a duration of hallucinogenic effects up to 10 to 14 hours. Toxicity includes agitation, hallucinations, and tonic-clonic seizures that may be delayed in onset.[77] Bromo-DragonFLY acts as a long-acting vasoconstrictor that can cause necrosis and gangrene several weeks after use. Bromo-DragonFLY has been associated with fatalities in several countries.[78] Two similar compounds, 2C-B-FLY and 3C-B-FLY, are also abused as hallucinogens.

Benzylpiperazine and trifluoromethylphenylpiperazine are synthetic phenylpiperazine analogues used as substitutes for amphetamine-derived designer drugs.[47,79] These two compounds are usually combined and sold as "**Legal X**" in attempt to mimic the effects of methylenedioxymethamphetamine. These drugs are legally available in many countries. Clinical effects include sympathomimetic effects such as palpitations, agitation, anxiety, confusion, dizziness, headache, tremor, mydriasis, insomnia, urinary retention, vomiting, and seizures.[47,80] Deaths have been associated, but in most cases, recovery occurs with supportive care and benzodiazepines.[81]

LESS COMMONLY ABUSED HALLUCINOGENS

Other drugs with hallucinogenic properties (**Table 188-2**) are enjoying increasing popularity because of information disseminated on the Internet that promotes the use of these "natural" psychoactive agents.[47,82]

SALVIA

Salvia divinorum ("**salvia**," "**Sally**," "**magic mint**") is a perennial herb in the mint family.[83] Salvia is sold as seeds, plant cuttings, whole plants,

TABLE 188-2 Less Commonly Abused Hallucinogens

	Typical Route of Use	Onset of Action	Duration of Action	Additional Features of Acute Toxicity
Salvia divinorum: salvinorin A	Smoking of dried leaves Chewed leaves held in SL or buccal location	20–60 s (smoking) 10–20 min (SL or buccal)	20–30 min (smoking) 30–90 min (SL or buccal)	Headache
Toad venom or eggs: bufotoxins	Ingestion of toad venom extract or food made with toad eggs	30–60 min (nausea and vomiting)	1–3 d (untreated)	Abdominal pain, vomiting Sympathomimetic effects Features similar to cardiac glycoside toxicity
Ipomoea species (morning glory): lysergic acid amide	Ingestion of seeds	1–2 h	6–10 h	None
Nutmeg: myristicin	Ingestion of seeds or ground spice	3–6 h	6–24 h	Some features resemble anticholinergic toxicity
Datura species (Jimson weed and angel's trumpet): scopolamine, atropine, and hyoscyamine	Ingestion of seeds Smoking dried plant parts	1–3 h (ingestion) 5 min (smoking)	24–48 h	Anticholinergic effects
Ketamine	Snorting dried powder or smoking of powder admixed with marijuana or tobacco	5–15 min (nasal insufflation) 1–3 min (smoking)	45–60 min (nasal insufflation) 30–45 min (smoking)	Sympathomimetic effects
Dextromethorphan	Ingestion of liquid Nasal insufflation of powder	20–60 min (ingestion)	4–6 h (ingestion)	Nausea, vomiting, and diarrhea

fresh and dried leaves, and liquid extracts purported to contain the active ingredient salvinorin A. Although salvia and salvinorin A are not currently regulated under the U.S. Controlled Substance Act, a number of states have placed controls on the plant and extract. When chewed, the leaf mass and juice are retained within the mouth, and absorption of the active ingredient is rapid, causing clinical effects within 5 to 10 minutes. Dried leaves, as well as extract-enhanced leaves, can be smoked. Smoking pure salvinorin A at a dose of 200 to 500 micrograms results in effects that begin within 30 seconds and last up to 30 minutes. Desired effects include perceptions of bright lights, vivid colors and shapes, body movements, and object distortions.[47,84,85] Adverse effects may include dysphoria, incoordination, dizziness, and slurred speech.[86] Treatment is supportive.

BUFOTOXINS

Bufotoxins (bufotenine and 5-methoxy-dimethyltryptamine) are hallucinogenic tryptamines found in the venom, skin, and eggs of many toads (e.g., *Bufo alvarius*, *Bufo marinus*).[87] Toad venom has also been used as an aphrodisiac ("**love stone**" or "**rock hard**") and in some traditional Chinese medicines (*chan su* and *kyushin*). Venom can be obtained by "milking" the toad's parotid glands and drying the liquid venom to form an extract. 5-Methoxy-dimethyltryptamine is a powerful psychedelic whereas bufotenine has weaker effects. In addition to psychoactive substances, the venom contains cardioactive steroids (bufagins or bufadienolides), catecholamines (epinephrine and norepinephrine) and noncardiac sterols (e.g., cholesterol). Bufagins are **cardioactive steroids** that can cause cardiac toxicity similar to digoxin.[88] Toxicity from toad venom varies considerably depending on the toad species and its geographic location.

Symptoms of toad venom poisoning occur almost immediately. Effects may be restricted to local gastrointestinal irritation, with copious salivation, nausea, vomiting, and abdominal discomfort persisting for hours. Systemic toxicity may develop due to sympathomimetic effects. Cardiac toxicity is similar to acute digoxin poisoning, with hyperkalemia, bradycardia, atrioventricular conduction block, ventricular tachycardia, ventricular fibrillation, and cardiac arrest.[89,90]

Serum digoxin immunoassay often yields a positive result. Bradyarrhythmias are initially treated with atropine and may require pacemaker placement. Antiarrhythmic drugs should be used for ventricular arrhythmias. Digoxin-specific Fab antibody treatment has been effective in animal models and human cases.[91,92]

MORNING GLORY SEEDS AND *IPOMOEA* SPECIES

Morning glory seeds (*Ipomoea violacea*, *Ipomoea tricolor*, and others) contain lysergic acid amide (ergine), a compound closely related to lysergic acid diethylamide. The seeds can be ingested for their hallucinogenic effects; typically several hundred seeds are ingested as one "dose." Physical and psychologic manifestations closely resemble the effects of lysergic acid diethylamide, and patients are managed similarly.

MYRISTICIN

Nutmeg is the dried seed from the tropical *Myristica fragrans* tree. Accidental or intentional ingestion of large amounts of nutmeg can cause delirium with hallucinations.[93] The hallucinogenic properties of nutmeg may be due to the component myristicin, but the mechanism is not well understood. Ingestion of one to three nutmegs or 5 to 15 grams of the ground spice produces psychologic effects that begin 3 to 6 hours later and lasts for 6 to 24 hours. Symptoms include tachycardia, flushing, dry mouth, nausea, and abdominal pain. Signs and symptoms may resemble anticholinergic poisoning, but pupils are usually small or midsized. Management is supportive care.

DATURA SPECIES

Jimson weed (*Datura stramonium*) and **angel's trumpet** (*Datura candida*) are plants that originated in the United States and Mexico but have spread worldwide throughout other areas with warm and temperate climates. All *Datura* species contain the anticholinergic alkaloids atropine, scopolamine, and hyoscyamine. Seeds or other parts of the plant can be ingested or smoked and produce delirium, hallucinations, and seizures along with other classic anticholinergic effects, such as mydriasis, tachycardia, dry mouth and skin, blurred vision, urinary retention, and hyperthermia (see chapter 202, Anticholinergics).[94,95] Gastric emptying is often delayed, and the small, plentiful seeds can become trapped among the gastrointestinal folds after ingestion; thus **gastric decontamination can be an important therapy.** Whole-bowel irrigation is also recommended for patients who have ingested a large number of seeds. Medications with anticholinergic properties, such as phenothiazines, should be avoided. Physostigmine, a reversible acetylcholine esterase antagonist, is effective treatment for severe anticholinergic poisoning.[95]

KETAMINE AND DEXTROMETHORPHAN

Ketamine and dextromethorphan are chemically related to phencyclidine. Ketamine and phencyclidine are described as dissociative drugs because they distort perceptions of sight and sound and produce feelings of detachment from the environment and self.[53,96] Ketamine, known by the street names "**vitamin K**" and "**special K**," can be abused by SC or IM injection, nasal insufflation of the dried powder, or smoking of the dried power admixed with marijuana or tobacco.[97] Ketamine abusers may come to the ED because of anxiety, palpitations, and chest pain.[98]

Dextromethorphan, available in over-the-counter cough-suppressant products, has become popular among adolescents.[99,100] A large quantity must be ingested for the user to experience hallucinogenic effects. Abuse among youths has prompted many states to enact restrictions regarding the age of the buyer and the maximum amount purchasable, and most retailers and pharmacists keep cough medicines containing dextromethorphan behind the counter. **Cold and cough products often contain other ingredients, such as antihistamines and acetaminophen, so investigate for toxic amounts of a co-ingestant in any patient who has ingested hallucinogenic doses of dextromethorphan.** Medical care is primarily supportive.

CHAPTER 189

Salicylates

Rachel Levitan
Frank Lovecchio

INTRODUCTION

The widespread availability of aspirin or acetylsalicylic acid in prescription and over-the-counter preparations can lead to both accidental and intentional toxicity. Morbidity and mortality increase significantly when the condition is not rapidly identified, if there is a delay to starting treatment, or if poisoned patients are not treated aggressively.

In additional to aspirin oral preparations, numerous forms of salicylate are available as karyolitic agents, liniments, flavoring agents, and combination products. These products may contain salicylate, methyl salicylate, or acetylsalicylic acid, but regardless of the product, all formulations are rapidly converted to salicylate once ingested.[1] Five mL of oil of wintergreen contains 7 g of aspirin and can be deadly to a toddler. Liniments and products used in hot vaporizers have high concentrations of methyl salicylate, and an ingestion of 5 to 10 mL can be lethal for an infant or a toddler.[2] Even though salicylate is poorly absorbed after ingestion of bismuth subsalicylate (Peptobismol®), significant exposures can occur from massive ingestions, such as in patients with human immunodeficiency virus/acquired immunodeficiency syndrome taking this medication for chronic diarrhea.[3]

PATHOPHYSIOLOGY

After ingestion of therapeutic doses in standard tablet formulation, absorption is variable and dependent on dosage form, presence of food, and gastric pH, with peak salicylate levels usually occurring in 1 to 2 hours. In overdose, peak serum salicylate concentrations may not be reached for hours. Enteric-coated aspirin exhibits erratic absorption in therapeutic doses, and peak levels may be delayed for hours after an overdose.[4] Salicylate itself impairs gastric emptying, which may account for delayed absorption in some cases[5] and create the potential for gastric bezoar formation, which can provide an additional source of ongoing absorption.[6] Ingestion of methyl salicylate or other liquid formulations may have much more rapid absorption and achieve peak levels more rapidly.

After absorption, aspirin is hydrolyzed to salicylic acid (salicylate) and is distributed throughout body tissues with 50% to 80% being bound to serum proteins. As salicylate concentrations increase and saturate protein-binding sites, free (unbound) concentrations of salicylate increase. In solution, salicylate exists in equilibrium between the ionized and nonionized state; only the unbound, nonionized salicylate can readily cross cell membranes. At physiologic pH (7.40), almost all salicylate is ionized, but acidemia will increase the nonionized fraction, enabling more salicylate to cross cell membranes and, importantly, substantially increasing brain salicylate concentration.[7] Patients with identical total salicylate serum concentrations may vary greatly in their degree of toxicity depending on their tissue burden, plasma protein concentrations, pH, and other factors.

Salicylate undergoes hepatic metabolism; however, this process rapidly becomes saturated even within the therapeutic ranges of drug use and changes to zero order kinetics; a set amount of salicylate is eliminated per unit of time.[8] Increased fraction of unbound salicylate also enhances renal clearance, making the kidney the major route of elimination during toxicity. Nonionized salicylate can be resorbed by renal tubules. Serum alkalinization can be used to keep salicylate in the plasma compartment and out of tissues, and urinary alkalinization can be used to enhance renal elimination. If the urine pH is above 7.5, more salicylate molecules in the urine will be ionized compared with the renal tubular cell pH of 7.4, and reabsorption across the urinary tubule will be reduced. This pH difference will also enhance secretion of nonionized salicylate down the concentration gradient.

Salicylate toxicity affects many physiologic systems (**Table 189-1**).

Salicylate directly stimulates the medullary respiratory center to produce tachypnea, hyperpnea, and respiratory alkalosis.[9] As toxicity worsens, inhibition of metabolism produces an acidosis that overwhelms the alkalosis. **Classically the acid-base disturbance associated with salicylate poisoning is mixed: early respiratory alkalosis, followed by an elevated anion gap metabolic acidosis, and possibly late respiratory acidosis**. Co-ingestion or administration of CNS depressants may blunt this initial respiratory stimulation. Salicylate stimulates skeletal muscle metabolism, which causes an increase in oxygen consumption and carbon dioxide production. Neurologic toxicity may impair ventilation so that it is unable to keep pace with increased carbon dioxide production, leading to respiratory acidosis—usually a late and ominous finding. Decreased ventilation can also be related to co-ingestions or iatrogenic medication.

Salicylate affects both central and peripheral glucose homeostasis. Although salicylate causes mobilization of glycogen stores, resulting in hyperglycemia, it is also a potent inhibitor of gluconeogenesis. Therefore, normoglycemia is the most common finding, hyperglycemia can occur, and hypoglycemia is a rare possibility during toxicity.[10] Animal studies demonstrate that toxic doses of salicylate produce a profound decrease in brain glucose concentration despite normal serum glucose concentrations.[7,11] This suggests that a patient may be relatively neuroglucopenic even if the blood glucose is normal.

Salicylate can cause corrosive injury of the GI tract with abdominal pain, nausea, and vomiting and occasional hematemesis. This can all lead to volume loss, metabolic alkalosis, and hypokalemia. Gastric perforation has been reported after significant aspirin ingestion.[12] Salicylate-induced acute lung injury (noncardiogenic pulmonary edema) has been observed in humans. Antiplatelet activity is a well-known, often desired effect of aspirin (but not other salicylate products), but hemorrhage is a rare complication of acute, single, massive overdose. Large doses of all salicylates may cause significant hypoprothrombinemia resulting from inhibition of vitamin K–dependent functions.[13]

Salicylate ototoxicity is common, and tinnitus often occurs with levels >20 milligrams/dL (1.4 millimol/L). Although classically described as tinnitus or "ringing in the ears," in practice most patients will describe decreased sounds or that their hearing is "muffled." The exact mechanism causing this is unknown, and hearing effects are not permanent. Cardiac arrhythmias are a rare complication of salicylate poisoning.[14]

TABLE 189-1 Pathophysiology of Salicylate Toxicity

Local gastric irritation
Stimulation of the chemoreceptor zone
Stimulation of medullary respiratory center
Stimulation of skeletal muscle metabolism
Uncoupling of oxidative phosphorylation
Enhancement of lipolysis
Inhibition of Krebs cycle
Increased vascular permeability
Mobilization of glycogen stores
Inhibition of gluconeogenesis
Reversible ototoxicity

CLINICAL FEATURES

Clinical manifestations of salicylate toxicity depend on the dose ingested, duration of exposure, age, and comorbidities of the patient.[7,15] In children and the elderly, end-organ toxicity can be seen with smaller doses and lower serum levels following an acute overdose. Chronic toxicity can produce insidious and severe neurologic changes that do not correlate well with dose or serum salicylate level. Patients with even a mild toxicity can become critically and severely ill if acidemia or dehydration develops.

INTOXICATION IN CHILDREN

In general, when the duration of salicylate intoxication is between 12 to 24 hours, metabolic acidosis and acidemia (pH <7.35) occur primarily in children <4 years old, and nearly all children <1 year old have acidosis. Young children can have a respiratory alkalosis, but this is often transient and missed because of their smaller ventilatory reserves.[16] In older children (>4 years old), the acid-base disturbance is usually a mixed disturbance with respiratory alkalosis, increased anion gap metabolic acidosis, and alkalemia (pH >7.45).

Chronic or "therapeutic" (repeated dose) pediatric salicylate poisonings are more serious and are associated with a higher mortality than acute salicylism.[7,15,17] Often, several days may elapse between the initial salicylate administration and the onset of symptoms. There is frequently a coincidental illness that prompted salicylate administration, and children usually appear more ill than those with acute intoxication. The presenting features are usually fever, hyperventilation, and altered mental status with volume depletion, acidosis, and severe hypokalemia.[15] Young children are prone to hyperpyrexia, which indicates a worse prognosis.[17] Renal failure may be a significant complication, but pulmonary edema is unusual in the pediatric population.[15,17] Chronic salicylism is often mistaken for an infectious process, and the resultant delay in diagnosis may account for the more severe clinical picture.

The diagnosis may be delayed if a history of salicylate ingestion is not available. The differential diagnosis includes diabetic ketoacidosis, sepsis, iron intoxication, and toxic alcohol poisoning.

INTOXICATION IN ADULTS

Acute salicylate intoxication in adults is often due to intentional ingestion. The typical clinical presentation includes nausea, vomiting,

tinnitus, hearing loss, sweating, and hyperventilation. Patients with tinnitus or hearing loss following an acute ingestion usually have an elevated serum salicylate value.[18]

Most adult patients with acute salicylate overdose have a mixed acid-base disturbance of alkalemia with respiratory alkalosis and metabolic acidosis. As toxicity progresses, acidosis worsens. CNS dysfunction manifests as agitation, lethargy, confusion, seizure, or coma. CNS dysfunction leading to cerebral edema is an ominous development and a sign of severe toxicity, requiring rapid and aggressive treatment.[7,19] Despite treatment and decreasing serum salicylate levels, patients may worsen and die from progressive neurologic impairment, possibly because of increasing CNS salicylate levels.

Salicylate-induced vomiting can produce a metabolic alkalosis. Other rare complications of salicylate toxicity include rhabdomyolysis, gastric perforation, and GI hemorrhage. Poor prognostic factors for acute salicylate toxicity include coma, fever, respiratory acidosis, seizure, and cardiac dysrhythmias.

Chronic salicylate intoxication (from repeated excessive dosing) in adults often presents with neurologic abnormalities such as lethargy, altered mental status, irritability, and hallucinations, particularly in the elderly.[20] Toxicity can develop even with small increases in doses due to saturable kinetics. Clinical features of chronic intoxication include hyperventilation, tremor, papilledema, agitation, paranoia, bizarre behavior, memory deficits, confusion, and stupor. Nausea and vomiting are less common than in acute salicylate toxicity, whereas increased liver function tests and increased prothrombin time are more common. Neurologic abnormalities in chronic salicylate poisoning may be nonspecific and may often mislead physicians. Chronic salicylism should be considered in a patient with unexplained neurologic or behavioral dysfunction, especially in the presence of a mixed acid-base disturbance, tachypnea, dyspnea, or unexplained pulmonary edema.[21] Compared with acute toxicity, adults with chronic salicylate toxicity have a higher tissue burden of salicylate leading to more significant toxicity at a lower serum concentration.

The distinction between acute and chronic salicylate toxicity may not always be clear. A patient may present many hours after an acute severe salicylate overdose, when altered mental status, acidosis, elevated prothrombin time, and a "therapeutic" serum salicylate concentration appear more consistent with a chronically poisoned patient. Significant toxicity may be evident despite declining or "therapeutic" serum salicylate concentrations. In these situations, the patient's clinical status is most important when assessing the severity of toxicity (**Table 189-2**).

Chronic salicylism may develop in patients taking carbonic anhydrase inhibitors for treatment of glaucoma. The normal anion gap (hyperchloremic) metabolic acidosis produced by carbonic anhydrase inhibitors increases the volume of distribution for salicylate and facilitates its entry into the CNS, causing toxicity at a "therapeutic" serum salicylate concentration.

The differential diagnosis of a triple-mixed acid-base disturbance of increased anion gap acidosis, metabolic alkalosis, and respiratory alkalosis seen in salicylate toxicity is limited. However, in clinical practice or at early stages of toxicity, this classic acid-base disturbance may be difficult to appreciate. The differential is very broad and includes but is not limited to sepsis, diabetic ketoacidosis, renal and hepatic failure, alcoholic ketoacidosis, poisoning by methanol and ethylene glycol, iron, theophylline, and caffeine.

TABLE 189-2 Severity Grading of Salicylate Toxicity in Adults

	Mild	Moderate	Severe
Acute ingestion (dose)	<150 milligrams/kg	150–300 milligrams/kg	>300 milligrams/kg
End-organ toxicity	Tinnitus Hearing loss Dizziness Nausea/vomiting	Tachypnea Hyperpyrexia Diaphoresis Ataxia Anxiety	Abnormal mental status Seizures Acute lung injury Renal failure Cardiac arrhythmias Shock

DIAGNOSIS

Diagnosis of salicylate toxicity is made by correlating a careful history, physical examination, and thoughtful ancillary testing. Supportive laboratory findings include an anion-gap metabolic acidosis and elevated serum salicylate levels. **The Done nomogram is misleading and can grossly underestimate toxicity; it *should not be used*.**

TOXICOLOGIC TESTING

A pitfall in treating salicylate toxicity is reliance on a single serum level. Salicylate toxicity can evolve rapidly. In patients with moderate or severe poisoning, it is prudent to obtain serial serum salicylate concentrations approximately every 1 to 2 hours, until the concentrations are declining and the patient's clinical status stabilizes.[22,23] Enteric-coated or modified-release preparations are formulated to remain intact in the acidic gastric environment but to dissolve in the alkaline intestinal fluids. Drug release is therefore primarily a function of gastric emptying, and peak levels may not be reached until up to 60 hours after ingestion in an overdose.[4]

Commercially available tests can qualitatively detect salicylate in the urine, but these tests have limitations, and a qualitative level does not help determine whether the patient is therapeutic or intoxicated with salicylate and cannot help guide treatment. Similarly, the ferric chloride test is very sensitive to small quantities of salicylic acid, but a positive test result does not indicate salicylate poisoning or toxicity. Serum salicylate levels should always be obtained in patients with salicylate or suspected salicylate toxicity.

Commercially available tests for serum salicylate concentration are very accurate; the only reported significant interference has been with diflunisal (a nonsteroidal anti-inflammatory drug), which produces false-positive results for significantly high serum salicylate concentrations.[24] Another pitfall is that units for measuring salicylate are not universal. Traditionally stated in milligrams/dL, measurement units can vary by laboratory and institution, with the potential for patients to be mistakenly diagnosed as "salicylate toxic" if the physician mistakenly assumes the unit of measurement used.

ADDITIONAL ANCILLARY TESTING

Essential laboratory tests include electrolytes, glucose, BUN, and creatinine. Arterial blood gases, chest and abdominal radiograph, ECG, CBC, serum calcium level, and urinalysis with urine pH determination should be obtained as clinically indicated. As in any ingestion, consider testing for acetaminophen as well, especially considering the number of combination products available in the market. Some enteric-coated medications are radiopaque and may be visible on an abdominal radiograph.[25]

A normal anion gap does not exclude salicylate toxicity in patients with an unknown ingestion. Mixed ingestions that include aspirin and the timing of exposure can alter "classic" metabolic disturbances. A negative anion gap metabolic acidosis may be noted in salicylate toxicity due to aberrant reading of salicylate ions as chloride ions by analyzer electrodes.[26]

TREATMENT

GENERAL MEASURES

Treatment priorities are (1) immediate resuscitation with stabilization of airway, breathing, and circulation; (2) correction of volume depletion and metabolic derangements; (3) GI decontamination; and (4) reduction in body salicylate burden.[22,23] Salicylate absorption is reduced by the administration of activated charcoal both for regular and modified-release formulations. A single dose of activated charcoal, 1 to 2 grams/kg, should be administered to appropriate patients who have ingested potentially toxic amounts of salicylate.[22,27,28] There are no convincing data to support the use of repeated or multiple doses of activated charcoal in salicylate overdose.[29]

Patients with severe salicylate intoxication are usually significantly volume depleted, have serious acid-base disturbances, and require aggressive IV volume and electrolyte replacement. Careful assessment of a patient's volume and electrolyte status is important, particularly in the elderly or in patients with a history of cardiac disease. Volume replacement is initially undertaken with normal saline or lactated Ringer's with administration of an initial bolus of 20 mL/kg. The average adult who presents several hours after ingestion is dehydrated by at least 4 to 6 L.

ALKALINIZATION

Systemic and urinary alkalinization are beneficial for salicylate toxicity, although the precise mechanism is debated.[23,30] As initial fluid resuscitation is undertaken, patients should undergo treatment with sodium bicarbonate with a goal of a serum pH of ~7.5. Hypokalemia is common, and potassium should be added to the infusion after adequate urine output has been established. Serum potassium should be maintained in the 4.0 to 4.5 mEq/L range.

Urinary salicylate clearance is directly proportional to urine flow rate, but, more importantly, it is logarithmically proportional to urine pH.[30] Urine alkalinization is more effective in enhancing salicylate elimination than forced diuresis and avoids the potential complication of fluid overload that may result from the large intravenous volume given to increase urine flow, especially in those with marginal cardiac reserve or cardiac performance. Urinary alkalinization should be considered as first-line treatment for patients with moderately severe salicylate poisoning.[22,31]

Hydration and alkalinization should be initiated simultaneously in patients with severe salicylate intoxication. A common approach is to volume restore patients with normal saline or lactated Ringer's to a target urine output of 1 to 2 mL/kg per hour. Concurrently, in a second IV line, an IV bolus of sodium bicarbonate (1 to 2 mEq/kg) is given followed by a continuous infusion (three ampules of either 44 or 50 mEq/ampule of sodium bicarbonate added to 1 L of 5% dextrose in water). Unless there is a contraindication, potassium should be added to the bicarbonate fluid as well. The infusion is run at two to three times maintenance and adjusted to maintain the urine pH >7.5 (**Figure 189-1**).

In moderate and severe overdoses, the patient's cardiopulmonary and neurologic status should be assessed frequently. Serum salicylate, urine pH, and electrolyte concentrations should be checked every 1 to 2 hours.[22,23] Once the serum salicylate concentration peaks and begins to decrease on serial measurement, repeat measurement can be obtained every 4 to 6 hours.

OTHER MEASURES

Patients with salicylate-induced acute lung injury (noncardiogenic pulmonary edema) should be managed as are patients with acute lung injury from other causes. Pulmonary edema begins to improve concomitantly with the lowering of serum salicylate concentrations. This suggests that aggressive efforts toward rapid elimination by hemodialysis may be beneficial in this subset of patients.[32] In addition, early hemodialysis enables removal of salicylate without the volume challenge that accompanies sodium bicarbonate administration, and it avoids the possibility of aggravating lung injury.

When a patient with severe salicylate toxicity requires endotracheal intubation, mechanical ventilation, and sedation, it is important to maintain hyperventilation; ventilator settings should not be based on standard age- and weight-based nomograms. Before intubation and mechanical ventilation, most patients with severe salicylate toxicity have a respiratory alkalosis. Controlling the ventilatory rate and volume to "normal" ranges produces a decrease in serum pH and causes a rapid shift of salicylate into the CNS. It is important to maintain respiratory alkalosis during

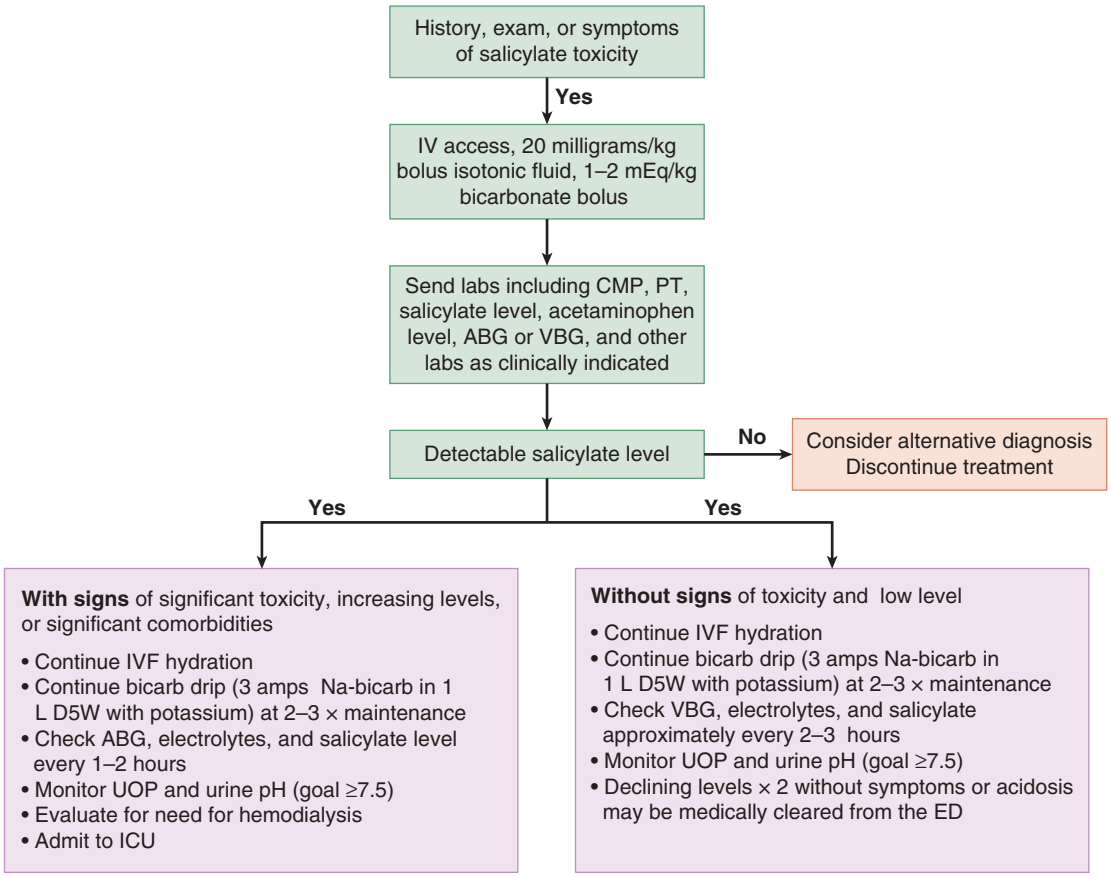

FIGURE 189-1. Management of salicylate poisoning. ABG = arterial blood gas; bicarb = bicarbonate; CMP = comprehensive metabolic panel; D5W = 5% dextrose in water; ICU = intensive care unit; IVF = intravenous fluids; PT = prothrombin time; UOP = urinary output; VBG = venous blood gas.

mechanical ventilation. Use the minimal amount of safe sedation that allows a patient to continue over-breathing the ventilator. Consider one to two ampules (88 to 100 mEq) of bicarbonate bolus immediately prior to intubation as a basic buffer for the transient decrease in ventilation that occurs during rapid-sequence induction intubation.

Hemorrhagic complications are rarely seen following single massive salicylate overdoses, but chronic administration of large doses may cause significant hypoprothrombinemia. However, even in this circumstance, hemorrhage is rarely seen in clinical practice or in animal experiments. When bleeding does occur, it rarely appears to be a contributing factor in mortality from salicylate toxicity. Patients with clinically significant bleeding should be treated with fresh frozen plasma. Observations in animals and humans indicate that administering large doses of vitamin K after the development of hypoprothrombinemia has little or no effect on the prothrombin time when serum salicylate concentration is high.

HEMODIALYSIS

Hemodialysis is considered the extracorporeal technique of choice for the treatment of serious salicylate toxicity because hemodialysis can correct acid-base and electrolyte abnormalities while rapidly reducing the body salicylate burden.[33,34] Anticipating the possible need for hemodialysis, thoughtful planning and prompt consultation with the nephrology service are strongly advised because of intrinsic delays to its immediate implementation. **Indications for hemodialysis include clinical deterioration or failure of improvement despite intensive supportive care, lack of success in establishing an alkalinization of serum and urine, renal insufficiency or renal failure, severe acid-base disturbance, altered mental status, and patients with acute lung injury. Consider hemodialysis for salicylism requiring respiratory and ventilatory support.**[34]

Serum salicylate concentration should not be the sole determinant in the decision to initiate hemodialysis; however, patients with acute toxicity and serum salicylate concentrations >100 milligrams/dL (>7.2 millimol/L), chronic patients with concentrations >60 milligrams/dL, (>4.3 millimol/L) and symptomatic patients with lower serum salicylate concentrations should be considered candidates for hemodialysis. Consider the early use of hemodialysis in patients who are elderly, have chronically ingested aspirin, have altered mental status, have acidemia, or have comorbidities (e.g., coronary artery disease or chronic obstructive pulmonary disease).

Emergency hemodialysis places a significant demand on the cardiovascular system, and hypotensive patients or those with underlying cardiac disease may not be able to tolerate the hemodynamic intensity of 4-hour hemodialysis treatments. Less demanding but a longer therapy, such as hemofiltration, hemodiafiltration, or sustained low-efficiency dialysis, may be used until hemodialysis can be tolerated. Once initiated, extracorporeal elimination techniques should be continued until the serum salicylate level is <20 milligrams/dL (<1.4 millimol/L).

DISPOSITION AND FOLLOW-UP

A patient may be discharged from the ED once it can be determined that the patient had an inconsequential salicylate overdose; and this requires demonstration of serial declining salicylate levels. Patients who have overdosed on enteric-coated or modified-release preparations of aspirin should be treated regardless of initial serum salicylate concentrations and be observed for approximately 24 hours, with serial serum salicylate concentrations until a declining level is confirmed. Salsalate overdoses may warrant an even longer period of observation.[35] Although the determination of serial salicylate concentrations offers valuable information regarding the effectiveness of the treatment implemented, it is not a substitute for clinical evaluation of a patient, and management decisions should not be solely based on a particular serum salicylate concentration. Early consultation with a clinical toxicologist or the regional poison control center is recommended.

CHAPTER 190

Acetaminophen

Oliver L. Hung
Lewis S. Nelson

INTRODUCTION AND EPIDEMIOLOGY

Acetaminophen (*N*-acetyl-*p*-aminophenol or paracetamol) is the most popular over-the-counter analgesic and is one of the most common toxic exposures reported to poison centers. Acetaminophen is available as a sole agent or combined with a variety of other medications prepared in many different forms, such as tablets, capsules, gels, and liquids. Poisonings often occur because of the erroneous belief that this medication is benign or because the victim was unaware that acetaminophen was an ingredient in the ingested preparation.[1] The U.S. Acute Liver Failure Study Group found that acetaminophen poisoning was the cause of acute liver failure in 18% of cases initially judged to be of unknown cause.[2] Acetaminophen–opioid combination products have been implicated in chronic overuse, likely due to an increasing opioid requirement leading to concomitantly increasing acetaminophen exposure. In response to these safety concerns, the U.S. Food and Drug Administration recently limited the prescription acetaminophen–opioid combination preparation strength to 325 milligrams per dosage unit and now requires a boxed warning to notify consumers of the potential risk for serious liver toxicity.[3]

During 2010, the American Association of Poison Control Centers received reports of 66,473 exposures to acetaminophen–opioid combinations and 73,307 exposures to acetaminophen alone.[4] There were 65 deaths attributed to isolated ingestions of acetaminophen combinations and 60 deaths attributed to isolated acetaminophen ingestions.[4] Combining ED, hospital, and poisoning databases, an estimated 450 deaths occur each year in the United States due to acetaminophen overdose, and approximately 100 of them are unintentional, primarily due to supratherapeutic dosing of child preparations.[5]

PHARMACOLOGY AND DOSING

ORAL ACETAMINOPHEN

The recommended maximum total daily dose is 3900 milligrams in adults using 325-milligram acetaminophen (regular strength) and 3000 milligrams when using the 500-milligram acetaminophen (extra strength) preparation. Adults should not use acetaminophen for more than 10 consecutive days unless directed by their physician. **For children, the recommended acetaminophen dose is 10 to 15 milligrams/kg every 4 to 6 hours as needed, with a maximum daily dose of 75 milligrams/kg or five doses in a 24-hour period.** In 2011, the infant acetaminophen formulation (80 milligrams/0.8 mL concentration) was discontinued to minimize the risk for medication error. All pediatric, both infant and child, acetaminophen liquid preparations are now standardized to a concentration of 160 milligrams/5 mL.

Patients with insufficient glutathione stores (e.g., alcoholics and acquired immunodeficiency syndrome patients) and patients with induced cytochrome P-450 enzymatic activity (e.g., alcoholics and those taking concurrent anticonvulsant or antituberculous medications) may be at greater risk for developing acetaminophen-induced hepatotoxicity following overdose (as opposed to therapeutic dosing described earlier). Although the evidence supporting this risk is not definitive, it may be prudent to reduce acetaminophen dosage for this population. In contrast, children, because of their greater ability to metabolize acetaminophen through hepatic sulfation, may be at decreased risk for developing hepatotoxicity following a moderate overdose.[6,7]

After ingestion of therapeutic doses, acetaminophen is rapidly absorbed from the GI tract, and peak serum concentrations are usually achieved within 30 minutes to 2 hours. In an overdose, peak serum concentrations are usually achieved within 2 hours, but delayed absorption of acetaminophen occurs following overdoses of preparations in which acetaminophen is combined with propoxyphene or diphenhydramine,

as well as those with altered-release kinetics such as extended-release preparations.[8-11] In therapeutic amounts, acetaminophen has nearly 100% bioavailability, is approximately 20% bound to serum proteins, has a volume of distribution of around 0.85 L/kg, and has an elimination half-life of approximately 2.5 hours. The therapeutic concentration for the antipyretic effect of acetaminophen is between 10 and 20 micrograms/mL (66 to 132 micromoles/L), but therapeutic concentrations for analgesia are not established.

Oral acetaminophen appears to be nontoxic when administered following therapeutic dosing guidelines. Both retrospective and prospective studies have yielded inconsistent results concerning the risk of acute liver injury with repeated use of therapeutic acetaminophen doses.[12] The prospective studies, which are better controlled than the retrospective ones, find a slight increase in liver injury but no evidence of increased hepatic failure or death when using therapeutic acetaminophen doses for sustained periods.[13] For **alcoholic patients**, no evidence of liver injury was seen when treated with the recommended maximal daily dose of acetaminophen for 3 consecutive days.[14,15]

IV ACETAMINOPHEN

An **IV acetaminophen** formulation was approved by the U.S. Food and Drug Administration in 2010 for adults and children 2 years of age or older. The recommended dosing of IV acetaminophen for adults or children weighing more than 50 kg is 650 milligrams every 4 hours or 1000 milligrams every 6 hours, with a maximum total daily dose of 4 grams. For adults or children weighing less than 50 kg, the recommended dosing is 12.5 milligrams/kg every 4 hours or 15 milligrams/kg every 6 hours (maximum individual dose of 750 milligrams), with a maximum total daily dose of 75 milligrams/kg or 3750 milligrams. Peak concentrations following IV administration occur at the end of the 15-minute infusion period.[16] Compared to a similar dose of oral acetaminophen, IV acetaminophen achieves a 70% greater maximum concentration but provides a similar total drug exposure.[16]

ACETAMINOPHEN METABOLISM

In therapeutic amounts, acetaminophen is primarily metabolized by the liver through sulfation (20% to 46%) and glucuronidation (40% to 67%), with <5% undergoing direct renal elimination. Normally, a small percentage is also oxidized by the cytochrome P-450 system to a reactive metabolite, *N*-acetyl-*p*-benzoquinoneimine (**NAPQI**). This is quickly detoxified by hepatic glutathione to a nontoxic acetaminophen-mercapturate compound that is renally eliminated (**Figure 190-1**). After acetaminophen overdose, hepatic metabolism through glucuronidation and sulfation may be saturated, and a larger proportion of acetaminophen is therefore metabolized by cytochrome P-450 to NAPQI, depleting intracellular glutathione. When hepatic stores of glutathione decrease to <30% of normal, NAPQI binds to other hepatic macromolecules, and hepatic necrosis ensues. Although the clinical manifestations of acetaminophen toxicity are classically delayed, hepatic injury actually occurs early, within 12 hours of exposure.

Within the hepatic lobule, cytochrome P-450 is concentrated within hepatocytes surrounding the terminal hepatic vein and is least concentrated within hepatocytes surrounding the portal triad. As a result, acetaminophen-induced hepatic injury develops in the characteristic pattern of centrilobular necrosis. Hepatic injury can be identified by microscopic evidence as well as immunofluorescent staining of NAPQI-hepatic protein adducts within hepatocytes. Observed hepatocyte damage typically progresses with cell lysis on the second day after an acute toxic exposure, releasing hepatic enzymes, such as transaminases, and NAPQI-hepatic protein adducts into the circulation where they are detectable in the serum. This corresponds generally to the development of overt clinical toxicity.

CLINICAL FEATURES OF ACETAMINOPHEN TOXICITY

The initial clinical findings of acetaminophen toxicity are nonspecific and delayed in onset.

FOUR STAGES OF ACETAMINOPHEN TOXICITY

The clinical presentation of human acetaminophen poisoning can be roughly divided into four stages (**Table 190-1**). During the first 24 hours after exposure (stage 1), patients often have minimal and nonspecific symptoms of toxicity, such as anorexia, nausea, vomiting, and malaise. **Hypokalemia and metabolic acidosis** may be seen during the first 24 hours and correlate with a high 4-hour acetaminophen concentration.[17-20] By days 2 to 3 (stage 2), symptoms seen in stage 1 often improve, but clinical signs of hepatotoxicity may occur, including right upper quadrant abdominal pain and tenderness, with elevated serum transaminases. Even without treatment, most patients with mild to moderate hepatotoxicity recover without sequelae. However, by days 3 to 4 (stage 3), some patients will progress to fulminant hepatic failure.[21,22] Characteristic stage 3 findings include metabolic acidosis, coagulopathy, renal failure, encephalopathy, and recurrent GI symptoms. Patients who survive the complications of fulminant hepatic failure begin to recover over the next 2 weeks (stage 4), with complete resolution of hepatic dysfunction in survivors after 1 to 3 months.

Acetaminophen may also cause acute, extrahepatic toxic effects, presumably because of the presence of cytochrome P-450 or similar enzymes (e.g., prostaglandin H synthase) in other organs. Ingestion of massive doses of acetaminophen (e.g., 4-hour acetaminophen concentrations >800 micrograms/mL or >5300 micromoles/L) is associated with the altered sensorium and a metabolic acidosis with an elevated lactate that can occur in the absence of either liver failure or hypotension.[23] Renal insufficiency occurs in 1% to 2% of patients following acetaminophen overdose, usually after hepatic failure is evident.[24-26] In rare cases, isolated renal injury, cardiac toxicity, and pancreatitis may occur.[27,28]

DIAGNOSIS

Acute acetaminophen poisoning is diagnosed by the serum acetaminophen concentration and estimating the time since ingestion.

A toxic exposure to acetaminophen is suggested when a patient ≥6 years old ingests (1) >10 grams or 200 milligrams/kg as a single ingestion, (2) >10 grams or 200 milligrams/kg over a 24-hour period, or (3) >6 grams or 150 milligrams/kg per 24-hour period for at least 2 consecutive days. For children <6 years old, ingestion of 200 milligrams/kg or more of acetaminophen as a single ingestion or over an 8-hour period, or of 150 milligrams/kg per 24-hour period for the preceding 48 hours is considered a toxic exposure. These values are empiric and not validated in human trials, but they are widely used as recommendations for emergency evaluation. Even though a patient's history of the amount ingested may be unreliable, a patient report of >10 to 12 grams ingested was associated with a 4-hour acetaminophen concentration above 150 micrograms/mL (1000 micromoles/L) in 40% to 70% of toxic exposures.[29,30]

Due to the widespread availability of acetaminophen-containing products, the delayed clinical manifestations after overdose, and the serious complications of acute toxicity without antidotal therapy, **measurement of a serum acetaminophen concentration is recommended for all patients presenting to the ED with an intentional overdose**.[31,32] Potentially toxic acetaminophen levels have been seen in ED overdose patients who denied ingesting acetaminophen.[33,34] Empirical testing of all patients with intentional overdoses may be cost-effective, as the estimated cost of treating a single patient for complications of acetaminophen-induced hepatotoxicity is judged to outweigh the cost of routine laboratory testing all intentional overdose patients. A qualitative acetaminophen urine screen can also be used to identify potential acetaminophen overdose patients.[35]

THE RUMACK-MATTHEW NOMOGRAM

The implication of a measured acetaminophen concentration is determined by plotting the value on the Rumack-Matthew nomogram (**Figure 190-2**).[36] This nomogram was derived from a retrospective analysis of oral acetaminophen overdose patients and their clinical outcomes. The original nomogram line separating possible toxicity from unlikely toxicity was based on a 4-hour acetaminophen concentration of

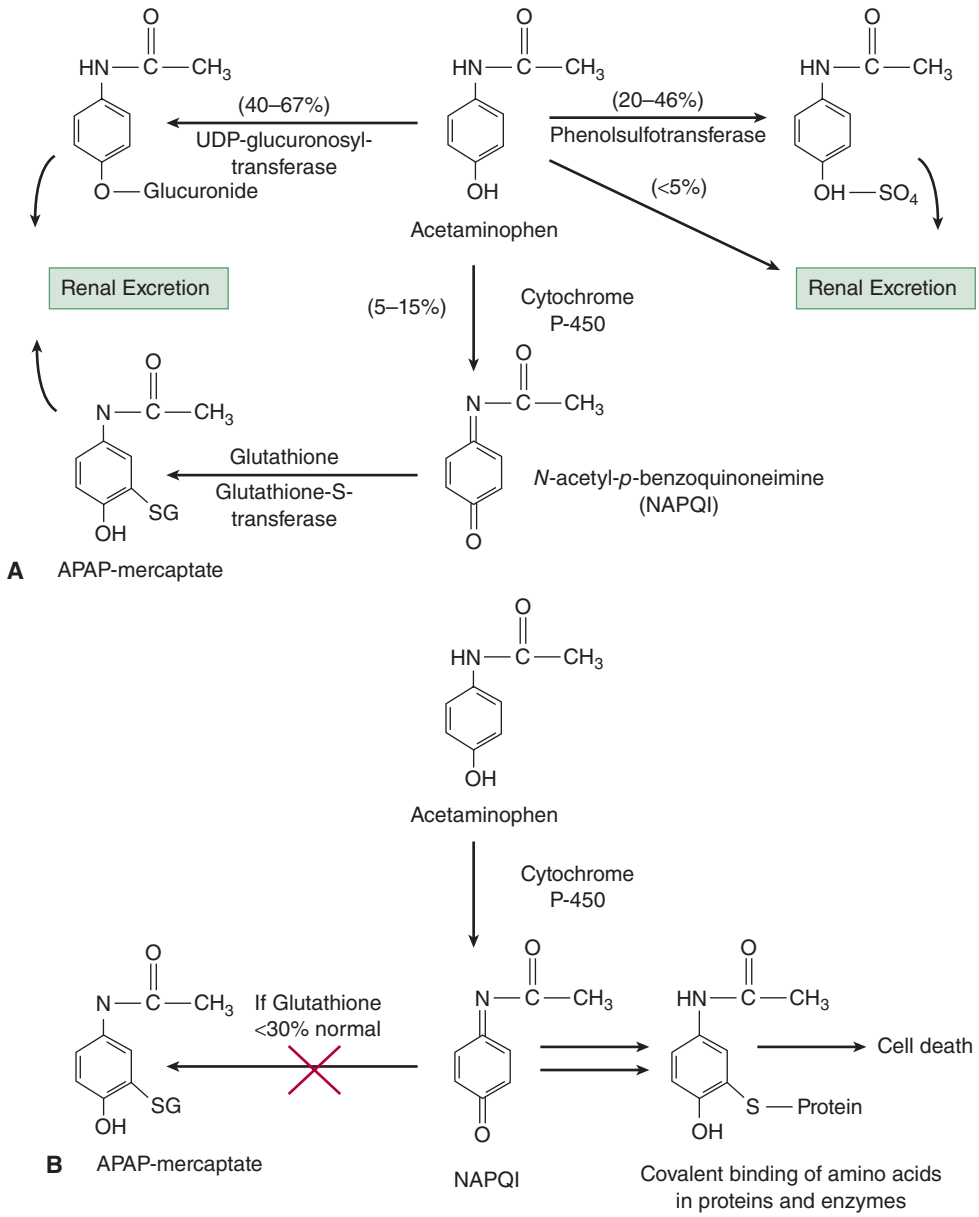

FIGURE 190-1. Acetaminophen metabolism. **A.** After ingestion of therapeutic amounts, predominant metabolism is via glucuronidation and sulfation. The small amount of *N*-acetyl-*p*-benzoquinoneimine (NAPQI) generated is conjugated with glutathione to a nontoxic compound. **B.** After ingestion of large amounts, glucuronidation and sulfation are saturated, and an increased amount of NAPQI is generated. Detoxification of NAPQI to a nontoxic compound soon depletes glutathione stores, leaving excess NAPQI to bind to intracellular proteins, causing cell death. APAP = *N*-acetyl-*p*-aminophenol (acetaminophen).

TABLE 190-1 Clinical Stages of Acute Acetaminophen Toxicity

	Stage 1	Stage 2	Stage 3	Stage 4
Timing	First 24 h	Days 2–3	Days 3–4	After day 5
Clinical manifestations	Anorexia Nausea Vomiting Malaise	Improvement in anorexia, nausea, and vomiting Abdominal pain Hepatic tenderness	Recurrence of anorexia, nausea, and vomiting Encephalopathy Anuria Jaundice	Clinical improvement and recovery (7–8 d) *or* Deterioration to multi-organ failure and death
Laboratory abnormalities	Hypokalemia	Elevated serum transaminases Elevated bilirubin and prolonged prothrombin time if severe	Hepatic failure Metabolic acidosis Coagulopathy Renal failure Pancreatitis	Improvement and resolution *or* Continued deterioration

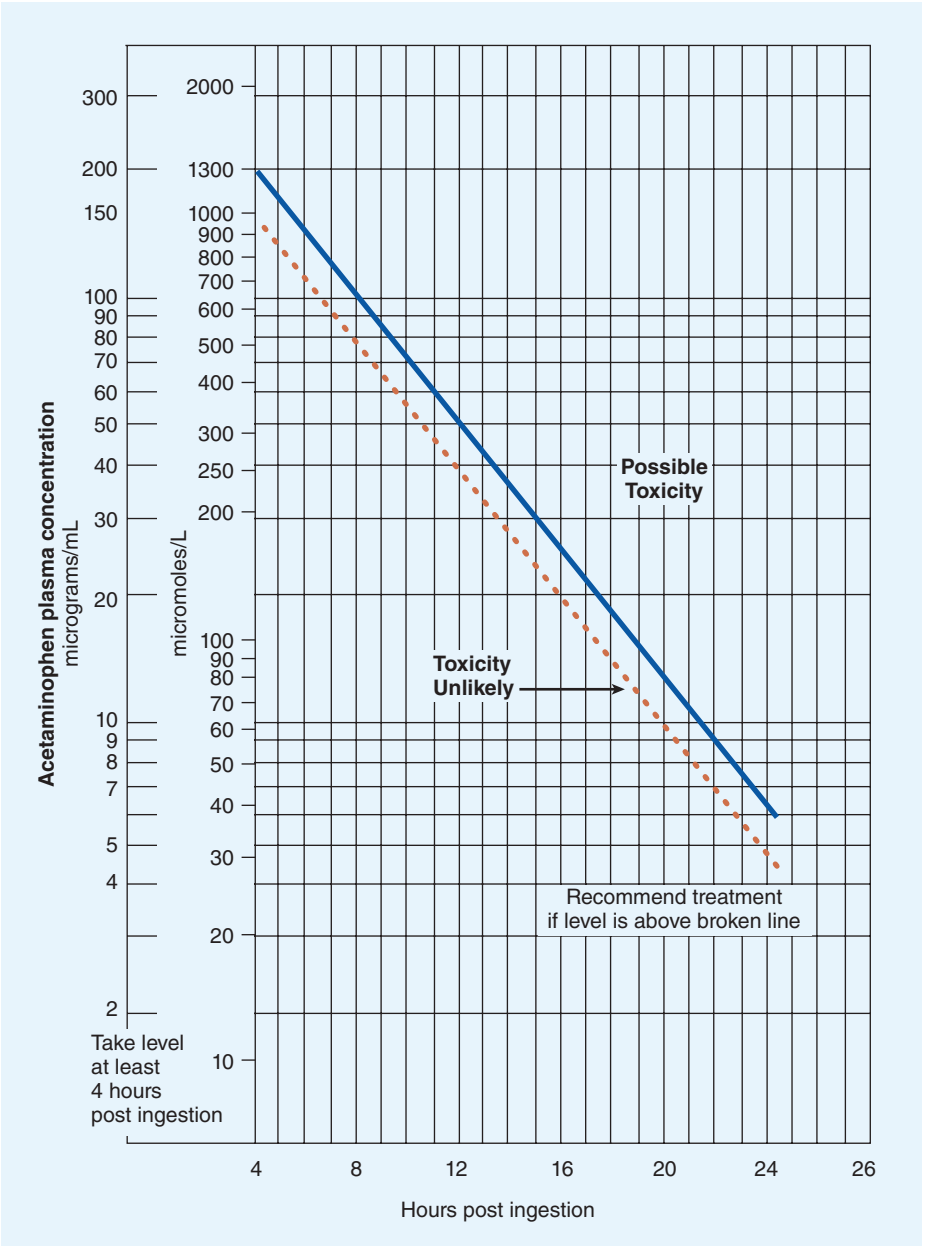

FIGURE 190-2. Rumack-Matthew nomogram.

200 micrograms/mL (1300 micromoles/L), but was subsequently modified by moving the line to a 4-hour acetaminophen concentration of 150 micrograms/mL (1000 micromoles/L) to increase the safety margin for treatment decisions. **The nomogram only directly applies to an acetaminophen concentration obtained after a single oral exposure and during the window between 4 hours and 24 hours postingestion.** Outcome prediction using this nomogram cannot be applied to acetaminophen concentrations obtained outside this 20-hour window or with chronic or recurrent exposures. Obtaining multiple acetaminophen concentrations following acute overdose is rarely indicated in the absence of hepatotoxicity.[37,38] An initial concentration below the nomogram line may rarely "cross the line" in patients who ingest acetaminophen preparations known to have prolonged absorption kinetics.[11] However, the clinical significance of "crossing the line" in this fashion is unknown. Similarly, because the nomogram was constructed and verified by using only a single serum concentration, the clinical implications of a concentration above the line that falls below it on repeat analysis are unknown.

Based on data obtained before the widespread use of antidotal therapy, patients with serum acetaminophen concentrations above the original line (4-hour postingestion concentration >200 micrograms/mL or >1300 micromoles/L) were observed to have a 60% risk of developing hepatotoxicity (defined as alanine aminotransferase >1000 IU/mL), a 1% risk of renal failure, and a 5% risk of mortality.[39] In addition, patients with extremely high serum acetaminophen concentrations (above a parallel line coinciding with a 4-hour postingestion concentration of 300 micrograms/mL or 2000 micromoles/L) were observed to have a 90% risk of developing hepatotoxicity. The prediction of a safe outcome below the nomogram line corresponding to a 4-hour postingestion concentration of 150 micrograms/mL (1000 micromoles/L) was confirmed in patients who did not receive antidotal therapy; the incidence of hepatotoxicity in patients with acetaminophen concentrations below this nomogram line was 1%, and all patients recovered without complications.[38]

A method to determine potential toxicity from IV acetaminophen overdose has not been established. Fortunately, the European experience with IV acetaminophen suggests that these overdoses appear to be rare

in-hospital occurrences that are likely to occur following an error in calculating the acetaminophen dose in pediatric patients.[40-42] However, the available clinical data for evaluating IV acetaminophen overdose remain limited to several published case reports.[42] Because the Rumack-Matthew nomogram was solely derived from oral acetaminophen overdose patients, strictly applying the nomogram to determine toxicity following IV acetaminophen overdose may not be appropriate at this time.

TREATMENT

GI DECONTAMINATION

Treatment of acetaminophen poisoning consists primarily of the timely use of the antidote acetylcysteine and supportive care.[1,36,37] For most cases of acetaminophen poisoning, adequate GI decontamination consists of the early administration of activated charcoal orally or through a nasogastric tube.[1,43,44] Inducing emesis by administering ipecac syrup is undesirable because it delays the administration of the oral antidote. In addition, more aggressive forms of decontamination, such as gastric lavage or whole-bowel irrigation, are unnecessary because of the rapid GI absorption of acetaminophen and the great success of treating acetaminophen poisoning with acetylcysteine.

ACETYLCYSTEINE

The mainstay for the prevention or treatment of acetaminophen toxicity is the administration of acetylcysteine.[1,45-47] The current "standard" acetylcysteine protocols were developed from primarily observational trials, and it is not clear if they represent the most effective regimens.[48]

Although its mechanisms of action are not fully understood, acetylcysteine is thought to have two important beneficial effects.[47,48] In early acetaminophen poisoning (<8 hours after ingestion), acetylcysteine averts toxicity by preventing the binding of NAPQI to hepatic macromolecules. Acetylcysteine may do this by acting as a glutathione precursor or substitute, or a sulfate precursor, or it may directly reduce NAPQI back to acetaminophen. In established acetaminophen toxicity or >24 hours after acetaminophen ingestion, acetylcysteine diminishes hepatic necrosis by acting as an antioxidant, decreasing neutrophil infiltration, improving microcirculatory blood flow, or increasing tissue oxygen delivery and extraction.

If acetylcysteine is given within 8 hours of an acute acetaminophen ingestion, it is nearly 100% effective in preventing the development of hepatotoxicity.[39] The longer the initiation of acetylcysteine therapy is delayed beyond 8 hours after ingestion, the greater the risk of developing hepatotoxicity.[49] **Even up to 24 hours following acetaminophen ingestion, however, acetylcysteine treatment is associated with a lower risk of hepatotoxicity than historical controls.**[39]

Clinical experience suggests that patients with poor glutathione reserves, such as alcoholics and the chronically ill, have similar excellent clinical outcomes when the standard treatment guidelines are applied to their care. As such, there is no need to alter the use of the acetaminophen treatment nomogram or modify the dosing of acetylcysteine for these patients.

The weight of evidence suggests that **acetylcysteine therapy is both safe and efficacious during pregnancy** and that the approach to treating a pregnant patient following an acetaminophen overdose should remain the same. Although an ovine model demonstrated that acetylcysteine is unable to cross the placenta, there are data in humans establishing that it does.[50] Acetylcysteine treatment has never been associated with fetal malformations in humans, but fetal demise and malformations have been described following delayed acetylcysteine treatment after acetaminophen overdose in first-trimester pregnant women.[51]

IV Acetylcysteine IV acetylcysteine has been used to supplant oral administration due to its greater ease of administration, greater patient acceptance, equivalent efficacy, and shorter duration of treatment for many cases of acetaminophen poisoning.[52-55] The major limitation of IV acetylcysteine is the occurrence of drug-related anaphylactoid reactions (occurring during the first 2 hours of administration), which in mild cases is treated with diphenhydramine and in severe cases is treated by temporarily slowing/stopping the acetylcysteine infusion.[56] The risk of anaphylactoid reaction from IV acetylcysteine ranges from 4% to 17%.[57-60] Asthmatics appear to have a greater risk of anaphylactoid reactions during IV acetylcysteine therapy, whereas overdose patients with high acetaminophen concentrations appear to have a lower risk of developing anaphylactoid reactions.[59-62] Approximately 13% of patients treated with IV acetylcysteine develop nausea and vomiting.[63] Rare complications, including status epilepticus, hemolytic uremic syndrome, cerebral edema, and death, have been reported following massive overdose of IV acetylcysteine.[64-67]

The standard regimen for IV acetylcysteine utilizes a 20-hour protocol with a loading dose of 150 milligrams/kg over 15 minutes to 1 hour, followed by a first maintenance dose of 50 milligrams/kg infused over 4 hours, and then followed by a second maintenance dose of 100 milligrams/kg infused over 16 hours (**Table 190-2**). Administering the initial dose over an hour appears to minimize the incidence of drug-related adverse effects, particularly anaphylactoid responses, although this belief has not been substantiated when prospectively studied.[58] Because the three-phase dosing regimen for IV acetylcysteine may result in dosing errors and produce side effects due to the initial high infusion rate, alternative dosing regimens are being explored.[68-70]

TABLE 190-2 Acetylcysteine Dosing Regimens

	Oral	IV Adult	IV Pediatric (<40 kg)
Preparation	Available as 10% and 20% solutions. Dilute to 5% solution for oral administration.	Available as 20% solution.	Available as 20% solution. Dilute to 2% solution by mixing 50 mL in 450 mL 5% dextrose in water.
Loading dose	140 milligrams/kg.	150 milligrams/kg in 200 mL 5% dextrose in water infused over 15–60 min.	150 milligrams/kg (7.5 mL/kg) infused over 15–60 min.
Maintenance dose	70 milligrams/kg every 4 h for 17 doses.	50 milligrams/kg in 500 mL 5% dextrose in water infused over 4 h (12.5 milligrams/kg per hour). *followed by* 100 milligrams/kg in 1000 mL 5% dextrose in water infused over 16 h (6.25 milligrams/kg per hour).	50 milligrams/kg (2.5 mL/kg) infused over 4 h (12.5 milligrams/kg per hour). *followed by* 100 milligrams/kg (5 mL/kg) infused over 16 h (6.25 milligrams/kg per hour).
Duration of therapy	72 h.	20 h.	20 h.
Comments	Dilute with powdered drink mix, juice, or soda. Serve chilled. Drink through a straw to reduce disagreeable smell.	Monitor for drug-related adverse effects and anaphylactoid reactions.	Monitor for drug-related adverse effects and anaphylactoid reactions. 500 mL of the 2% solution prepared as described above is enough to treat a 33-kg child for the full 20-h course.

IV acetylcysteine is commercially available as a 20% solution and requires dilution to a 2% solution for infusion into a peripheral vein. Both 5% dextrose in water and half-normal saline can be used as diluents.[71] **Given the volume and hypotonicity of fluid required, children and small adults should be carefully monitored to avoid fluid overload and hyponatremia during treatment.**[52]

Despite the lack of randomized direct comparisons, IV acetylcysteine is as effective and safe as oral therapy for patients with early acetaminophen poisoning, as compared with retrospective cohorts and historical controls.[54,72-75] IV acetylcysteine is the route of choice for patients with acetaminophen-induced fulminant hepatic failure, because oral acetylcysteine has not been adequately studied in this setting.[76] There is the potential for delayed hepatic toxicity after the completion of acetylcysteine therapy, especially the 20-hour IV protocol.[77]

Oral Acetylcysteine The standard 72-hour oral acetylcysteine regimen used in the United States consists of a loading dose of 140 milligrams/kg followed by maintenance doses of 70 milligrams/kg every 4 hours for 17 additional doses (**Table 190-2**). It may still be appropriate in certain patients, such as those at high risk for anaphylactoid responses to the IV formulation and asthmatics. The taste is disagreeable, and some patients with persistent nausea and vomiting may require concomitant antiemetics such as ondansetron.

EXTRACORPOREAL ELIMINATION

Case reports describe the use of extracorporeal detoxification in patients presenting late after a serious acetaminophen overdose to both remove the drug and treat the hepatic encephalopathy.[78,79] The role of such therapy in the overall management of serious acetaminophen toxicity remains to be defined.

TREATMENT GUIDELINES BASED ON TIME TO ED PRESENTATION

Treatment guidelines for oral acetaminophen poisoning are based on the time to presentation to the ED after ingestion: <4 hours, between 4 hours and 24 hours, and unknown time or >24 hours before presentation (Figure 190-3).[37] In toxic overdoses, the risk of hepatotoxicity increases with the lag time between ingestion and initiation of acetylcysteine therapy.[49] The optimal outcome with acetylcysteine therapy is seen if it is administered within 8 hours after ingestion, so the optimal "decision-time window" for treatment is between the 4-hour acetaminophen concentration measurement and 8-hour goal to initiate acetylcysteine.[39] No further acetaminophen serum measurements are necessary once the need for acetylcysteine therapy has been determined until the completion of the course of therapy.

Presentation Within 4 Hours of Ingestion For patients who present to the ED within 4 hours and are likely have a significant acetaminophen overdose, treatment begins with GI decontamination (usually activated charcoal) while awaiting the 4-hour postingestion acetaminophen concentration. If the clinical laboratory can report an acetaminophen concentration within 8 hours postingestion, wait for the serum acetaminophen concentration and plot the result on the nomogram to determine whether acetylcysteine therapy is necessary. If the acetaminophen concentration will not be available by 8 hours postingestion, empirically initiate acetylcysteine therapy without waiting for the result. Subsequently, when the acetaminophen concentration

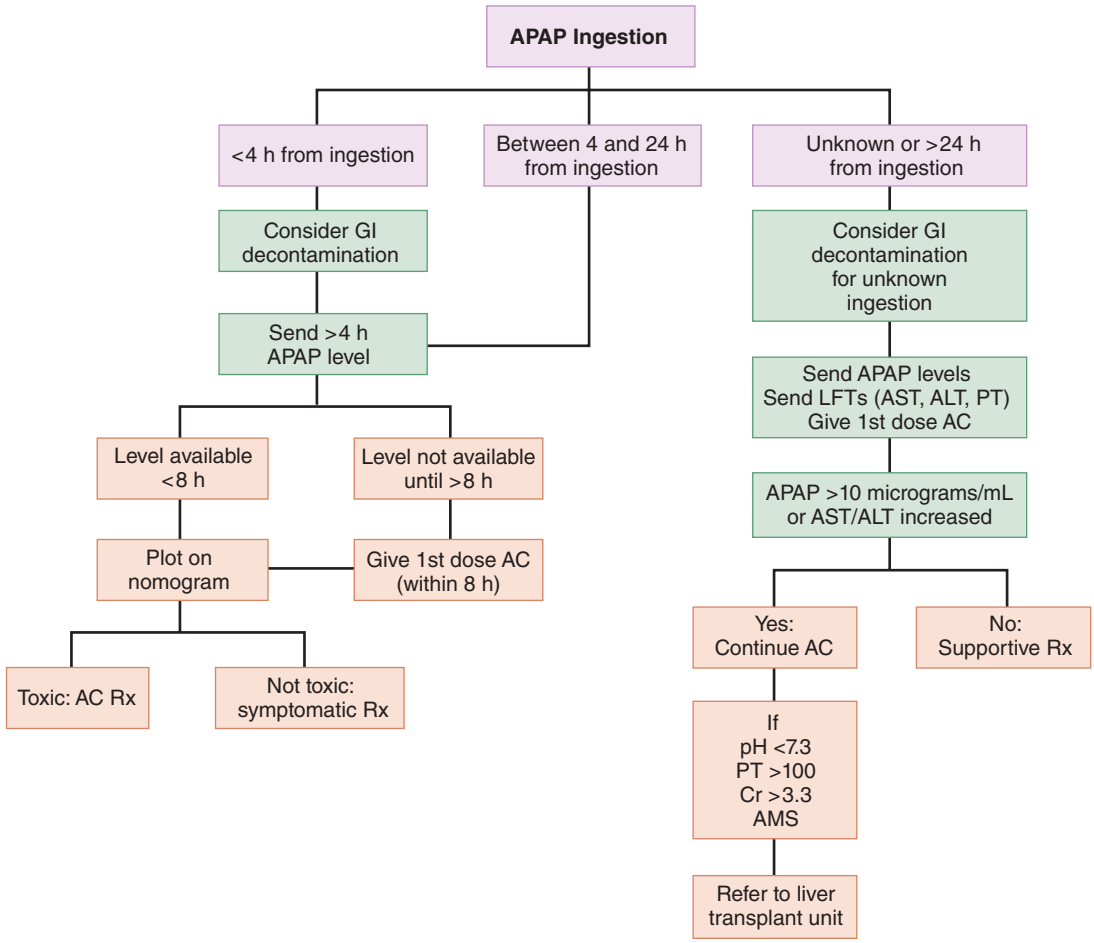

FIGURE 190-3. Treatment guidelines for acetaminophen (APAP) ingestion. All times noted are postingestion. AC = acetylcysteine; ALT = alanine aminotransferase; AMS = altered mental status; AST = aspartate aminotransferase; Cr = creatinine; LFTs = liver function tests; PT = prothrombin time; Rx = treatment.

is determined, the need for acetylcysteine therapy can be determined with the use of the nomogram.

Presentation >4 and <24 Hours After Ingestion For patients who present >4 hours but <24 hours following acetaminophen ingestion, determine the serum acetaminophen concentration as soon as possible. GI decontamination may be performed, particularly for suspected coingestants, but it may have limited effectiveness because of the delay in presentation. If the laboratory can determine the acetaminophen concentration within 8 hours postingestion, await the acetaminophen concentration and plot the result on the nomogram to determine if acetylcysteine therapy is necessary. Otherwise, empirically administer acetylcysteine.

Presentation >24 Hours After Ingestion or Time of Ingestion Unknown For patients in whom the time of acetaminophen ingestion remains unknown or is >24 hours or for those with suggestive clinical findings of acetaminophen poisoning, a serum acetaminophen concentration and serum transaminase, bilirubin, and prothrombin time tests should be determined. Initiate acetylcysteine therapy as soon as possible while awaiting laboratory results. In this scenario, a detectable acetaminophen concentration (>10 micrograms/mL or >66 micromoles/L) suggests that the patient may be at risk for developing hepatotoxicity. Similarly, elevated serum transaminases suggest the possibility of ongoing hepatic toxicity. Therefore, continued acetylcysteine therapy is indicated if the acetaminophen concentration is measurable or if the serum transaminases are elevated. If serum acetaminophen concentration is <10 micrograms/mL (<66 micromoles/L) and the serum transaminases are not elevated, then acetylcysteine can be discontinued.

DISPOSITION AND FOLLOW-UP

Many experts recommend **rechecking serum acetaminophen and transaminase levels** at the completion of acetylcysteine therapy with continuation of acetylcysteine infusion at the rate of 6.25 milligrams/kg per hour until the serum acetaminophen concentration is not detectable or is less than 10 micrograms/mL (66 micromoles/L) and transaminase concentrations are normal or rapidly decreasing.[48,55]

All patients requiring acetylcysteine therapy should be admitted to the hospital until the completion of the therapy. In general, admission to a hospital floor bed is adequate unless the coingestant is of concern, hepatotoxicity is severe, or the patient is suicidal and 24-hour direct observation cannot be arranged. Patients who are not at risk for developing acetaminophen-induced hepatotoxicity (e.g., acetaminophen concentration below the nomogram or unmeasurable acetaminophen concentration with normal hepatic transaminase concentrations) should be observed in the ED for 4 to 6 hours to exclude potentially toxic coingestants before disposition. Psychiatric evaluation should be considered for patients with intentional acetaminophen overdoses. Cases of acetaminophen ingestion or toxicity should be reported to the regional poison control center for both data collection purposes and assistance with management.

SPECIAL CONSIDERATIONS

FULMINANT HEPATIC FAILURE

Unfortunately, a small percentage of patients who overdose with acetaminophen will develop fulminant hepatic failure. Acetaminophen poisoning is the number one cause of acute liver failure, accounting for 39% to 46% of cases in the United States.[80,81] The mortality rate for patients with acetaminophen-induced fulminant hepatic failure without acetylcysteine therapy is estimated to be between 5% and 80%. Most fatalities occur on days 3 to 5 after overdose and are attributed to hepatic complications such as cerebral edema, hemorrhage, shock, acute lung injury, sepsis, and multi-organ failure. Patients who eventually survive fulminant hepatic failure generally begin to show evidence of recovery by days 5 to 7. Survivors will eventually develop complete hepatic regeneration without any persistence of hepatic impairment.

Acetylcysteine treatment decreases the incidence of cerebral edema, reduces vasopressor requirements, and improves survival in acetaminophen-induced fulminant hepatic failure.[76,82] Acetylcysteine also appears to be beneficial in the treatment of other forms of hepatic failure, including viral hepatitis and alcoholic cirrhosis.[83]

Prognostic indicators associated with the highest risk of mortality from acetaminophen-induced fulminant hepatic failure include metabolic acidosis (arterial pH <7.30) despite fluid and hemodynamic resuscitation, or a combination of coagulopathy (prothrombin time >100 seconds), renal insufficiency (serum creatinine >3.3 milligrams/dL or >292 micromoles/L), and grade III or IV hepatic encephalopathy.[84] Other predictors of a poor prognosis include an Acute Physiology and Chronic Health Evaluation II score >15, elevated serum lactate (>26 milligrams/dL or >3.0 mmol/L) after fluid resuscitation, and elevated serum phosphate (>3.71 milligrams/dL or >1.2 mmol/L) on the second day after ingestion.[85-87] Multifactor scoring systems have also been developed to predict hepatotoxicity in single and staggered overdoses.[88-90]

Treatment for acetaminophen-induced fulminant hepatic failure includes acetylcysteine therapy, correction of coagulopathy and acidosis, monitoring for and aggressive treatment of cerebral edema, and early patient referral to a liver specialty/transplant center. Unlike the treatment of early acetaminophen toxicity, IV acetylcysteine therapy should be continued past the 20-hour standard regimen until the patient recovers, receives a liver transplant, or dies.

MULTIPLE-DOSE AND EXTENDED-RELEASE ACETAMINOPHEN INGESTIONS

Patients with staggered acetaminophen ingestions and liver injury often have delayed presentation to the hospital and a higher rate of adverse outcomes.[91] **Multiple closely spaced acetaminophen ingestions and extended-release acetaminophen ingestions represent two unique aspects of acetaminophen poisoning for which the Rumack-Matthew nomogram cannot be readily applied because a single time of ingestion does not exist.** A conservative approach is to assume that a single ingestion occurred at the earliest possible time stated by the patient, with the acetaminophen concentration plotted on the Rumack-Matthew nomogram based on this artificial time and treatment decisions made accordingly. For example, if the patient ingests five doses of 50 milligrams/kg of acetaminophen over a 4-hour period beginning 8 hours ago, a single acetaminophen ingestion is assumed to have occurred 8 hours ago, and the serum concentration accordingly is plotted on the nomogram.

Extended-release acetaminophen formulations consist of a bilayered tablet containing a 325-milligram immediate-release outer layer and a 325-milligram slow, continuous-release, highly compressed inner layer. Because there are little clinical data concerning overdose with these preparations, treatment guidelines remain conservative, and the manufacturer recommends obtaining a second acetaminophen concentration 4 to 6 hours after the first concentration in those situations in which the first measured concentration (4 to 8 hours postingestion) is elevated but below the nomogram line.[92,93] A full course of acetylcysteine therapy should be instituted (or continued if already started) if the second acetaminophen concentration is above the nomogram line. If the initial concentration is above the nomogram line, standard therapy should be administered, and there is no need to obtain a second concentration.

IV ACETAMINOPHEN OVERDOSE

Accepted guidelines for treatment of IV acetaminophen overdose do not currently exist in the United States. The local poison center should be contacted for guidance following any suspected IV acetaminophen overdose.

CHAPTER 191

Nonsteroidal Anti-Inflammatory Drugs

Joseph G. Rella
Wallace A. Carter

INTRODUCTION

Nonsteroidal anti-inflammatory drugs (NSAIDs) are among the most widely used class of drugs in the United States, and all share inhibition of the cyclooxygenase enzyme as a mechanism of action. NSAIDs are effective antipyretics, analgesics, and anti-inflammatory agents. Because of their large therapeutic window, acute ingestion with overdoses rarely produces serious complications.[1,2] The morbidity from NSAIDs in acute overdose is far overshadowed by complications of NSAIDs at therapeutic doses, which include GI bleeding, drug-induced renal failure, and atherosclerotic heart disease.[3-6] Due to their increased risk for cardiovascular disease, rofecoxib and valdecoxib were withdrawn from the U.S. market in 2004 and 2005, respectively.

PHARMACOLOGY

OVERVIEW

NSAIDs are structurally varied compounds with common therapeutic effects (**Table 191-1**). NSAIDs reversibly inhibit the enzyme cyclooxygenase, which is responsible for the production of prostaglandins from arachidonic acid (**Figure 191-1**). The anti-inflammatory effect of NSAIDs is through the inhibition of prostaglandin production, and they may also inhibit neutrophil migration via unclear mechanisms. NSAIDs are antipyretics through inhibition of prostaglandin E_2 in the hypothalamus. NSAIDs attenuate prostaglandin-mediated hyperalgesia and local pain fiber stimulus.

CYCLOOXYGENASE

Two isoforms of cyclooxygenase (abbreviated COX-1 and COX-2) vary in presence and distribution.[7] COX-1 is present with steady level of activity and is found primarily in blood vessels, kidneys, and stomach. In contrast, COX-2 is not normally found to a significant degree in human tissue with the possible exception of the brain and kidneys, unless its production is induced by local inflammation.

Cyclooxygenase inhibitors can be categorized as nonselective, partially selective, or selective regarding their inhibition of COX enzyme isoforms (Table 191-1). Most NSAIDs nonselectively inhibit both COX-1 and COX-2. COX-1 inhibition is responsible for most of the unwanted GI side effects of NSAIDs. Drugs, such as etodolac and meloxicam, were created to inhibit preferentially COX-2, theoretically reducing the unwanted GI effects. Unfortunately, the COX-2–selective compounds do not appear to be more effective mediators of inflammation or analgesia and are still associated with GI side effects in addition to usually being more expensive.[8,9]

PHARMACOKINETICS

All NSAIDs are rapidly absorbed from the GI tract, and most achieve peak serum levels within approximately 2 hours. They are highly protein bound in the plasma, have low volumes of distribution (approximately 0.2 L/kg), and cross the blood–brain barrier. NSAIDs undergo metabolism mainly in the liver via glucuronic acid conjugation or via liver enzymes before elimination in the urine or feces. Plasma half-lives of NSAIDs range from 2 hours for ibuprofen to greater than 50 hours for the long-acting agents piroxicam and phenylbutazone (Table 191-1). Creation of active metabolites may prolong the therapeutic effect beyond that of the parent compound.

Ingestion of large amounts of some drugs, such as ibuprofen and naproxen, exhibits slower absorption, taking 3 to 4 hours to achieve peak plasma levels. As greater amounts of NSAIDS are absorbed in large overdoses, greater fractions of free drug become available for toxicity in a nonlinear manner because protein binding is limited.

TABLE 191-1 Nonsteroidal Agents Available in the United States

Class and Agent	Half-Life with Therapeutic Doses of Standard Oral Tablets or Capsules* (h)
Nonselective NSAIDs	
Salicylates	
Aspirin	6 (salicylic acid)
Diflunisal	8–12
Salsalate	16
Acetic acids	
Diclofenac	2
Indomethacin	4–5
Ketorolac	5
Meclofenamate	1–2 (15†)
Mefenamic acid	2
Nabumetone	<1 (22–26†)
Sulindac	8 (16†)
Tolmetin	5
Propionic acids	
Fenoprofen	3
Flurbiprofen	6–8
Ibuprofen	2
Ketoprofen	2–4
Naproxen	12–17
Oxaprozin	16–45 (38–57‡)
Pyrazolones	
Phenylbutazone	72
Oxicams	
Piroxicam	50
Partially selective COX-2 inhibitors	
Etodolac	6–8
Meloxicam	20–24
Selective COX-2 inhibitors	
Celecoxib	11
Rofecoxib	17
Valdecoxib	8–11

Abbreviation: COX-2 = cyclooxygenase 2.
*Not sustained-release or enteric-coated preparations.
†Half-life of active metabolite.
‡Half-life of protein-bound drug.

Topical NSAIDS Topical NSAIDS are well absorbed through the skin and reach therapeutic levels in synovial fluid. They provide good pain relief for osteoarthritis, with very low blood levels and no toxic effects described to date.[10,11]

SIGNIFICANT DRUG–DRUG INTERACTIONS

Aspirin Daily aspirin therapy reduces the incidence of recurrent myocardial infarction and stroke via impairment of platelet aggregation. Ibuprofen administered three times per day competitively inhibits this aspirin effect on platelets via its interaction with the thromboxane pathway, undermining its cardioprotective effect. This observation may extend to other NSAIDs but not to diclofenac or the COX-2 inhibitors.[12]

Antihypertensive Agents NSAIDs can decrease the effectiveness of some antihypertensives including angiotensin-converting enzyme

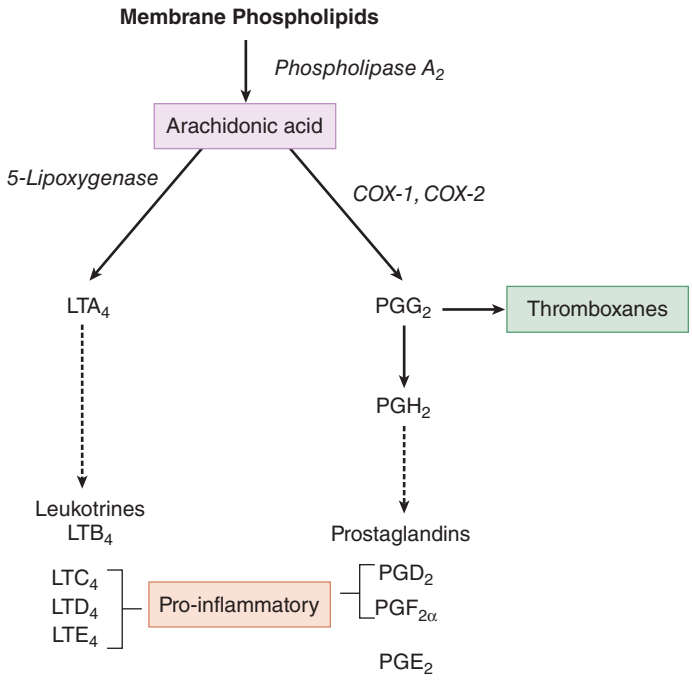

FIGURE 191-1. The arachidonic acid cascade is the primary pathway for the formation of arachidonic acid within cells from which inflammatory mediators—prostaglandins, leukotrienes, and thromboxanes—are generated. NSAIDs target this cellular mechanism to produce their anti-inflammatory effect. COX = cyclooxygenase; LT = leukotriene; PG = prostaglandin.

TABLE 191-2 NSAID Toxicity at Therapeutic Doses

Organ System	Clinical Toxicity
CNS	Behavioral changes, cognitive difficulties, headache, psychosis, aseptic meningitis
Cardiovascular	Increased risk of myocardial infarction and risk of sudden death following myocardial infarction
Pulmonary	Bronchospasm, hypersensitivity pneumonitis, pulmonary edema
GI	Dyspepsia,* nausea,* heartburn,* gastritis, gastric and duodenal erosions, mucosal bleeding,* gastric and duodenal perforation
Hepatic	Spectrum of hepatic injury ranging from asymptomatic elevation of serum transaminases to fulminant hepatic failure
Renal	Sodium and water retention,* hyperkalemia, azotemia,* acute tubular necrosis, interstitial nephritis, renal failure
Hematologic	Increased risk of bleeding, bone marrow suppression, aplastic anemia, agranulocytosis, red cell aplasia, hemolytic anemia, thrombocytopenia
Dermatologic	Maculopapular rashes, photosensitivity reactions, Stevens-Johnson syndrome, toxic epidermal necrolysis
Bone	Delayed wound and fracture healing
Reproductive	Slowed uterine contractions, premature closure of ductus arteriosus, fetal intracranial hemorrhage, necrotizing enterocolitis, oligohydramnios

*Common side effects.

inhibitors, diuretics, and α- and β-adrenergic antagonists. Inhibition of prostaglandin synthesis is believed to be a central mechanism for these effects. Lower prostaglandin levels result in alterations in the renin-angiotensin system causing decreased renal sodium clearance, water retention, and changes in vascular tone.[13]

Warfarin Warfarin and NSAIDs have several important interactions that may increase the risk of bleeding.[14] Some NSAIDs may displace warfarin from plasma proteins, but the effect is small and does not lead to increased anticoagulation. The selective COX-2 inhibitors at therapeutic doses also elevate prothrombin times, likely through decreased elimination of warfarin. Other nonselective NSAIDs have not been reported to change warfarin protein binding or elimination, but their use is not recommended in warfarin users because they inhibit platelet aggregation and can significantly increase the risk of bleeding.

Decreased Renal Clearance of Drugs NSAIDs may also decrease renal clearance via inhibition of renal prostaglandin synthesis, decreasing their vasodilatory effect, causing a decrease in renal blood flow and glomerular filtration rate, and ultimately decreasing the rate of elimination of certain drugs. Therefore, NSAID use can lead to increased concentrations of consequential drugs such as lithium, methotrexate, and metformin. NSAIDs are a potential risk factor in the development of metformin-associated lactic acidosis, a rare complication of metformin therapy with a high mortality.[15]

CLINICAL FEATURES

TOXICITY AT THERAPEUTIC DOSES

NSAIDs are generally safe drugs but have a number of well-reported side effects at therapeutic doses (**Table 191-2**). It is generally believed that indomethacin and other long-acting agents, such as piroxicam, are responsible for a greater proportion of side effects, whereas the propionic acid agents, such as ibuprofen, are responsible for fewer side effects.

Central Nervous System CNS adverse effects at therapeutic doses include headache, cognitive difficulties, behavioral change, and aseptic meningitis.[16,17] Acute psychosis has been reported with indomethacin and sulindac use, which is hypothesized to result from the structural similarity of these NSAIDs to serotonin.

Patients with NSAID-induced aseptic meningitis may experience symptoms of headache, fever, and neck stiffness occurring within hours of a therapeutic dose.[16-18] Cerebrospinal fluid analysis of these patients finds elevated WBC counts and protein levels with normal or decreased glucose levels. Symptoms resolve after NSAID use is stopped and in some cases recur with repeat NSAID challenges.[18,19] This phenomenon is most often seen in patients who have underlying autoimmune diseases, such as systemic lupus erythematosus, and is thought to be a hypersensitivity reaction. Exclusion of an infectious cause is necessary before the diagnosis of NSAID-induced aseptic meningitis can be assigned. Agents associated with aseptic meningitis include celecoxib, diclofenac, ibuprofen, ketoprofen, naproxen, rofecoxib, sulfasalazine, sulindac, and tolmetin.

Cardiovascular Increased cardiovascular events, including myocardial infarction, have been reported with long-term use of both nonselective NSAIDs and selective COX-2 agents.[20] The observed risk increase is variable among the different agents, but risk is dose and duration dependent, as well as more profound in patients with established coronary artery disease.[20,21] Selective COX-2 inhibitors are associated with a doubling of the relative risk of myocardial infarction and heart failure.[22] For nonselective NSAIDs, no increase in major vascular events has been observed with naproxen, whereas ibuprofen and diclofenac regimens were associated with a relative risk for major vascular events as much as 1.5 that of placebo.[22] A stepped-care approach to NSAID use for managing musculoskeletal symptoms in those with known cardiovascular disease or risk factors is recommended.[22,23] Begin therapy with medications not associated with increased cardiovascular effects, such as acetaminophen, and progress carefully to nonselective NSAIDs, or for patients over 75 years of age, use a topical rather than oral NSAID.[24-26]

Pulmonary NSAIDs have been associated with adverse pulmonary reactions, including bronchospasm in asthmatics, hypersensitivity pneumonitis, and pulmonary edema. Patients with NSAID-related hypersensitivity pneumonitis may complain of fever, cough, and shortness of breath. Chest radiographs may show pulmonary infiltrates, and blood work may show leukocytosis and eosinophilia. Cessation of NSAID use resolves the symptoms, whereas rechallenging causes recurrence. NSAIDs implicated in hypersensitivity pneumonitis include diclofenac, diflunisal, naproxen, piroxicam, and sulindac. The mechanism of NSAID-mediated

pneumonitis is also thought to be an immune-mediated hypersensitivity reaction.

NSAID-induced bronchospasm is a well-described phenomenon in patients with reactive airways disease. The spectrum of this reaction ranges from rhinitis to severe bronchospasm with laryngeal edema.[27] Patients with underlying reactive airways disease and nasal polyps are at greater risk for these complications. The mechanism of this hypersensitivity reaction to NSAIDs in asthmatics does not appear to be immunoglobulin E–mediated but rather may result from excessive production of leukotrienes.

Gastrointestinal The greatest morbidity caused by therapeutic use of NSAIDs is GI.[9,28] These effects derive from inhibition of cytoprotective gastric prostaglandins resulting in injuries ranging from dyspepsia, heartburn, and nausea, to life-threatening bleeding.[5] During long-term therapy (>3 months), endoscopic ulcers are observed in 10% to 30% of patients, but only 1% to 2% experience serious ulcer complications, such a bleeding or perforation. Patients at higher risk for GI bleeding include those with a history of ulcers, those taking high doses of NSAIDs or corticosteroids, and the elderly.[29-31] Reduced incidence of GI side effects has been observed with celecoxib, but not other COX-2–selective agents, such as rofecoxib.

Hepatic Clinically apparent liver injury caused by NSAIDs is most likely idiosyncratic and rare, occurring in 1 to 10 cases per 100,000 prescriptions.[32,33] More commonly, asymptomatic elevations of serum transaminases are seen in up to 18% of users taking NSAIDs over a long period. Diclofenac and sulindac are the two NSAIDs most commonly linked to hepatotoxicity. Stopping the drug should lead to complete recovery while also avoiding other NSAIDs that may cause recurrence.

Renal NSAIDs exert many toxic effects on the kidney.[5,6] COX inhibition decreases prostaglandin synthesis, leading to vasoconstriction of the renal vascular supply with resultant reversible prerenal azotemia. Continued use may lead to acute tubular necrosis. Interstitial nephritis may result from NSAID-associated activation of inflammatory cells. Glomerular injury may be caused by caused by proinflammatory leukotrienes stimulated by NSAIDs resulting in alteration of glomerular permeability. Chronic renal injury in the form of patchy necrosis, as well as medullary ischemia, is associated with chronic, large cumulative doses of NSAIDs, resulting from chronic inhibition of vasodilatory prostaglandins. Additionally, chronic interstitial fibrosis, hyperkalemia, and hyponatremia may be caused by NSAID use.[34]

Hematologic Nonselective NSAIDs inhibit platelet formation of thromboxane A_2, a potent stimulator of platelet aggregation, resulting in qualitative platelet deficiencies. The new COX-2 inhibitors have far fewer antiplatelet effects than traditional NSAIDs, which may explain why an increase in cardiac and neurovascular events in patients taking the COX-2 inhibitor rofecoxib was observed versus the nonselective COX-1 inhibitor naproxen. Most NSAIDs decrease platelet aggregation only when significant concentrations of the drug are present, and therefore, increased bleeding tendencies from NSAIDs are not widely reported.

Bone marrow suppression and aplastic anemia are rare hematologic complications of almost all NSAIDs with indomethacin, diclofenac, and phenylbutazone responsible for most reported cases. NSAID use has also resulted in agranulocytosis, hemolytic anemia, red cell aplasia, and thrombocytopenia.

Dermatologic NSAIDs account for approximately 10% to 27% of all cutaneous drug reactions.[35] The agents most frequently involved in dermatologic complications include benoxaprofen, phenylbutazone, and piroxicam. Drug reactions to NSAIDs range from benign maculopapular rashes to Stevens-Johnson syndrome and toxic epidermal necrolysis. NSAIDs are among the most commonly implicated drugs in cases of toxic epidermal necrolysis, accounting for up to one third of drug-related cases. NSAIDs of all types (oral and topical) can cause photosensitivity reactions including increased sensitivity to sun exposure (phototoxic) and true photoallergic reactions (see chapter 249, "Generalized Skin Disorders"). Ketoprofen and piroxicam are the most frequently involved in photoallergic reactions. Isoxicam was removed from the U.S. market after fatal skin reactions.

Bone Controversy surrounds the use of NSAIDs for control of pain resulting from a fractured bone. Although NSAIDs are well known to treat musculoskeletal pain effectively, bone healing is a complex cascade of events that involves prostaglandins' influence on the balance between bone formation and resorption.[36] With conflicting results regarding wound healing, some orthopedists recommend delayed administration of NSAIDs for 3 to 4 weeks following a fracture, using judicious doses, and possibly avoiding NSAIDs altogether in cases of spinal fusion.[37]

Reproductive Prostaglandins are found in high concentration in the uterus at term and have a stimulatory effect on normal labor. NSAIDs will impair uterine motility through inhibition of prostaglandin synthesis. Although NSAIDs are not believed to be teratogenic in humans, they cross the placenta in late pregnancy. One of the most significant effects of fetal exposure to NSAIDs is premature constriction of the ductus arteriosus that may result in fetal pulmonary hypertension. Other reported effects of in utero exposure to NSAIDs include fetal intracranial hemorrhage, necrotizing enterocolitis, oligohydramnios, and renal dysfunction. NSAID-induced inhibition of platelet aggregation may place the fetus and the mother at increased risk for peripartum hemorrhage. **The safest recommendation is to avoid NSAID use during pregnancy, especially during the third trimester.**

TOXICITY WITH ACUTE OVERDOSE

Although the vast majority of patients with acute overdoses suffer little morbidity, some fatalities occur with massive NSAID ingestions that often include the clinical features of altered mental status, metabolic acidosis, and shock.[38-41] Historically, phenylbutazone was most commonly associated with severe toxicity following an overdose, and although it was withdrawn from the U.S. market in the 1970s, it is still available from veterinary sources and in other countries. By a wide margin, ibuprofen is the most common agent currently reported in NSAID overdoses. Patients who develop symptoms following an ibuprofen overdose usually ingest more than 100 milligrams/kg, and initial symptoms predominantly include abdominal pain, nausea, and vomiting, all beginning within 4 hours of ingestion (**Table 191-3**). Most patients who manifest severe toxicity, including apnea, coma, and metabolic acidosis, ingest more than 400 milligrams/kg. There is limited published experience concerning acute overdose of COX-2 inhibitors, but they are assumed to have similar profiles as the nonselective NSAIDs.

Central Nervous System CNS manifestations of acute NSAID overdose are usually minimal, although patients with significant overdose may have headache, diplopia, nystagmus, and altered mental status including coma.[17] Mefenamic acid has been identified as a drug with high potential for seizures in overdose.[42] Muscle twitching and seizures that are responsive to benzodiazepines have been reported.

Cardiovascular Acute NSAID overdose can result in hypotension and bradydysrhythmia. NSAIDs are not known to be a primary cause of dysrhythmias, but fluid and electrolyte abnormalities provoked by NSAID toxicity may induce cardiac rhythm abnormalities. Cardiovascular dysfunction from acute NSAID overdose is responsive to conventional critical care management.

Metabolic Electrolyte and acid-base abnormalities may occur in acute NSAID overdoses. Alterations in serum electrolytes may develop

TABLE 191-3 NSAID Toxicity after an Acute Overdose

Initial symptoms within 4 h after ingestion	Abdominal pain, nausea, vomiting
CNS	Headache, nystagmus, diplopia, altered mental status, coma, muscle twitching, and seizures (mefenamic acid)
Cardiovascular	Hypotension, shock, bradydysrhythmia
Metabolic	Hyperkalemia, hypocalcemia, hypomagnesemia
GI and hepatic	Continued abdominal pain, nausea, vomiting, hepatic injury, pancreatitis (rare)
Renal	Acute kidney injury

secondary to decreased prostaglandin synthesis or from NSAID-induced renal failure. Sodium and water retention may lead to volume overload in patients with preexisting cirrhosis, heart failure, or renal failure. Hyperkalemia, hypocalcemia, and hypomagnesemia have been reported in NSAID overdoses complicated by acute renal failure.

Increased anion gap metabolic acidosis has been observed with large overdoses of ibuprofen and naproxen, which may be due to these NSAIDs and their metabolites being weak acids. Concurrent lactic acid production in the setting of NSAID-induced seizures and shock may exacerbate the acidosis in some cases.

GI and Hepatic Patients presenting after acute NSAID overdose may have abdominal pain, nausea, and vomiting, but life-threatening GI hemorrhage is not a typical finding after acute overdoses. Overdose may also result in hepatic injury, as measured by cholestasis and elevated transaminase levels. Rare cases of pancreatitis have been reported after overdoses of ibuprofen, naproxen, and indomethacin.[43-45]

Renal NSAID overdose rarely causes acute kidney injury but may place a stressed renal system at risk for failure. The clinical presentation may include hematuria and oliguria. Most patients with acute renal failure due to an NSAID overdose have eventual recovery of renal function, but some may need long-term dialysis.

TREATMENT

Most patients who present following an NSAID overdose will be asymptomatic. Follow the general principles for managing the poisoned patient (see chapter 176, "General Management of Poisoned Patients"), including screening for possible co-ingestants, consultation with a toxicologist, and consideration of GI decontamination. Attempt to ascertain whether the amount of drug ingested was less than 100 milligrams/kg (unlikely to result in toxicity) or more than 400 milligrams/kg (significant risk for toxicity).

Asymptomatic NSAID ingestions usually require minimal laboratory evaluation and supportive care (**Figure 191-2**). GI decontamination is best accomplished with activated charcoal and may be considered depending on the perceived risk of severe ingestion and clinical condition. Gastric lavage is not useful in the majority of cases but may be considered for a patient who has ingested a massive quantity within the past hour, especially mefenamic acid or phenylbutazone. Fluid and electrolyte replacement is given as necessary. Consider screening for potentially dangerous co-ingestants by measuring the serum acetaminophen and salicylate levels and obtaining a 12-lead ECG.

Patients who are symptomatic with altered mental status, seizures, shock, respiratory distress, or cardiac dysrhythmias require aggressive resuscitation and stabilization (Figure 191-2). Establish an airway as needed, institute mechanical ventilation when necessary, treat hypotension with fluid boluses and/or vasopressors, and manage seizures initially with IV benzodiazepines. Consider gastric lavage for recent ingestions involving mefenamic acid or phenylbutazone. Whole-bowel irrigation is recommended for severe overdose with enteric-coated formulations. Multidose activated charcoal has no proven benefit in symptomatic NSAID overdoses. Hemodialysis, hemofiltration, or charcoal hemoperfusion are not effective in enhancing elimination because NSAIDs are highly protein bound. Likewise, manipulation of serum and urine pH through IV alkalinization is not beneficial in enhancing renal elimination.

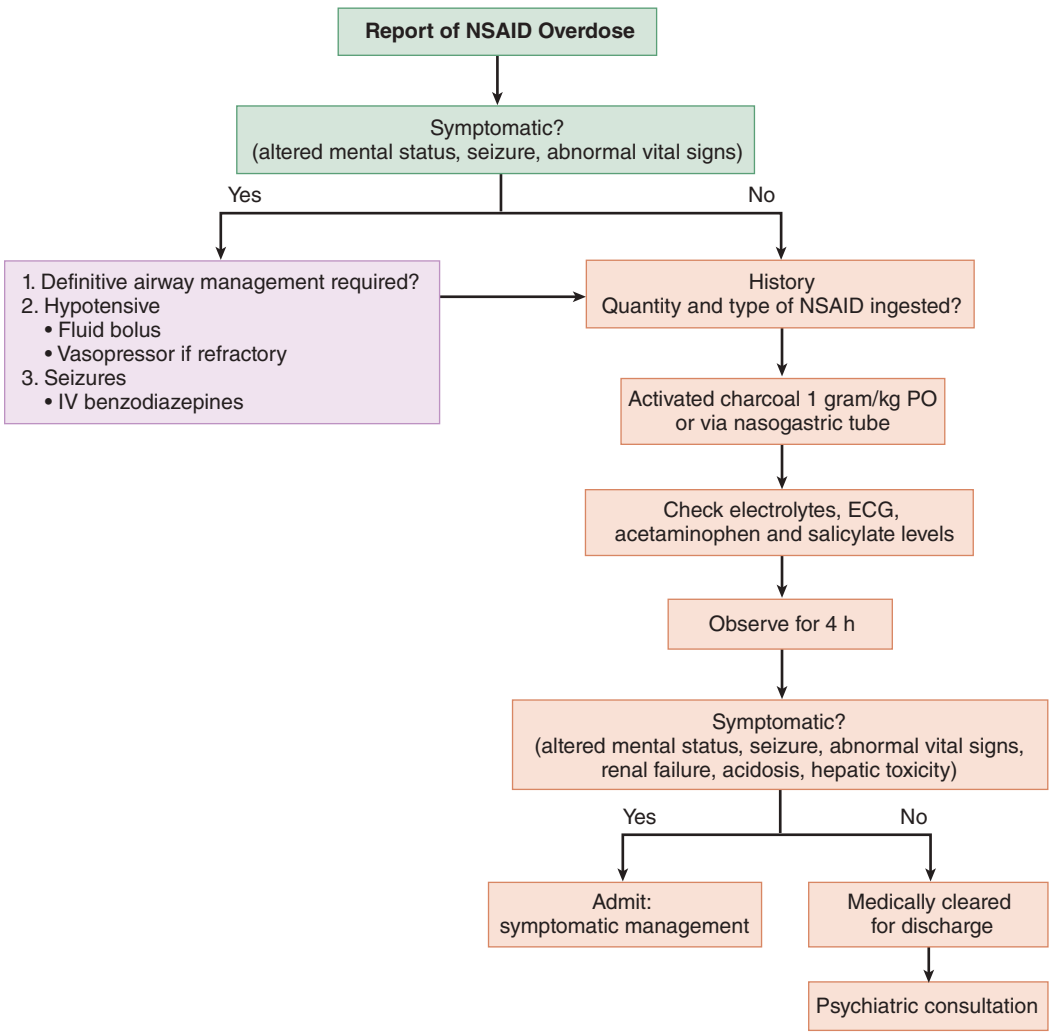

FIGURE 191-2. Approach to treatment of acute nonsteroidal anti-inflammatory drug (NSAID) overdose.

Patients with symptomatic NSAID overdoses should have a serum chemistry panel, hepatic profile, CBC, coagulation profile, and serum salicylate and acetaminophen levels measured. Serum NSAID levels do not correlate with observed toxicity or outcomes, so serum levels for specific NSAIDs are not indicated.

DISPOSITION AND FOLLOW-UP

Most patients with asymptomatic NSAID ingestions can be safely discharged after a 4-hour period of observation. Patients with a symptomatic overdose (altered mental status, abnormal vital signs, electrolyte abnormalities, or acute renal failure) should be admitted for observation and supportive care. All overdoses should be reported to the regional poison control center both for management assistance and for statistical tracking. The majority of NSAID overdoses will not cause significant sequelae. Even patients with major symptoms have a good prognosis if they overcome the initial insult.

CHAPTER 192

Methylxanthines and Nicotine

Chip Gresham
Daniel E. Brooks

INTRODUCTION

Methylxanthines include **caffeine**, **theophylline**, **theobromine**, and **nicotine**. These agents are plant-derived alkaloids with ubiquitous use in beverages (caffeine in coffee and soda), foods (theobromine in chocolate), tobacco products (nicotine), and medications (theophylline and caffeine). Newer methylxanthine derivatives include pentoxifylline (improves peripheral blood flow) and doxofylline (a bronchodilator).[1,2] All methylxanthines have shared pharmacologic properties and very similar pharmacodynamic effects.

METHYLXANTHINES

EPIDEMIOLOGY

Caffeine (1,3,7-trimethylxanthine), a methylxanthine and structural analog of adenosine, is the most commonly used psychoactive drug in the world and the only one that can be legally purchased by children. It is found in varying amounts in beverages and "energy-enhanced" foods, such as candy bars, potato chips, and oatmeal (**Table 192-1**).[3] Nearly 6 billion caffeinated "energy drinks" were purchased in the United States in 2012.[4] Many "energy drinks" contain guarana, a plant whose seeds contain high concentrations of caffeine and other methylxanthines. Drinks with guarana may not list caffeine as an ingredient.[5] Other uses for caffeine include apnea of prematurity, analgesic adjuncts, appetite suppression for weight loss, sleep prevention, and diuresis.

Theophylline (1,3-dimethylxanthine) and its water-soluble salt, **aminophylline**, were used extensively in the past for the treatment of asthma and chronic obstructive pulmonary disease. However, theophylline's use has declined due to its narrow therapeutic window and the development of safer agents. Theophylline is still used in patients with debilitating bronchospastic disease, particularly outside the United States, and has been studied for the treatment of other diseases, including acute mountain sickness and contrast-induced nephropathy.[6,7]

Theobromine (3,7-dimethylxanthine) is found in the seeds of *Theobroma cacao*, from which chocolate and cocoa are derived; and *Commelia thea*, from which teas are steeped; and is an ingredient in numerous "energy drinks" in addition to caffeine. There are very few cases of human toxicity, but theobromine has been associated with atrial fibrillation.[8]

TABLE 192-1 Caffeine Content of Various Products

Source	Caffeine Content (milligrams)
Coffee (8 oz or 240 mL, brewed)	60–120
Tea (8 oz or 240 mL, brewed)	20–90
Colas, caffeinated (8 oz or 240 mL)	20–40
Dark chocolate (1 oz or 30 mL)	5–35
"Higher caffeine energy drinks" (8–24 oz)	70–505
Acetaminophen-aspirin-caffeine tablet	65
Nonprescription antidrowsiness tablet	200

PHARMACOLOGY

Caffeine is most commonly consumed orally; however, it can be administered rectally or parenterally. Theophylline is usually taken orally, although its absorption may be affected by food. It is available as an elixir or as extended-release and controlled-release tablets. Controlled-release tablets can result in erratic or rapid absorption. Theophylline can also be administered IV as aminophylline.

All methylxanthines are rapidly absorbed with early peak levels; they cross the blood–brain barrier and placenta and are excreted in breast milk (**Table 192-2**). Half-lives are only accurate at therapeutic concentrations and vary based on several factors, including drug level, age extremes, smoking, organ system dysfunction (e.g., cirrhosis), infection, and cytochrome P-450 inhibition (**Table 192-3**).

Methylxanthines exhibit Michaelis-Menten kinetics; that is, metabolism changes from first-order to zero-order kinetics at increased concentrations such that a fixed amount, not percentage, of drug is eliminated per unit of time, making accurate half-life calculations impossible following an overdose. This also explains why patients who chronically use theophylline may develop a large increase in serum theophylline concentration with only a small increase in dose. Methylxanthines are metabolized in the liver by the cytochrome P-450 1A2 pathway. Theophylline undergoes significant enterohepatic recirculation, so toxic serum levels can be maintained longer than anticipated.

TABLE 192-2 Pharmacokinetics of Methylxanthines

Parameter	Caffeine	Theophylline
Therapeutic serum concentration	5–20 micrograms/mL (25–100 micromoles/L)	8–20 micrograms/mL (44–110 micromoles/L)
Bioavailability (oral)	~100%	~100%
Oral peak absorption (h) (delayed in overdose)	0.5–1.0	1–2 (up to 8 h with sustained release preparations)
Volume of distribution (L/kg)	~0.6	~0.5
Protein binding	~35%	~60%
Major active metabolites	Paraxanthine Theobromine Theophylline	Caffeine (only if <6 mo old)
Clearance	Hepatic	<1 y old: 50% hepatic and 50% renal >1 y old: 90% hepatic and 10% renal
Half-life (accurate only at therapeutic concentrations)	Neonates: >50 h <1 y old: 20 h >1 y old: 5 h	Neonates: 20–30 h Children and adults: 5 h > 60 y old: 10 h

TABLE 192-3 Factors Affecting Theophylline Clearance

	Increases Theophylline Clearance	Decreases Theophylline Clearance
Medications	Barbiturates Benzodiazepines (suspected) Carbamazepine Phenytoin St. John's wort	Cimetidine Ethanol (coingested) Erythromycin (all macrolides suspected) Oral contraceptives Propranolol (metoprolol suspected) Fluoroquinolones (most) Verapamil
Medical conditions		Cirrhosis Heart failure Pneumonia (other infections suspected)
Other	Hyperthyroid Tobacco Marijuana (cannabis)	Pregnancy Obesity Fever (suspected)

TABLE 192-5 Clinical Manifestations of Methylxanthine Toxicity

Organ System	Manifestation
GI	Nausea Vomiting Gastritis
Neurologic	Headache Tremor Agitation Seizure
Cardiovascular	Hypotension Tachycardia Atrial arrhythmias Ventricular ectopy
Metabolic	Hypokalemia Metabolic acidosis Hyperglycemia Hyperthermia Rhabdomyolysis

CLINICAL FEATURES OF TOXICITY

Theophylline has the most potential for significant toxicity, followed by caffeine and then theobromine. The underlying pathophysiology involves adenosine antagonism, increased endogenous adrenergic stimulation, and, at toxic levels, phosphodiesterase inhibition (**Table 192-4**).

The main organ systems involved in methylxanthine toxicity are GI, neurologic, cardiovascular, and metabolic (**Table 192-5**).

GI Toxic Effects **Nausea and vomiting** are reported in >70% of acute overdoses.[9] Theophylline can also induce esophageal reflux by decreasing lower esophageal sphincter pressure.

Neurologic Toxic Effects **Methylxanthine-induced seizures** can be severe and refractory to treatment. First-time seizures in the setting of heavy caffeinated "energy drink" consumption have been reported.[4,10] In theophylline toxicity, incidence of seizures is approximately 50% when serum levels are >40 micrograms/mL (>200 micromoles/L) during chronic therapy and >120 micrograms/mL (>600 micromoles/L) after an acute ingestion.[9] Seizures at a lower serum concentration, even as low as 20 micrograms/mL (100 micromoles/L), are more likely in chronic toxicity due to relatively higher tissue levels. In chronic toxicity, seizures can occur without prior neurologic symptoms of tremor or agitation.

Cardiovascular Toxic Effects Methylxanthines induce the release of endogenous catecholamines, stimulating β-adrenergic receptors, resulting in increased inotropy and chronotropy, vasodilation, hypotension, and reflex tachycardia. Sinus tachycardia is the most common cardiac manifestation of both caffeine and theophylline use and toxicity. Atrial fibrillation and supraventricular tachycardia are described with excessive caffeine intake.[11,12] Theophylline toxicity may result in atrial arrhythmias such as multifocal tachycardia and fibrillation/flutter. Ventricular ectopy are more common with chronic toxicity and in patients with advanced age or underlying cardiac dysfunction.[13] Ventricular fibrillation and tachycardia are rare.

Metabolic Toxic Effects Methylxanthine toxicity is associated with hypokalemia, hyperglycemia, and metabolic acidosis. Hypokalemia is most common in acute overdose, due to increased catecholamines. Rhabdomyolysis has been reported in caffeine and theophylline overdoses, presumably due to the hypermetabolic state, agitation, and seizures.

Chronic use of methylxanthines, particularly caffeine, can lead to tolerance, dependence, or withdrawal. Caffeine withdrawal syndrome has a varied course depending on use. Withdrawal symptoms typically start at 6 to 24 hours after the last dose, peak at about 36 hours, and can last for several days. Headache and fatigue are the most common symptoms and are seen after either chronic use or short-term, high-dose exposures. **Caffeine withdrawal headaches** can be debilitating and should be included in the differential diagnosis of ED patients with headache.

DIAGNOSIS OF TOXICITY

Caffeine Toxicity There is no clearly defined toxic dose or level of caffeine. Following a single ingestion of 120 milligrams of caffeine, an average peak serum concentration of 3 micrograms/mL (15 micromoles/L) results at 1 hour. Caffeine doses around 120 milligrams enhance arousal and performance of both cognitive and psychomotor skills.[14]

Ingestions of 100 to 150 milligrams/kg or serum levels >100 micrograms/mL (>500 micromoles/L) are likely to cause life-threatening toxicity, and an acute ingestion of >200 milligrams/kg can be lethal.[5,15] Serum caffeine concentrations are not readily available in most clinical

TABLE 192-4 Methylxanthine Mechanisms of Action and Toxicity

	Adenosine Antagonism	Increased Catecholamines	Inhibition of Phosphodiesterase
Mechanism	Inhibition of adenosine-1 and adenosine-2 > adenosine-3 receptors	Increased circulating catecholamines (epinephrine and norepinephrine)	Phosphodiesterase inhibition (at toxic levels)
Effect	Decreased adenosine activity Increased excitatory neurotransmitters activity	Stimulation of β_1 and β_2 receptors	Increased concentration of cyclic adenosine monophosphate and catecholamine effects
Therapeutic effect	Bronchodilation	Bronchodilation	No role at therapeutic doses
Clinical toxicity	Vasoconstriction Arrhythmias Seizures	Tachycardia Vasodilation Hypotension	Enhanced β-adrenergic effects

TABLE 192-6 Methylxanthine Toxicity Classifications

	Acute Toxicity	Acute on Chronic Toxicity	Chronic Toxicity
Clinical scenario	Acute exposure: one-time ingestion of a bottle of theophylline or caffeine tablets	Acute exposure in a person chronically using that methylxanthine: an acute ingestion of a bottle of theophylline in a patient taking theophylline	An ongoing exposure to a stable amount with bioaccumulation; typically due to decreased clearance: a newly prescribed medication inhibits theophylline metabolism, leading to slowly increasing tissue concentrations
Risk of clinical effects	Variable, depends on amount	High, depends on amount ingested and comorbidities	High, depends on tissue level of drug, age, and comorbidities
Timing of peak serum concentration	Often delayed for many hours	Usually delayed	Often immediately available
Correlation of peak serum concentration with clinical effects	Moderate correlation	Moderate correlation	Weak correlation

settings and offer little in terms of clinical decision making, so management of caffeine toxicity is guided by clinical findings.

Theophylline Toxicity Although there is an established therapeutic serum concentration for theophylline, clinical effects are determined by the amount of free drug in tissue, not the serum. **The best predictor of major theophylline toxicity after an acute overdose—seizures, hypotension, or cardiac arrhythmias—is the peak serum concentration. In chronic toxicity, although serum levels are elevated, the level itself does not necessarily predict major toxicity.** An elevated theophylline level is more likely to be associated with major toxicity in those >65 years old (odds ratio, 7.8; 95% confidence interval, 2.9–21.1) than in those 30 to 65 years old (odds ratio, 3.2; 95% confidence interval, 1.03–10.1).[16] In an acute ingestion, monitor serial theophylline levels to establish a trend in absorption, document the peak concentration, and assist in the medical clearance of patients as peak levels may be delayed many hours following a massive, acute overdose (**Table 192-6**). Conversely, management decisions should be based on symptoms and the patient's clinical condition, not on drug levels alone.

TREATMENT

As with the majority of poisoned patients, there are three main components to caring for a patient with methylxanthine toxicity: resuscitation (stabilizing cardiovascular and pulmonary function), GI decontamination to interrupt continued absorption (when appropriate), and minimizing end-organ effects. Supportive care and an appropriate observation period are required to prevent secondary sequelae. Monitor patients in a high-acuity setting. Treatments specific to methylxanthines, particularly theophylline, include use of activated charcoal, treatment of arrhythmias and seizures, and enhanced elimination.

Initial ancillary studies should include ECG, serum electrolytes, creatinine, urea, glucose, and total creatinine kinase. Other laboratory tests may be required based on patient presentation, available medications, and comorbidities. After an intentional ingestion, consider comorbid poisonings, such as with acetaminophen or salicylate. Consult with a medical toxicologist or a regional poison control center to discuss optimal, case-specific treatment.

GI Decontamination Consider GI decontamination when dealing with a potentially life-threatening **theophylline** poisoning provided there are no contraindications, such as an unprotected airway, intractable nausea or vomiting, ileus, bowel obstruction, or need for emergent endoscopy (**Table 192-7**).[17] In **caffeine** ingestion, there is little benefit to GI decontamination because of the rapid absorption and associated nausea.

Ondansetron is the preferred antiemetic to control any associated nausea or vomiting. Do not use phenothiazines (i.e., promethazine) because these agents lower the seizure threshold. Ranitidine can be used to decrease gastric acid hypersecretion. **Do not give cimetidine as it can prolong methylxanthine half-life.**

Multidose activated charcoal can enhance theophylline elimination by interrupting enterohepatic recirculation.[18] Consult with a toxicologist or poison center regarding the use of whole-bowel irrigation for the ingestion of sustained-release preparations.[19] Endoscopic removal of a slow-release, theophylline-containing bezoar may be necessary. Ipecac syrup, cathartics, and gastric lavage after theophylline ingestion have no proven benefit, have potential adverse effects, and are not recommended.[20,21]

Seizures Due to adenosine antagonism, seizures may be difficult to control, particularly with theophylline toxicity. Benzodiazepines, such as lorazepam 2 to 4 milligrams IV or diazepam 5 to 10 milligrams IV in adults, are first-line agents. Repeated, larger doses may be necessary. Barbiturates, such as phenobarbital 10 to 20 milligrams/kg IV in adults, should be used if escalating doses of benzodiazepines are ineffective. At high doses, benzodiazepines and barbiturates can compromise the airway or lead to respiratory depression, so maintain a low threshold for endotracheal intubation. Phenytoin is not useful or recommended.[22]

Patients who fail to respond to anticonvulsant therapy should be sedated, intubated, and paralyzed with a neuromuscular blocking agent; general anesthesia may be required. Paralyzed patients should have an electroencephalogram to monitor for continued seizure activity. Due to the severity of theophylline-induced seizures, some toxicologists recommend prophylactic use of a γ-aminobutyric acid agonist (e.g., lorazepam) to raise seizure threshold in patients presenting with markedly elevated theophylline levels, but this approach has not been validated in human studies.

Cardiovascular Support Manage hypotension initially with IV fluids. The most commonly reported methylxanthine-induced tachyarrhythmias are atrial fibrillation and supraventricular tachycardia, presumably due to excessive β-adrenergic stimulation. Ventricular arrhythmias are uncommon.[23] Cardioselective β-blockers (esmolol or metoprolol) are an option for serious supraventricular dysrhythmias if routine interventions (vagal maneuvers, adenosine) are ineffective. Nonspecific β-blockers, such as propranolol, can lead to bronchospasm, so cardioselective β-blockers, such as esmolol or metoprolol, are preferred.

Enhanced Elimination The use of enhanced elimination techniques can prevent or help treat significant toxicity following methylxanthine poisonings. Multidose activated charcoal is recommended for toxic or potentially toxic theophylline ingestions.[18]

TABLE 192-7 GI Decontamination for Methylxanthine Toxicity

GI Decontamination Technique	Indication*	Dosing
Activated charcoal (single dose)	Acute ingestion	<12 y old: 0.5–1.0 gram/kg PO >12 y old: 25–100 grams PO
Multidose activated charcoal (requires close observation)	Acute ingestion	Normal activated charcoal loading dose, followed by: 0.25–0.5 gram/kg PO every 2–4 h for 12 h (frequency and duration may vary)
Whole-bowel irrigation using iso-osmolar polyethylene glycol electrolyte solution	Acute ingestion of sustained-release preparations	9 mo–6 y: 25 mL/kg per hour 6–12 y old: 1000 mL/h >12 y old: 1500–2000 mL/h Duration: 4–6 h or until clear rectal effluent

*Consider contraindications; for details see http://www.clintox.org/positionstatements.cfm.

Hemodialysis is safe and is as efficacious as hemoperfusion for the treatment of theophylline toxicity.[24] Hemodialysis is also effective for massive caffeine ingestions and pentoxifylline toxicity.[25,26]

Hemodialysis is readily available in many centers and provides fluid and electrolyte correction. The criteria for using hemodialysis in methylxanthine toxicity vary, but most experts suggest that a methylxanthine-induced life-threatening event, such as seizures or intractable arrhythmias, is an indication. **In addition, we suggest that dialysis should be considered when (1) after an acute ingestion, a symptomatic patient has a serum theophylline level >90 micrograms/mL (>500 micromoles/L), or (2) a chronic toxicity patient has a serum theophylline level >40 micrograms/mL (>220 micromoles/L) with significant symptoms or comorbidities.** Published experience suggests that most patients who receive hemodialysis **after** a methylxanthine-induced life-threatening event, such as a seizure or arrhythmia, will continue to have them, whereas as few as 5% of patients who received hemodialysis **before** manifesting severe toxicity will go on to develop a life-threatening event.[27]

Supportive Care Treat vomiting with antiemetics, and correct volume depletion with isotonic fluids. Hypokalemia may not require treatment unless there are clinical findings such as ECG changes, cardiac ectopy, or muscle weakness, because potassium is shifted intracellularly and total body potassium is only mildly depleted. Provide continuous cardiac monitoring until toxicity has resolved. Assess for hyperthermia, rhabdomyolysis, and compartment syndrome, and provide specific treatment. Patients who are sedated and paralyzed should undergo continuous electroencephalographic monitoring to evaluate for occult sustained or recurrent seizures.

DISPOSITION AND FOLLOW-UP

Following an intentional or accidental methylxanthine ingestion, patients are judged nontoxic when they are asymptomatic, have a normal physical examination and vital signs, and, if available, have normal or decreasing serum concentrations. Patients who remain asymptomatic for at least 6 hours after an acute ingestion of immediate-release tablets can be considered nontoxic. Patients with an ingestion of sustained-release medication should be monitored for 12 hours or longer. Patients with intentional ingestions should receive a behavioral health or psychiatric evaluation to assist with appropriate disposition and follow-up.

NICOTINE

EPIDEMIOLOGY

Nicotine is the primary alkaloid in tobacco, a product produced from the dried leaves of plants in the genus *Nicotiana*. Tobacco is consumed as smoked (i.e., cigarettes) or smokeless (i.e., chewing tobacco) products.[28] A typical cigarette contains approximately 20 milligrams of nicotine but only about 1 milligram is absorbed during smoking. Nicotine gums usually contain 2 or 4 milligrams per piece; formulation and mastication assist in higher absorption compared to smoking a cigarette. There is no consensus on the estimated lethal dose of nicotine, but experts do agree that while nicotine is potentially toxic, accidental ingestion of tobacco products, even in children, rarely results in serious outcomes.[29] Other nicotine sources include smoking cessation products (gums, patches, nasal inhalers), pesticides, traditional remedies, and plants, including dermal exposures during tobacco harvest causing "green-tobacco sickness."[30]

PHARMACOLOGY

Nicotine is rapidly absorbed in the lungs, as well as across mucous membranes, the intestinal tract, and intact skin. Smoking tobacco leads to a peak serum nicotine concentration of approximately 40 nanograms/mL (250 micromoles/L), depending on depth of inhalation. Nicotine crosses the blood–brain barrier and affects the CNS within seconds of smoking. Absorption across mucous (oral) membranes is slower than absorption from smoking and is further delayed by acid in the stomach. Therapeutic use of a 4-milligram piece of nicotine gum leads to a peak nicotine concentration of about 10 nanograms/mL (60 micromoles/L) at approximately 45 minutes.[31] The half-life of nicotine is variable, averaging approximately 2 hours in adults. Metabolism is by the liver, mainly by cytochrome P-450 2A6, with 85% being converted to **cotinine**.

Once absorbed, nicotine binds to nicotinic acetylcholine receptors throughout the body, including the central nervous, autonomic, and neuromuscular systems. Early in toxicity, nicotine acts as an agonist, activating these ion channels, leading to increased neuronal firing with release of neurotransmitters, including acetylcholine, dopamine, glutamate, norepinephrine, and serotonin. At higher concentrations and/or as toxicity persists, the acetylcholine receptors are inhibited by persistent membrane depolarization, ultimately leading to receptor inactivation.

TABLE 192-8 Clinical Effects of Nicotine Toxicity

	Signs and Symptoms of Nicotine Toxicity*	
Organ System	Immediate (<1 h)	Delayed (>1 h)
GI	Hypersalivation Nausea Vomiting	Diarrhea
Cardiovascular	Tachycardia Hypertension	Arrhythmias Bradycardia Hypotension
Neurologic	Tremor Headache Ataxia	Hypotonia Seizure Coma
Respiratory	Bronchorrhea	Hypoventilation Apnea

*Onset of toxicity is varied and can be delayed for hours following dermal exposure.

CLINICAL FEATURES OF TOXICITY

In overdose, nicotine mainly affects the GI, cardiovascular, neurologic, and respiratory systems (**Table 192-8**). Nausea and vomiting are the most common effects and can limit absorbed amounts following ingestion. Early effects are due to acetylcholine receptor activation and include tremor, dizziness, tachycardia, and bronchorrhea. Delayed effects, manifesting after larger exposures, occur due to receptor inactivation and include bradycardia, arrhythmias, hypoventilation, and coma. Seizures are possible and are due to centrally mediated actions.

Nicotine poisoning in children usually results from the ingestion of tobacco or nicotine-containing products. **A child who ingests one or more intact cigarettes, or three or more cigarette butts, has a 90% chance of becoming symptomatic, usually within 30 minutes.**[32] More severe poisonings, such as ingestion of nicotine-containing pesticides or abuse of dermal patches, can result in seizures, respiratory failure, hypotension, arrhythmias, and death. Because nicotine freely crosses the placenta and is found in small concentrations in breast milk, neonatal withdrawal is possible.[33]

Green-tobacco sickness is characterized by nausea, vomiting, weakness, dizziness, and headaches, due to the dermal absorption of nicotine during tobacco harvesting.[30] Onset of symptoms may be delayed for several hours. Patients with significant comorbidities, particularly underlying cardiovascular or seizure disorders, are theoretically at higher risk for morbidity.

Chronic nicotine use has been associated with insulin resistance in diabetics, increased cardiovascular risks, arrhythmias, and the potential for withdrawal.[34] Nicotine withdrawal manifests with irritability, depression, drowsiness, trouble sleeping, increased appetite, and headaches, with symptoms peaking at 2 to 3 days after last use. Withdrawal can occur in smokers as well as smokeless tobacco and nicotine gum users.

DIAGNOSIS OF TOXICITY

The diagnosis of acute nicotine toxicity is based on reliable history and physical examination, with laboratory analysis being of little value. Qualitative toxicologic screening assays can detect nicotine and cotinine in the urine but may only reflect exposure.

TABLE 192-9 Treatment of Nicotine Toxicity

Clinical Condition	Intervention	Considerations
Nausea, vomiting, gastritis	Antiemetics Proton pump inhibitors	Ondansetron, 4 milligrams IV Pantoprazole, 40 milligrams IV
Tremor, seizures	Benzodiazepines	Lorazepam, 1–2 milligrams IV Diazepam, 5–10 milligrams IV
Hypotension	Fluid resuscitation	Monitor and replace serum electrolytes
Hypoventilation	Intubation and mechanical ventilation	—
Withdrawal	Nicotine replacement therapy	Requires outpatient follow-up

TREATMENT OF TOXICITY

The treatment of nicotine toxicity is symptomatic. Fortunately, because nicotine has a very short half-life, symptoms typically resolve rapidly. Cardiovascular and ventilatory support may be required in severe toxicity (**Table 192-9**). Benzodiazepines may be used for seizures, and endotracheal intubation and mechanical ventilation may be required if significant neuromuscular weakness or respiratory depression develops. Ipecac syrup or activated charcoal is not recommended. Decontamination with soap and water may be beneficial following dermal exposures. There is no role for enhanced elimination or urine acidification.

Nicotine withdrawal can be distressing but is not life threatening. Treatment options include the use of nicotine replacement therapy and antidepressants.

DISPOSITION AND FOLLOW-UP

Monitor patients with known or suspected nicotine toxicity; the length of observation depends on the type of product ingested. Patients who remain asymptomatic with normal vital signs after 3 hours from an acute ingestion of nicotine-containing product (except intact transdermal patches) can be discharged from medical care. **Those who ingest intact transdermal patches should be observed longer, at least 6 hours.** Patients with intentional ingestions should receive a behavioral health or psychiatric evaluation to assist with appropriate disposition and follow-up.

CHAPTER 193

Digitalis Glycosides

Michael Levine
Aaron B. Skolnik

INTRODUCTION

The medicinal benefits of cardiac glycosides have been recognized for centuries, and even with other alternative medications, digitalis preparations, such as digoxin, are still used for the treatment of atrial fibrillation and symptomatic congestive heart failure.[1] In addition to availability as pharmaceuticals, cardiac glycosides are also found in plants such as foxglove, oleander, red squill, and lily of the valley. Similar cardioactive steroids are also found in the skin of toads in the Bufonidae family and in some herbal medications. Despite declining use of digoxin, the prevalence of patients diagnosed with digoxin toxicity has remained constant, and the use of digoxin-specific antibody fragments has increased.[2] Digitoxin, a cardiac glycoside similar in structure to digoxin but with a longer half-life, is no longer commercially available in the United States, but is available in Canada and elsewhere in the world.

PATHOPHYSIOLOGY

Digoxin is a cardiac glycoside available for oral or intravenous use. Following oral absorption, digoxin reaches a maximal serum concentration 1 to 3 hours after ingestion. It is approximately 25% protein bound and has a large volume of distribution (6 to 7 L/kg). The drug is primarily eliminated through the kidneys.

Digoxin, like other cardiac glycosides, inhibits sodium-potassium ATPase.[3] This inhibition results in increased intracellular sodium and increased extracellular potassium. As a result of the increased intracellular sodium, the sodium-calcium antiporter is not able to effectively remove calcium from the myocyte. Consequently, there is an increase in intracellular calcium, which augments inotropy. The increased intracellular calcium can contribute to delayed after-depolarizations, which may lead to premature ventricular contractions and dysrhythmias. In addition, there is a decreased refractory period of the myocardium, which increases automaticity and hence is associated with an increased risk of dysrhythmias. Furthermore, cardiac glycosides shorten atrial and ventricular repolarization, thereby decreasing the refractory period and thus increasing automaticity.

Cardiac glycosides also increase vagal tone via action at the carotid body, thereby reducing conduction through the sinoatrial and atrioventricular nodes. In toxic concentrations, cardiac glycosides can increase sympathetic tone. Digoxin can reduce plasma renin concentrations in patients with advanced heart failure, thereby resulting in peripheral vasodilation.[4] In contrast, in those without heart failure, digoxin can cause vasoconstriction. This difference is likely due to increased sensitivity of the carotid baroreceptors in patients with advanced, chronic heart failure.[5]

CLINICAL FEATURES

Digoxin has a narrow therapeutic index, and toxicity results from an exaggeration of its pharmacologic activity. The timing and clinical presentation of acute versus chronic digoxin toxicity differ significantly (**Table 193-1**).[6] In addition to cardiac manifestations such as syncope and dysrhythmia, digoxin toxicity may present with GI distress, dizziness,

TABLE 193-1 Clinical Presentation of Digitalis Glycoside Toxicity

	Acute Toxicity	Chronic Toxicity
Clinical history	Intentional or accidental ingestion	Typically elderly cardiac patients taking diuretics; may have renal insufficiency
GI effects	Nausea and vomiting, abdominal pain, anorexia	Nausea, vomiting, diarrhea, abdominal pain
CNS effects	Headache, dizziness, confusion, coma	Fatigue, weakness, confusion, delirium, and coma are often prominent features
Cardiac effects	Bradydysrhythmias or supraventricular tachydysrhythmias with atrioventricular block	Almost any ventricular or supraventricular dysrhythmia can occur; ventricular dysrhythmias are common
Electrolyte abnormalities	Hyperkalemia	Normal, decreased, or increased serum potassium, hypomagnesemia
Digoxin level	Marked elevation (if obtained within 6 h)	Minimally elevated or within "therapeutic" range

headache, weakness, malaise, delirium, or confusion. Thus, an elderly patient taking digoxin who presents with mental status changes should be evaluated for toxicity.

ACUTE TOXICITY

Patients with acute digoxin toxicity tend to have more abrupt onset of symptoms than those with chronic toxicity. In acute cardiac glycoside poisoning, there may be an asymptomatic period of several hours before the onset of symptoms. GI symptoms, such as nausea, vomiting, anorexia, and vague abdominal pain, are often the earliest manifestations of acute toxicity. Increased central vagal tone typically produces cardiac manifestations such as bradydysrhythmias or atrioventricular block. Neurologic manifestations such as weakness or confusion can occur independently of the blood pressure. The classic description of digoxin toxicity includes viewing yellow-green halos around objects, termed *xanthopsia*. However, patients more frequently describe nonspecific changes in their color vision.[7]

Hyperkalemia is an important finding in acute toxicity and may develop due to inhibition of sodium-potassium ATPase. Digoxin levels obtained with the first 6 hours following an acute ingestion may be falsely elevated as the level represents a predistribution level rather than reflecting the amount ingested. **Overall, the severity of acute toxicity correlates most closely with the degree of hyperkalemia and correlates poorly with the early serum digoxin levels.[8]**

CHRONIC TOXICITY

Chronic toxicity occurs most typically in the elderly and is often the result of drug–drug interactions or declining renal function. Some of the more common drug interactions that predispose to chronic digoxin toxicity include calcium channel antagonists, amiodarone, β-receptor antagonists, diuretics, indomethacin, clarithromycin, quinidine, procainamide, and erythromycin. In particular, interaction between digoxin and clarithromycin contributes to increased hospitalizations for digoxin toxicity in elderly patients.[9] A common scenario involves a patient starting to take a diuretic, which results in mild dehydration and hypokalemia; dehydration reduces the clearance of digoxin, and hypokalemia increases susceptibility to digoxin, resulting in chronic toxicity.

Decreases in renal function and lean body mass associated with aging may alter the pharmacokinetics of digoxin, leading to toxicity at normally therapeutic doses.[10] This population may also possess a higher risk due to coexisting diseases and polypharmacy.[10,11]

The patient with chronic digoxin toxicity often has vague and nonspecific signs and symptoms compared to the patient with acute digoxin toxicity. GI symptoms may occur but may be less pronounced. **Neurologic manifestations, such as weakness, fatigue, confusion, or delirium, are more prominent features in chronic toxicity.[6,12]**

DIAGNOSIS

The diagnosis of digoxin toxicity is a composite picture, using history, physical examination, and laboratory studies; no single element excludes or confirms the diagnosis. In patients with heart failure and normal renal function, daily digoxin doses are usually between 125 and 250 micrograms. Digoxin toxicity can occur with a single ingestion of 1 to 2 milligrams in an adult, and fatalities have been reported following an acute ingestion of 10 milligrams in an adult and 4 milligrams in a child.

Differential diagnosis includes other toxins that may induce bradydysrhythmias such as calcium channel antagonists, β-receptor antagonists, class IA antidysrhythmics (procainamide and quinidine), class IC antidysrhythmics (flecainide and encainide), clonidine and other imidazolines, and organophosphate or carbamate insecticide poisoning. Glycoside-containing and other cardiotoxic plants should also be considered (e.g., foxglove, squill, lily of the valley, oleander, rhododendron, monkshood, tobacco, false hellebore, and yew berry). Sick sinus syndrome, with its combination of supraventricular dysrhythmias and cardiac conduction blocks, can also mimic digoxin toxicity. Hyperkalemia from any cause may produce bradycardia and abnormal cardiac conduction and should be considered in the differential diagnosis.

ELECTROCARDIOGRAM

Almost any cardiac dysrhythmia may be observed in digoxin toxicity, with the exception of rapidly conducted atrial dysrhythmias.[13,14] **The most common dysrhythmia in digoxin toxicity is premature ventricular contractions.** Ventricular dysrhythmias occur more frequently in chronic than in acute poisonings. Although rare and not pathognomonic for digoxin toxicity, bidirectional ventricular tachycardia should be investigated for possible toxicity because only a few xenobiotics are known to produce this unique dysrhythmia, digoxin included.

Four specific electrocardiographic findings are seen with therapeutic levels of digoxin and are not indicators of toxicity, although they may also be seen in poisoned patients. These findings include T-wave changes such as flattening or inversion, QT-interval shortening, a "scooped" appearance of the ST segment with ST-segment depression, and an increase in U-wave amplitude (**Figure 193-1**).[14]

LABORATORY

In acute poisonings, the serum potassium and digoxin levels can provide useful diagnostic information.[15] As noted, acute poisoning of the sodium-potassium ATPase pump may result in markedly elevated serum potassium levels, and the serum potassium level is a better indicator of end-organ toxicity and a better prognostic indicator than the serum digoxin level in this circumstance.[8]

With chronic toxicity, in contrast to acute poisoning, the serum potassium and digoxin levels are less diagnostic. In these patients, the serum potassium is usually normal or low due to concomitant diuretic therapy, but may be elevated due to renal insufficiency. Thus, in the setting of chronic toxicity, measured serum potassium is more reflective of underlying comorbidities than the degree of inhibition of sodium-potassium ATPase by digoxin. Also, the serum digoxin level does not correlate with the clinical manifestations and *may be within therapeutic ranges* despite significant cardiac toxicity.

Serum digoxin levels should be interpreted in the overall clinical context and not relied upon as the sole indicator of the presence or absence of toxicity. Generally accepted therapeutic digoxin levels are 0.5 to 2.0 nanograms/mL (1.0 to 2.6 nmol/L), with corresponding toxic levels above 2.5 nanograms/mL (above 3.2 nmol/L). Due to a relatively slow distribution phase, high digoxin levels sampled from the serum following a recent acute ingestion are not always an accurate indicator of concentration at receptor sites. Serum levels are most reliable when obtained 6 hours after ingestion, when distribution is complete.[15] However, given the preceding limitations, it is still common that the higher the serum level, the greater is the likelihood of toxicity.[16] **Importantly, the serum digoxin level should not be the sole factor in establishing the diagnosis of digoxin toxicity, so do not wait for a digoxin level before implementing therapy in an unstable patient.**

Digoxin-like immunoreactive substances are substances that can be found in certain individuals that cross-react with the digoxin assay, artificially elevating the serum digoxin level, even in the absence of cardiac glycosides. Digoxin-like immunoreactive substances may be found in neonates, third-trimester pregnant women, patients with subarachnoid hemorrhage, and patients with renal or hepatic dysfunction. In addition, naturally occurring cardiac glycosides and cardioactive steroids from plants and animals may cross-react with digoxin assays. The degree of cross-reactivity is variable, and no reproducible correlation has been established between serum levels of these substances and toxicity.[17]

TREATMENT

Management of a digoxin-poisoned patient includes general supportive care, treatment of specific complications of toxicity, prevention of further drug absorption, enhancement of drug elimination, antidote administration when indicated, and safe disposition (**Table 193-2**).[6] Although patients with intentional or accidental ingestions may present with no symptoms, life-threatening complications of toxicity should be anticipated. Management of the asymptomatic patient should focus on preventing drug absorption and closely monitoring for the development of toxicity. Continuous cardiac monitoring, IV access, and frequent

FIGURE 193-1. ECG demonstrating findings seen with digoxin use. **A.** ECG shows scooping of ST segments and small U waves with a serum digoxin level of 0.9 nanogram/mL (1.15 nmol/L). **B.** ECG shows scooping of ST segments, flattening of T waves, and first-degree atrioventricular block with a serum digoxin level of 1.2 nanograms/mL (1.54 nmol/L).

reevaluations should be provided for any patient with a potentially toxic ingestion of digoxin.

For the patient with life-threatening dysrhythmias, identify and rapidly correct conditions such as hypoxia, hypoglycemia, hypovolemia, and electrolyte abnormalities. IV magnesium may counteract ventricular irritability seen with cardiac-glycoside toxicity.[18] Use atropine and/or transvenous cardiac pacing as a temporizing treatment for bradydysrhythmias while preparing or obtaining digoxin-specific antibody fragments.[19]

Digoxin-specific antibody fragments (digoxin-Fab) are the treatment of choice in acute poisoning with hyperkalemia (potassium >6.0 mEq/L) and in acute or chronic toxicity with any life-threatening dysrhythmia.[20-22] Hyperkalemia is not typically the cause of the death; it is a predictor of severe poisoning and increased mortality. Treatment of digoxin-induced hyperkalemia with insulin, dextrose, sodium bicarbonate, or exchange resins does not reduce mortality.[8]

Administration of calcium salts in cardiac glycoside–induced hyperkalemia is controversial. Older literature indicated an increased incidence of ventricular dysrhythmias and a higher mortality when calcium was administered to digoxin-toxic patients. However, data from an animal model and retrospective review of a limited number of human patients with digoxin toxicity who received IV calcium found no increase in ventricular dysrhythmias or mortality.[23-25] **In summary, hyperkalemia in acute digoxin poisoning indicates severe toxicity and digoxin-Fab should be given to reduce mortality.**

In chronic toxicity, hypokalemia and hypomagnesemia should be corrected, because both predispose to digoxin toxicity.

GI DECONTAMINATION AND ENHANCED ELIMINATION

Administrating activated charcoal may have utility in early acute ingestion of digoxin.[22] Activated charcoal may be of benefit following the acute ingestion of yellow oleander, although results of large, randomized trials have been mixed.[26] Gastric lavage is not recommended; asystole has been reported in a digoxin-toxic patient, presumably from vagal stimulation during lavage, and no clinical benefit has been demonstrated. Cathartics, forced diuresis, hemodialysis, and hemoperfusion have no role in enhancing elimination of digitalis glycosides. In patients with chronic renal failure who develop digoxin toxicity, there are limited data for the use of binding resins such as cholestyramine to help enhance elimination.[27,28]

DIGOXIN-SPECIFIC ANTIBODY FRAGMENTS (DIGOXIN-FAB)

Digoxin-Fab are derived from ovine antibodies to digoxin. Following IV infusion, the antibody fragments bind digoxin in the plasma and

TABLE 193-2 Overview: Treatment of Digitalis Glycoside Poisoning

Asymptomatic patients
Obtain accurate history
Secure IV access
Initiate continuous cardiac monitoring
GI decontamination: activated charcoal, 1 gram/kg PO, can be considered in an awake, alert, cooperative patient who presents within 1 h of ingestion
Frequent reevaluation
Symptomatic patients
Obtain accurate history
Secure IV access
Initiate continuous cardiac monitoring
GI decontamination: activated charcoal, 1 gram/kg PO, in an awake, alert, cooperative patient who presents within 1 h of ingestion
Bradydysrhythmias
Atropine: 0.5–1.0 milligram IV as a temporizing measure for bradydysrhythmias while awaiting digoxin-specific Fab antibodies
Transcutaneous pacing while awaiting digoxin-specific Fab antibodies for symptomatic bradycardia that does not respond to atropine
Digoxin-specific antibody fragments: IV infusion (see discussion below for dose)
Cardiac arrest
CPR with current advanced cardiac life support protocols
Digoxin-specific antibody fragments: IV bolus (5–10 vials if amount ingested is unknown)

TABLE 193-3 Calculation of Digoxin-Specific Antibody Fragment Full Neutralizing Dose

Based on suspected amount ingested	Digoxin body load (milligrams) = 0.8 × suspected ingested amount (milligrams)* Digoxin body load (milligrams) = serum digoxin concentration (nanograms/mL) × 5.6 L/kg × weight (kg)/1000 One vial (about 40 milligrams) of digoxin-Fab neutralizes 0.5 milligram of digoxin ingested
Based on total serum digoxin concentration	Number of vials = serum concentration (nanograms/mL) × patient weight (kg)/100

*0.95 should be used instead of 0.8 if the preparation is an elixir or gel tablet; 1 should be used if the cardiac glycoside is digitoxin.

distribute widely throughout the body, removing digoxin from tissues. In severely poisoned patients after digoxin-Fab administration, 90% will show reversal or significant improvement in life-threatening dysrhythmia; in most cases, clinical improvement occurs within 1 hour. Patients in cardiac arrest had a 50% survival when receiving digoxin-Fab during the resuscitation, which is significantly better than historical survival with treatment with conventional therapies.[20] Because of cross-reactivity with other cardiac glycosides, digoxin-Fab are also beneficial in treating digitoxin, foxglove, and oleander poisonings, although large doses have sometimes been required.[17,26] Indications for digoxin-Fab are life-threatening dysrhythmias (including hemodynamically significant bradydysrhythmias unresponsive to standard therapy) and hyperkalemia in excess of 6 mEq/L associated with acute poisoning.

Digoxin-Fab administration is associated with few adverse effects.[20,21] Cardiogenic shock has been reported in patients dependent on digoxin for inotropic support.[29] In addition, ventricular response to atrial fibrillation may be increased. Hypokalemia may develop rapidly as digoxin toxicity is reversed. Mild, acute hypersensitivity reactions, including rash, flushing, and facial swelling, have been reported. No incidences of serum sickness or anaphylaxis have been observed, even in patients with repeated administration.[29] Skin testing has not proven to be useful in predicting allergic responses and may delay urgently needed treatment.[30] Failures to digoxin-Fab therapy have been attributed to inadequate dosing, moribund state before administration, and incorrect diagnosis of digoxin toxicity.[29]

A full neutralizing dose of digoxin-Fab is based on an estimation of the total-body load of digoxin, which can be calculated from either the dose ingested or a steady-state serum digoxin level (**Table 193-3**). In an acute poisoning, each vial of digoxin-Fab reverses approximately 0.5 milligram of ingested digoxin. In hemodynamically stable patients, half the calculated full neutralizing dose is infused, and the other half is given if an adequate clinical response is not seen in 1 to 2 hours.[31] Observational studies report that a total of 200 to 480 milligrams of digoxin-Fab (5 to 12 vials) were required to effectively treat severely digoxin-toxic patients.[20] When the ingested dose is unknown and serum level is unavailable, 10 vials are recommended as initial treatment in life-threatening situations. Digoxin-Fab are administered IV through a 0.22-mm filter over 30 minutes, except in cardiac arrest, when the dose is given as an IV bolus.

Calculations of a full neutralizing dose may overestimate the amount of digoxin-Fab necessary, and smaller doses may adequately eliminate digoxin from the central compartment.[32] An alternative approach in acute poisoning with a hemodynamically stable patient is to give an 80-milligram (two vials) bolus of digoxin-Fab, evaluate the effect, and repeat the dose every 30 to 60 minutes as necessary until dysrhythmias have resolved and potassium has normalized. Such a protocol may reverse toxicity with less than half of a calculated full neutralizing dose.

In chronic toxicity, an acceptable approach in the hemodynamically stable patient is to give a 40-milligram (one vial) bolus of digoxin-Fab and repeat after 1 hour if the patient is still symptomatic. One to three vials (40 to 120 milligrams) of digoxin-Fab are often adequate in reversing chronic toxicity.[32]

Total serum digoxin levels obtained following digoxin-Fab administration have little correlation with clinical toxicity. Because most laboratory assays do not distinguish between antibody-bound and unbound digoxin, total serum levels obtained following digoxin-Fab administration may increase 10- to 20-fold.[20] However, because the Fab-digoxin complex is not pharmacologically active, this increased level does not correlate with clinical toxicity. The Fab-digoxin complex is eliminated by renal excretion.[33]

In the presence of renal failure, the Fab-digoxin complex may persist in the circulation for prolonged periods.[34] Recurrent toxicity can occur up to 10 days after digoxin-Fab administration in patients with renal failure as the complex degrades. Due to the large molecular weight of the Fab-digoxin complex (45,000 to 50,000 Da), hemodialysis does not enhance its elimination, although plasma exchange may be of benefit.[33,35,36] New liver support devices incorporating albumin-based dialysis and plasma filtration would be expected to be able to clear the Fab-digoxin complex on the basis of molecular weight alone; some devices have been reported to clear substances up to 100 kDa.[37] However, there is no experience using this technique with digoxin-poisoned patients.

DISPOSITION AND FOLLOW-UP

Extended observation with serial digoxin and potassium levels is recommended for anyone with a confirmed acute ingestion. Asymptomatic patients should be observed until the serum digoxin level is decreasing on serial measurements and the potassium level has remained normal. Patients with signs of toxicity or a history of a large (>6 milligrams in an adult) ingested dose should be admitted to a monitored unit. Consultation with a medical toxicologist or the regional poison control center is recommended. Patients receiving digoxin-Fab require intensive care unit observation for 6 to 12 hours.[31] Patients in renal failure who receive digoxin-Fab may be at risk of delayed toxicity, as the Fab-digoxin complex can dissociate several days later. Finally, patients with suspected suicidality should undergo behavioral health or psychiatric evaluation before discharge.

CHAPTER 194

Beta-Blockers

Jennifer L. Englund
William P. Kerns II

INTRODUCTION

β-Adrenergic receptor antagonists (β-blockers) are medications used in the treatment of various cardiovascular, neurologic, endocrine, ophthalmologic, and psychiatric disorders. Among all the exposures to cardiovascular agents, β-blocker exposures were the leading cause of poison center calls and ranked among the top three in this class as a cause of severe toxicity and mortality.[1]

PHARMACOLOGY

The β-adrenergic receptors are membrane glycoproteins present as three subtypes in various tissues (**Table 194-1**). These receptors play a critical role in cardiovascular physiology by modulating cardiac activity and vascular tone.

During times of stress (i.e., catecholamine release), β-adrenergic receptor stimulation increases myocardial and vascular smooth muscle cell activity through a sequence of intracellular events (**Figure 194-1**).[2,3]

The β-receptor is coupled to a stimulatory G_s protein. This G_s protein stimulates adenylate cyclase, which in turn catalyzes the formation of cyclic adenosine monophosphate, the so-called *intracellular second messenger*. Increased cyclic adenosine monophosphate ultimately phosphorylates the L-type calcium channel, which leads to channel opening and calcium entry into the cell. Extracellular calcium is then coupled to the ryanodine receptor to carry the calcium current to the sarcoplasmic reticulum, which then releases its stored calcium. This process is termed *calcium-induced calcium release*. Stored calcium becomes available to participate in mechanical contraction via the actin and myosin complex. Like the cardiac myocyte, the vascular smooth muscle uses L-type calcium channels to regulate intracellular calcium and subsequently coordinate vascular tone. To prevent overdrive of the cell, phosphodiesterase breaks down cyclic adenosine monophosphate to adenosine 5'-monophosphate, thus removing the stimulus for calcium channel opening, and the contractile process ceases.

The β-blockers modulate the activity of myocyte and vascular smooth muscle contraction by decreasing calcium entry into the cell.[2,3]

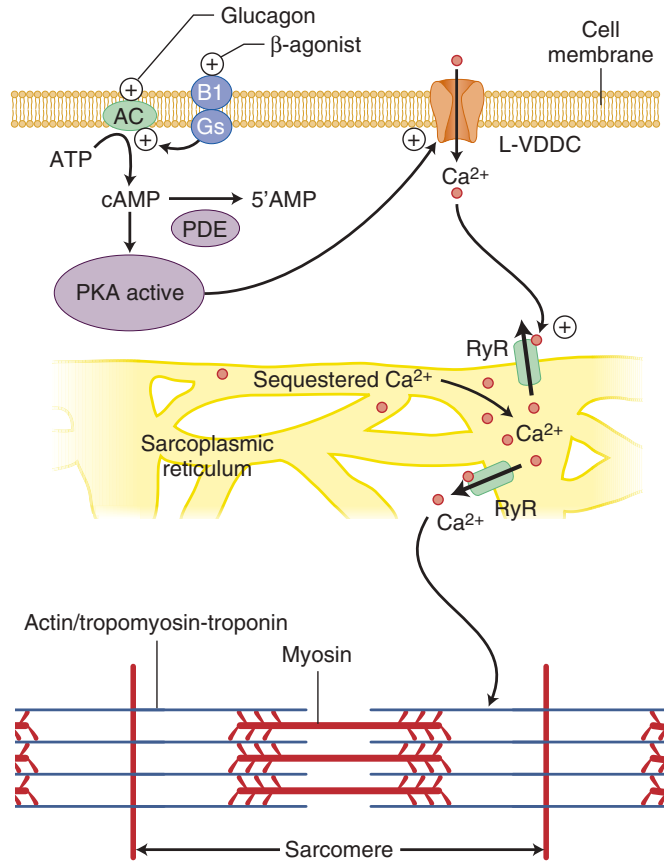

FIGURE 194-1. Cardiac myocyte β_1-receptor and calcium signaling. Following myocyte depolarization, extracellular calcium (Ca^{2+}) enters the cell via the L-type or voltage-gated calcium channel (L-VDCC) and binds to the ryanodine receptor (RyR) in the sarcoplasmic reticulum, causing an efflux of sequestered Ca^{2+} out of the sarcoplasmic reticulum into the cytosol. Free Ca^{2+} binds to troponin that allows the myosin and actin interaction, resulting in contraction of the cardiac myocyte. Binding of a β-agonist to the β_1-adrenergic receptor (B1) on the cell surface activates the Gs protein. The Gs protein then activates adenylate cyclase (AC), which converts adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP). The increased cAMP activates protein kinase A (PKA). Activated PKA serves as further stimulus for the L-VDCC opening. Glucagon independently activates adenylate cyclase. cAMP is metabolized by phosphodiesterase (PDE) into inactive adenosine 5'-monophosphate (5'AMP).

TABLE 194-1 Location and Activity of β-Adrenergic Receptors

β-Receptor Type	Location	Agonism	Antagonism
β_1	Myocardium	Increases inotropy	Decreases inotropy
		Increases chronotropy	Decreases chronotropy
	Kidney	Stimulates renin release	Inhibits renin release
	Eye	Stimulates aqueous humor production	Inhibits aqueous humor production
β_2	Bronchial smooth muscle	Causes bronchodilation	Causes bronchospasm
	Visceral smooth muscle	Relaxes uterus	—
		Causes ileus	
	Skeletal muscle	Increases force of contraction	—
		Stimulates glycogenolysis	
	Liver	Stimulates glycogenolysis and gluconeogenesis	Inhibits glycogenolysis and gluconeogenesis
	Vascular	Vasodilation	Minimal vasoconstriction
β_3	Adipose tissue	Stimulates lipolysis	Inhibits lipolysis
	Skeletal muscle	Stimulates thermogenesis	Inhibits thermogenesis

Therapeutically, β-blockade lessens the work performed by the diseased or injured myocardium and lowers elevated blood pressure. On the other hand, excessive β-blockade may lead to profound pump failure, with bradycardia, decreased contractility, and hypotension.[2]

The pharmacologic properties of various β-blockers influence their spectrum of action, adverse drug reactions, and toxicity (**Table 194-2**).[4,5] These properties include receptor selectivity, sodium channel blockade (also known as *membrane-stabilizing activity*), lipid solubility, protein binding, and partial agonist activity (also known as *intrinsic sympathomimetic activity*). For example, highly lipid-soluble agents, such as propranolol, readily cross the blood–brain barrier and achieve high concentrations in brain tissue.[2,3] This may contribute to the more severe CNS manifestations of mental status depression, seizures, and coma seen after an overdose of such agents.[2,3] Several β-blockers inhibit myocardial sodium channels, similar to quinidine and cyclic antidepressants, rendering these drugs potentially more cardiodepressant following overdose.[3] However, in massive overdoses, all β-blockers can be severely cardiodepressive.[6]

Although β_1 cardioselective medications have less risk of unwanted β_2 effects, such as bronchospasm, selectivity is often lost following large overdoses.[3] Several β-blockers like pindolol have partial agonist activity, causing weak stimulation of the β-receptor, with a lessor

TABLE 194-2 β-Blocker Pharmacologic Profiles

Agent	β_1 Selectivity	Lipophilicity	Partial Agonism	Protein Binding (%)	Sodium Channel Blockade	Half-Life (h)
Acebutolol	+	Moderate	+	25	+	3–4
Atenolol	+	Weak	0	6–16	0	6–9
Betaxolol	+	High	0	55	±	14–22
Bisoprolol	++	Moderate	0	30–40	0	9–12
Carvedilol	0	Moderate	0	>95	±	7–10

Propranolol	0	High	0	>90	++	3–4
Sotalol	0	Weak	0	Minimal	0	12
Timolol	0	High	±	10–60	0	4–5

Abbreviations: + = some activity; ++ = strong activity; ± = possible activity; 0 = no activity.

tendency for bradycardia during therapeutic use.[4] Some β-blockers, such as labetalol and carvedilol, are also antagonists at α_1-adrenergic receptors, which can result in exaggerated hypotension during therapeutic use. Sotalol is unique among β-blockers in its ability to block potassium channels important for repolarization, as do other class III antiarrhythmic drugs.[2-4]

In addition to having cardiopulmonary effects, β-blockers also alter metabolism in the liver, skeletal muscle, and adipose tissue. Under normal conditions, the heart uses free fatty acids as its primary energy source, but during times of stress, it switches to using carbohydrates to maintain metabolism. Inhibition of glycogenolysis and gluconeogenesis reduces the availability of carbohydrates for use by metabolically active cells. Although hypoglycemia can occur as a consequence of β-blocker toxicity, it is actually uncommon.[2] In the presence of adequate glucose stores, euglycemia and hyperglycemia are more common than hypoglycemia.

Clinically relevant pharmacokinetic characteristics include drug formulation (regular or extended release), rate of drug absorption, protein binding, lipid solubility, elimination mostly by hepatic metabolism, and volume of distribution. These properties determine onset of symptoms, duration of symptoms, target organ toxicity, and potential treatment modalities.

CLINICAL FEATURES

Toxicity due to β-blockers can produce a spectrum of clinical symptoms (**Table 194-3**).[2,3,7] The timing of symptom appearance depends upon the formulation. Absorption of regular-release β-blockers occurs rapidly, often with peak effects within 1 to 4 hours. However, delays of up to 6 hours following acute ingestion have occurred.[8] Experience is limited regarding onset of symptoms with poisoning following an ingestion of sustained-release β-blocker formulations, but based on other sustained-release cardiac drugs, it is assumed that symptoms may be delayed >6 hours after ingestion.[2,3] Co-ingestants that alter gut function, such as opioids and anticholinergics, may affect absorption of β-blockers and subsequent onset of symptoms.[2]

The primary organ system affected by β-blocker toxicity is the cardiovascular system, and the hallmark of severe toxicity is bradycardia and shock.[2,3,7,9] Bradycardia due to sinus node suppression or conduction abnormalities occurs in virtually all significant β-blocker intoxications, although ingestion of β-blockers with partial agonist activity may initially present with hypertension and tachycardia.[9] The β-blockers with sodium channel antagonism can worsen conduction abnormalities, causing a wide-complex bradycardia (especially when the QRS interval is >100 milliseconds).[9]

The cardiotoxic profile of sotalol is different from that of other β-blockers due to its ability to block potassium channels and prolong the QT interval.[3] Thus, sotalol is more often associated with ventricular dysrhythmias, including premature ventricular contractions, bigeminy, ventricular tachycardia, ventricular fibrillation, and torsades de pointes.[3]

β-Blockers also affect the CNS and pulmonary system. Neurologic manifestations include depressed mental status, coma, and seizures.[2] These symptoms most likely occur as a result of a combination of hypoxia due to poor perfusion, sodium channel antagonism, and direct neuronal toxicity.[2] More lipophilic β-blockers, such as propranolol, cause greater neurologic toxicity than the less lipophilic agents.[9] Seizures are generally brief, and status epilepticus is rare.[2] Nonselective β-blockers may antagonize the β_2-receptor in bronchial smooth muscle causing bronchospasm. Similarly, in large ingestions of cardioselective β-blockers, the β_1 selectivity may be lost.

TABLE 194-3 Common Findings with β-Blocker Toxicity

Cardiovascular
Hypotension
Bradycardia
Conduction delays and blocks (first-degree atrioventricular block)
Ventricular dysrhythmias (sotalol)
Asystole
Decreased contractility
CNS
Depressed mental status
Coma
Psychosis
Seizures
Respiratory arrest
Pulmonary
Bronchospasm
Electrolytes
Hypoglycemia
Hyperkalemia

TABLE 194-4 Toxicologic Causes of Bradycardia and Hypotension

Cause	Differentiating Features
Calcium channel blockers	Elevated lactate level and hyperglycemia
Naturally occurring cardiac glycosides (oleander, foxglove, lily of the valley, rhododendron, and toad-derived bufotoxin)	Ventricular ectopy May cross-react with digoxin immunoassay
Class IC antiarrhythmic drugs (propafenone)	Wide-complex bradycardia
Clonidine	Opioid-like manifestations: coma, miosis, decreased respirations
Cyanide	Profound metabolic acidosis and elevated lactate level
Digoxin (acute)	Hyperkalemia Elevated level on digoxin immunoassay
Organophosphates	Muscarinic toxidrome

DIAGNOSIS

The diagnosis of β-blocker toxicity is primarily made on clinical grounds, including patient history, physical examination findings, and results of basic diagnostic testing. Patients commonly present with a history of intentional overdose or therapeutic misadventure. The diagnosis may be more challenging in the case of polypharmacy "heart or blood pressure medication" overdose or with suspected chronic drug toxicity in the patient on multiple cardiovascular drugs. Exposure to other drugs and toxins can present with bradycardia and hypotension, but useful features can help differentiate toxicity from these agents from that due to β-blockers (**Table 194-4**).

Laboratory testing is recommended to assess renal function, glucose level, oxygenation, and acid-base status. Although specific β-blocker drug levels might be of value for later confirmation of an ingestion, these levels are not helpful initially because they do not correlate with the degree of toxicity and are generally not available in a timely fashion to affect acute management.[2,3,7] False-positive amphetamine results can be seen on urine drug screens from labetalol, because one of its metabolites is structurally similar to amphetamine and methamphetamine.[10] Cardiac function is evaluated with a 12-lead ECG, rhythm monitor, and bedside cardiac US.[11] A drug-induced Brugada pattern may be observed in an overdose of propranolol, a β-blocker that also affects cardiac sodium channels.[12]

TREATMENT

GENERAL MANAGEMENT

Evaluate patients with suspected β-blocker overdose in a critical-care area of the ED with appropriate monitoring because these patients may experience abrupt cardiovascular collapse or neurologic depression. If orotracheal intubation is needed, the drugs used to sedate and paralyze may worsen hypotension in the face of an already depressed myocardium.[2,3,7]

GI DECONTAMINATION

Although there is little evidence to support routine GI decontamination following overdose of most substances, ingestion of a significant quantity of β-blockers with the risk of severe toxicity is a circumstance in which decontamination should be considered.[13] Activated charcoal may be of benefit if it can be given within 1 hour after ingestion and the patient is able to maintain the airway.[14,15] There may be an additional window of opportunity for activated charcoal therapy following ingestion of sustained-release β-blockers. Ipecac syrup and cathartic agents are not recommended.[16] Gastric lavage is not recommended.[13] Whole-bowel irrigation may be beneficial after a large ingestion of an extended-release product.[17]

PHARMACOLOGIC TREATMENT

Specific pharmacologic therapies are directed at restoring perfusion to critical organ systems by improving myocardial contractility, increasing heart rate, or both.[2,3,7] This is done through fluid resuscitation and administration of glucagon, adrenergic agonists, high-dose insulin, calcium, and phosphodiesterase inhibitors (**Figure 194-2**). Individual pharmacologic therapies have variable effectiveness and are often used simultaneously.[7] Aggressive measures such as hemodialysis, hemoperfusion, cardiac pacing, placement of intra-aortic balloon pumps, and extracorporeal circulatory support have also been used when patients are refractory to pharmacologic therapy.[18]

GLUCAGON

Glucagon is a first-line agent in the treatment of acute β-blocker–induced bradycardia and hypotension.[2,19] Glucagon, produced in the pancreatic α-cells from proglucagon, independently activates myocardial adenylate cyclase, bypassing the impaired β-receptor (Figure 194-1). Effects from an IV bolus of glucagon are seen within 1 to 2 minutes, reach a peak in 5 to 7 minutes, and have a duration of action of 10 to 15 minutes.[2,3] Due to the short duration of effect, a continuous infusion is often necessary after bolus administration. The bolus dose of glucagon is 3 to 10 milligrams (30 to 150 micrograms/kg in children), and if a response is not seen within 15 minutes, a repeat bolus can be given. If a beneficial effect is seen from the glucagon bolus, a continuous infusion of 1 to 5 milligrams/h (20 to 70 micrograms/kg per hour in children) can be used to maintain this effect. Glucagon infusion should be titrated to rate to achieve adequate hemodynamic response. There is no identified maximum therapeutic dose or duration of treatment.[19]

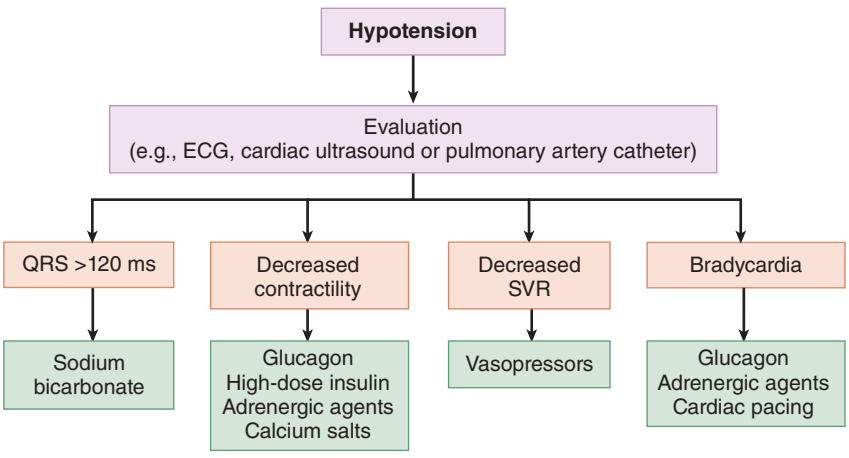

FIGURE 194-2. Management strategies in β-blocker toxicity. Cardiac function is evaluated using ECG, cardiac US, and/or central hemodynamic monitoring. For wide QRS interval, consider sodium bicarbonate therapy. For impaired myocardial contractility, consider glucagon, high-dose insulin, adrenergic agents, and calcium therapy. For decreased systemic vascular resistance, consider vasopressors, such as norepinephrine, epinephrine, dopamine, and phenylephrine. For bradycardia, consider glucagon, adrenergic agents, and cardiac pacing. (See text for details.) SVR = systemic vascular resistance.

The amount of glucagon required to treat a significant β-blocker overdose may exceed the total amount available at any given hospital.[19] The positive inotropic and chronotropic effects of glucagon may not be maintained for a prolonged period due to possible tachyphylaxis. Nausea and vomiting are commonly reported side effects of high-dose glucagon therapy and may be related to esophageal sphincter relaxation. Intubation prior to glucagon administration may be warranted in any patient with altered mental status to limit the risk of aspiration.[2,3,7]

Prior to 1998, glucagon was derived from porcine and bovine pancreas and contained other pancreatic compounds such as insulin and phenol as a preservative.[2] The contribution of this insulin content to the original glucagon's overall efficacy is unclear (see discussion below in "High-Dose Insulin Therapy"). Since 1998, glucagon has been produced via recombinant technology and is devoid of insulin or phenol.

ADRENERGIC RECEPTOR AGONISTS

The β-adrenergic receptor agonists—such as norepinephrine, dopamine, epinephrine, and isoproterenol—are used routinely to treat β-blocker toxicity.[2,19] However, results have been variable even when dosages far exceed those recommended in standard guidelines for cardiac resuscitation.[3] The most effective adrenergic receptor agonists may be norepinephrine and epinephrine due to their chronotropic and vasopressor effects. Phenylephrine may also be beneficial as a vasopressor. Although isoproterenol may increase heart rate, it does so at the expense of vasodilation. Dobutamine has a similar downside: potential improvement in inotropy but worsening of hypotension due to vasodilation.

HIGH-DOSE INSULIN THERAPY

High-dose insulin therapy, sometimes called hyperinsulinemia-euglycemia therapy, is an important treatment modality for β-blocker toxicity.[17,20-22] Insulin acts as an inotrope by facilitating myocardial utilization of glucose, the desired energy substrate during stress, in contrast to glucagon, epinephrine, and calcium, which promote free fatty acid utilization.[20-23] In animal models, high-dose insulin therapy improved survival in severe β-blocker overdose compared with glucagon, epinephrine, or vasopressin administration.[24,25] The most consistent cardiodynamic effect in these models was an increase in contractility.

High-dose insulin therapy dosing used for treatment of β-blocker toxicity is much higher than that used for traditional glucose control in diabetes (**Table 194-5**). The initial dose is regular insulin 1 unit/kg IV bolus and is followed by a continuous infusion of 0.5 to 1 unit/kg per hour that is titrated to the desired hemodynamic response of a heart rate at least 50 beats/min and systolic blood pressure of at least 100 mm Hg (13.3 kPa).[20-22] The maximum dose has not yet been established, although an animal model of propranolol overdose[26] found that cardiac output increased in a dose-response manner when the insulin dose was raised from 1 to 10 units/kg per hour, and human case reports have used doses this high.[22]

The onset of action with high-dose insulin therapy is reported to be 15 to 45 minutes, but a delayed response of several hours has been noted.[20] High-dose insulin therapy is continued until resolution of toxicity; the duration of high-dose insulin therapy infusion described in case reports ranges from 9 to 49 hours.[22] The insulin infusion can be gradually weaned or abruptly halted. Reinstitute the insulin infusion if the heart rate or blood pressure falls after cessation of high-dose insulin therapy.

Potential adverse effects from high-dose insulin therapy are hypoglycemia and lowered serum potassium. Dextrose infusion is used to prevent hypoglycemia and often required during the duration of therapy.[22] Serum potassium is monitored and supplemental replacement is given if the level is below 2.8 mEq/L (2.8 mmol/L).[20,22] An increase in the dextrose infusion rate required to maintain serum glucose between 100 and 200 milligrams/dL (5.3 and 10.7 mmol/L), along with signs of clinical improvement, may be an indication that metabolic status is normalizing; that is, that the stress response is diminishing, the heart is reverting back to basal energy substrates, and extra insulin is no longer needed.

TABLE 194-5 Protocol for High-Dose Insulin Therapy in Severe β-Blocker Overdose

Check serum glucose, and if <200 milligrams/dL (<11 mmol/L), administer 50 mL of 50% dextrose (0.5 gram/mL) in water IV (children 1 mL/kg of 25% dextrose).
Administer regular insulin 1 unit/kg IV bolus.
Begin regular insulin infusion at 0.5–1.0 unit/kg per hour along with dextrose 10% (0.1 gram/mL) in water at 200 mL/h (adult) or 5 mL/kg per hour (pediatric).
Titrate infusion rate up to 10 units/kg per hour according the hemodynamic goal of HR >50 beats/min and SBP >100 mm Hg (>13.3 kPa).
Monitor serum glucose every 15–20 min.
Titrate dextrose infusion rate to maintain serum glucose level between 100 and 200 milligrams/dL (5.3 and 10.7 mmol/L).
Once dextrose infusion rates have been stable for 60 min, glucose monitoring may be decreased to hourly.
Monitor serum potassium level and start IV potassium infusion if serum potassium level is <2.8 mEq/L (<2.8 mmol/L).
Maintain serum potassium between 2.8 and 3.2 mEq/L (2.8 and 3.2 mmol/L).

Abbreviations: HR = heart rate; SBP = systolic blood pressure.

INTRAVENOUS LIPID EMULSION THERAPY

Intravenous lipid emulsion therapy, also known as fat emulsion therapy or lipid rescue, is effective in treating toxicity from local anesthetics, calcium channel blockers, typical and atypical antipsychotics, cyclic and other antidepressants, and some β-blockers.[27-29] The exact mechanism is not fully understood, but the likely explanation is that lipid emulsion acts as a pharmacologic sink, by sequestering lipophilic drugs into a separate lipid compartment, and the amount of free drug available to target tissues is reduced ("lipid sink" model).[30] Other potential mechanisms may include supplying the myocardium with free fatty acids and phospholipids, increasing myocardial contractility by increasing myocyte calcium concentration, and elevating blood pressure by central sympathetic activation.

Animal models suggest that intravenous lipid emulsion may be most effective in the lipophilic β-blockers (Table 194-2), such as propranolol and carvedilol, and may be less effective in more hydrophilic agents, such as metoprolol and atenolol.[31]

The dosing regimen for intravenous lipid emulsion is based on treatment of local anesthetic systemic toxicity. The standard 20% lipid emulsion is given as a 1.5 mL/kg bolus over 1 minute, followed by a infusion at 0.25 mL/kg per minute.[30] If the blood pressure remains low, an additional 1.5 mL/kg bolus may be repeated followed by an increase in the infusion rate to 0.5 mL/kg per minute. The recommended upper limit is about 10 mL/kg over the initial 30 minutes. If the patient's hemodynamic stability is dependent on continued lipid infusion, the treatment may be continued beyond this level. Duration of therapy has not been fully established. If cardiac arrest occurs, a bolus dose can be given during the resuscitation.

Adverse effects reported with the use of lipid emulsion for the treatment of overdose and toxicity include lipemia causing interference with laboratory analysis, hypertriglyceridemia, pancreatitis, and possibly acute lung injury, acute renal failure, deep vein thrombosis, and cardiac arrest.[32-34] Lipid emulsion may clog the hemofiltration filter precluding renal replacement therapy during the infusion and until the lipid has been cleared from the blood.[35] Given the current understanding and limited clinical experience using intravenous lipid emulsion as an antidote, this treatment should be reserved for refractory shock.

ATROPINE

Atropine, a muscarinic blocker, is unlikely to be effective in the management of β-blocker–induced bradycardia and hypotension, although its use is unlikely to cause harm.[3,4,7] Its use may be beneficial for co-ingestants.

CALCIUM

Canine studies and limited case reports suggest that calcium therapy may reverse depression of the myocardium via positive inotropic action,

although with few chronotropic effects.[2,3] Calcium administration is not routinely recommended in β-blocker overdose, but may be considered in patients with refractory shock unresponsive to other therapies. Calcium for IV administration is available in two forms, gluconate and chloride, both in a 10% solution. A 10-mL dose of 10% calcium chloride solution contains three times more elemental calcium, 13.6 mEq (6.8 mmol), than 10 mL of 10% calcium gluconate solution, 4.5 mEq (2.23 mmol). Thus, one 10-mL ampule of 10% calcium chloride equals three 10-mL ampules of 10% calcium gluconate.

Potential adverse effects of calcium therapy include hypercalcemia, conduction blocks, worsening bradycardia, and inefficient cardiac energetics during shock (see "High-Dose Insulin Therapy"). Most patients tolerate transient increases in total calcium level without difficulty, and conduction blocks are rare. Severe soft tissue injury associated with inadvertent IV infiltration of the chloride formulation is the most concerning adverse event. Thus, calcium chloride is ideally given via a central line. Calcium gluconate is only rarely associated with tissue injury and is the preferred form for peripheral administration.

The optimum dose of calcium in β-blocker toxicity is unknown. Animal studies and limited human studies suggest that large amounts of calcium are needed to treat drug-induced cardiac toxicity, but these data come from experience derived from treating calcium channel blocker toxicity.[2,3] The recommended dose of 10% calcium gluconate is 0.6 mL/kg given over 5 to 10 minutes, followed by a continuous infusion of 0.6 to 1.5 mL/kg per h.[2,3] The equivalent dosage of 10% calcium chloride is 0.2 mL/kg given via central line over 5 to 10 minutes, followed by a continuous infusion of 0.2 to 0.5 mL/kg per h. Ionized calcium levels should be checked every 30 minutes initially and then every 2 hours to achieve an ionized calcium level of twice the normal value.[2]

PHOSPHODIESTERASE INHIBITORS

Phosphodiesterase inhibitors such as milrinone have been used to treat β-blocker toxicity. These agents inhibit the breakdown of cyclic adenosine monophosphate, thereby sustaining intracellular calcium levels (Figure 194-1).[2,3] In animal models, phosphodiesterase inhibitors produce positive inotropic effects without increasing myocardial oxygen demand but have no appreciable effect on heart rate. Compared with glucagon, phosphodiesterase inhibitors do not provide any additional benefit and therefore have no advantage over glucagon. However, if glucagon is not available or pharmacy stores have been exhausted, a phosphodiesterase inhibitor is a reasonable alternative. In the setting of a β-blocker overdose, milrinone is administrated as a continuous IV infusion, starting with a 50 micrograms/kg IV bolus, followed by an IV infusion of 0.375 to 0.75 micrograms/kg per minute for milrinone.[36]

SODIUM BICARBONATE

Sodium bicarbonate is used to treat severe acidosis and wide QRS-interval dysrhythmias secondary to sodium channel blockade. β-Blockers with sodium channel–blocking ability (Table 194-2) can interfere with ventricular depolarization, predisposing to cardiac dysrhythmias. When the QRS interval is longer than 120 to 140 milliseconds, it is reasonable to administer sodium bicarbonate.[2] The suggested dose is a rapid bolus of 2 to 3 mEq/kg over 1 to 2 min.[2,3,6] Thus, a 70-kg adult receives a bolus of 140 to 210 mEq of sodium bicarbonate, or three to four ampules (50 mL each) of 8.4% sodium bicarbonate. Repeat boluses or an infusion may be required to maintain the QRS interval at <120 milliseconds.

CARDIAC PACING

Internal or external pacing may be considered to treat bradycardia in the setting of β-blocker toxicity.[2,3] Electrical capture and restoration of blood pressure is not always successful, potentially due to the lack of intracellular calcium needed for contraction.[2,3] Cardiac pacing may be most beneficial in treating torsades de pointes associated with sotalol toxicity.

EXTRACORPOREAL ELIMINATION (HEMODIALYSIS)

The high degree of protein binding and lipid solubility of β-blockers, as well as their large volume of distribution, renders extracorporeal drug removal useless for most drugs in this class. Acebutolol, atenolol, nadolol, and sotalol may be amenable to removal through hemodialysis owing to their lower protein binding, water solubility, and lower volume of distribution.[37]

EXTRACORPOREAL CIRCULATION

Occasionally, extreme means of resuscitation, including extracorporeal circulation (extracorporeal membrane oxygenation) and intra-aortic balloon pumps, have been successful when pharmacologic measures have failed to reverse cardiogenic shock.[38,39]

TREATMENT OF SOTALOL TOXICITY

Treatment of sotalol toxicity may require pharmacologic measures different from those required for other β-blockers due to its potassium channel effects. In addition to the therapies discussed above, magnesium supplementation, lidocaine, and cardiac overdrive pacing may be of specific benefit.

SUMMARY

No one particular treatment is consistently effective in cases of β-blocker toxicity, and multiple simultaneous treatment measures may be required to resuscitate the critically ill patient. Tailor therapy based on the ECG, bedside cardiac US, and/or central hemodynamic monitoring. The goal of resuscitation is to improve hemodynamics and organ perfusion. Specific end points of therapy may include a cardiac ejection fraction of 50% or greater, a reduction of the QRS interval to <120 milliseconds, a heart rate of >50 to 60 beats/min, a systolic blood pressure of >90 to 100 mm Hg (12.0 to 13.3 kPa) in an adult, a urine output of 1 to 2 mL/kg per hour, and improved mentation.

DISPOSITION AND FOLLOW-UP

Patients who develop altered mental status, bradycardia, conduction delays, or hypotension should be managed in an intensive care unit. A patient who ingests a sustained-released β-blocker product warrants admission and monitoring for the development of delayed toxicity.[2,3,9] Patients ingesting an overdose of regular-release β-blocker tablets who remain asymptomatic and have normal vital signs for 6 hours after ingestion can be deemed medically safe for discharge or admission to a psychiatric facility.[9]

CHAPTER 195

Calcium Channel Blockers

Alicia B. Minns
Christian Tomaszewski

INTRODUCTION

Calcium channel blockers (CCBs) are commonly used for the treatment of hypertension and angina pectoris and for ventricular rate control in supraventricular dysrhythmias. Less common uses include prophylactic treatment of migraine headaches, treatment of arterial vasospasm due to Raynaud's disease, esophageal spasm, and pulmonary hypertension.[1] For the last 50 years, CCBs have accounted for more poisoning deaths than any other cardiovascular drug and are the second most common cause of prescription drug poisoning death.

PHARMACOLOGY

Intracellular calcium is the primary stimulus for smooth and cardiac muscle contraction and for impulse formation in sinoatrial pacemaker cells. At therapeutic concentrations, CCBs bind to the subunit of the L-type calcium channel, causing the channel to favor the closed state and thereby decreasing calcium entry during the plateau phase (phase 2) of the transmembrane action potential. At very high concentrations, some CCBs (notably verapamil) may occupy the channel canal and completely block calcium entry. The result is profound smooth muscle relaxation, weakened cardiac contraction, blunted cardiac automaticity, and intracardiac conduction delay.[1] Clinically, these effects produce hypotension and bradycardia. Animal data suggest that verapamil overdose also impairs myocardial carbohydrate intake, which contributes to the negative cardiac inotropy.[2]

The three main pharmacologic classes of CCBs are phenylalkylamines (verapamil and gallopamil), benzothiazepines (diltiazem), and dihydropyridines (nifedipine, amlodipine, and most newer agents—aranidipine, azelnidipine, barnidipine, benidipine, cilnidipine, clevidipine, efonidipine, felodipine, lacidipine, lercanidipine, manidipine, nicardipine, nilvadipine, nimodipine, nisoldipine, nitrendipine, and pranidipine).

All of these drugs relax vascular smooth muscle, reduce pacemaker activity, and decrease cardiac contractility; however, these effects occur at different dose ranges for each drug. In addition, all three classes increase coronary blood flow in a dose-dependent fashion.[3] Each group binds a different region of the calcium channel and has different affinities for calcium channels in various tissues. Verapamil is the most potent negative inotrope of all CCBs, causing at least equal depression of heart contraction and vascular smooth muscle dilatation at any concentration.[4] This combined cardiovascular effect may be one reason that verapamil overdose causes more deaths than all other CCBs combined.

Dihydropyridines bind more selectively to vascular smooth muscle calcium channels than to cardiac calcium channels and therefore relax smooth muscle at concentrations that produce almost no negative inotropy. The differences in the effects of these agents is the reason for preferential use of specific agents in particular clinical situations.[5] For example, verapamil and diltiazem are used to manage hypertension, to achieve rate control in atrial flutter and atrial fibrillation, and to abolish supraventricular reentrant tachycardias. Dihydropyridines are typically used to treat diseases with increased peripheral vascular tone such as hypertension, Prinzmetal's angina, and vasospasm after subarachnoid hemorrhage.[1]

The original three CCBs—verapamil, nifedipine, and diltiazem—all have relatively short serum half-lives (**Table 195-1**). Consequently, extended-release formulations have been developed for all of these agents. Because extended-release formulations prolong drug absorption, onset of symptoms may be delayed and toxicity may be prolonged following overdose.[6,7] Several of the newer dihydropyridines have prolonged duration of action, and therefore are generally not formulated as extended-release products. Because newer formulations are released frequently, it is helpful to contact a regional poison control center for help in determining if a given product ingested in an overdose is formulated as an extended-release preparation.

TABLE 195-1 Oral Calcium Channel Blockers

	Metabolism	Half-Life (standard preparation, not extended-release)	Maximum Recommended Adult Daily Dose (milligrams)
Verapamil*	Liver extensively	2–5 h	480
Diltiazem*	Liver extensively	3–5 h	480 for regular-release and 540 for extended-release
Nifedipine*	Liver	2 h	180 for regular-release and 90 for extended-release
Amlodipine	Liver extensively	30–50 h	10
Felodipine*	Liver extensively	9 h	10
Isradipine	Liver	8 h	10
Nicardipine*	Liver extensively	8–14 h	120
Nimodipine	Liver extensively	Early: 1–2 h Terminal: 8–9 h	360
Nisoldipine*	Liver extensively	7–12 h	34

*Also available in extended-release preparations.

CLINICAL FEATURES

The most prominent and life-threatening effects are an extension of the therapeutic effects on the cardiovascular system, particularly myocardial depression and peripheral vasodilation. Hypotension is the most common physiologic abnormality after overdose.[8,9] Patients with moderate verapamil or diltiazem poisoning often have sinus bradycardia, varying degrees of atrioventricular block, and hypotension. Atrioventricular block occurs more often with verapamil than with diltiazem or nifedipine.[10] Mild or moderate dihydropyridine overdoses usually cause peripheral vasodilatation with resultant hypotension and reflex tachycardia.[10] In severe overdose, any of these agents may cause complete heart block, depressed myocardial contractility, and vasodilatation that ultimately results in cardiovascular collapse.

Pulmonary and CNS effects are generally secondary to decreased myocardial function and impaired organ perfusion. Cardiogenic pulmonary edema is sometimes observed in severe overdoses, especially if large volumes of crystalloid are infused during resuscitation. Acute lung injury (noncardiogenic pulmonary edema) has also been reported.[11,12] Seizures, delirium, and coma have been described and are presumed to be secondary to cerebral hypoperfusion. Alteration in consciousness in the absence of hypotension should not be attributed to CCB toxicity; prompting an evaluation for other causes. GI symptoms, such as nausea and vomiting, are uncommon.[13]

DIAGNOSIS

POTENTIAL TOXICITY

Estimations have been made of the lowest doses and mean doses ingested that produce toxicity (**Table 195-2**).[7] A history of ingestion that is near these doses should be considered potentially toxic, and doses in excess of the lowest toxic dose reported should be expected to produce toxicity.[7] Adults receiving long-term therapy with CCBs can develop hypotension, bradycardia, or cardiac conduction abnormalities if they ingest twice their regular daily dose.[14] It is hypothesized that patients receiving long-term CCB therapy have comorbidities and may be taking additional medications, such as other antihypertensives, that render these patients sensitive to the adverse effects of an additional amount of their CCB. Children may be sensitive to CCB toxicity, and deaths have been reported after ingestion of a single tablet: nifedipine, 10 milligrams, in a 14-month-old child[15] and verapamil, 25 milligrams, in a 7-day-old infant.[16] **Therefore, all pediatric CCB ingestions should be referred for medical attention and observation.**

Extended-release preparations are increasingly used for patient convenience and enhancing patient adherence to the drug regimen. These preparations complicate the management of overdosed patients by delaying the onset of toxicity. Therefore, it is important to determine the exact formulation of the ingested agent to guide management decisions. If the history cannot identify the exact formulation, the clinician should assume it is extended-release and modify treatment in a conservative way. In a review of CCB overdose cases, 52% of patients ingested extended-release preparations, and of these, 8% had no evidence of toxicity on initial evaluation but developed delayed toxicity 6 hours or later

TABLE 195-2 Single-Ingestion Toxicity from Calcium Channel Blockers

Agent	Lowest Toxic Dose (adult)	Mean Toxic Dose (adult)	Mean Toxic Dose (pediatric)
Verapamil	720 milligrams	2708 milligrams	16 milligrams/kg
Diltiazem	420 milligrams	2167 milligrams	5.7 milligrams/kg
Nifedipine	50 milligrams	245 milligrams	8.0 milligrams/kg

Hypothermia
Acute coronary syndrome
Hyperkalemia
Cardiac glycoside toxicity
β-Blocker toxicity
Antiarrhythmic drugs class IA and IC toxicity
Central α-adrenergic agonist (clonidine or tetrahydrozoline) toxicity

TABLE 195-4 General Treatment for Calcium Channel Blocker Toxicity*

Treatment	Comments
Monitoring	Initiate cardiopulmonary monitoring and obtain ECG
Point-of-care glucose	If altered mental status, and also in anticipation of insulin therapy
Naloxone	If signs of opioid toxicity
Single-dose activated charcoal	If ingestion within 1 h and no vomiting or altered mental status; for children even if one tablet ingested
Multidose activated charcoal	For extended-release preparations
IV crystalloid for hypotension	Overaggressive treatment can cause pulmonary edema
Endotracheal intubation	Early intubation if altered mental status or hemodynamic instability

*See Figure 195-1 for treatment of severe toxicity.

after ingestion.[10] In addition to the exact formulation ingested, other important aspects in the history are the time of ingestion and the possibility of co-ingestants that may contribute to toxicity.

ECG findings include sinus bradycardia, varying degrees of atrioventricular block, and slowing of intraventricular conduction. Reflex tachycardia is commonly seen with low to moderate toxic ingestions of dihydropyridines, whereas junctional rhythms and ventricular escape rhythms are frequently noted in severe overdoses with verapamil or diltiazem.

Laboratory testing is done to assess the overall metabolic state of the patient; none is crucial in the acute management of CCB toxicity. Hyperglycemia is often noted after CCB ingestion, which differentiates it from β-blocker ingestion, which is typically euglycemic or sometimes hypoglycemic.[17] CCBs inhibit calcium-mediated insulin secretion from the beta islet cells in the pancreas, impeding the use of carbohydrates, and also increase insulin resistance by unclear mechanisms.[18]

Systemic hypoperfusion may cause a lactate acidosis with an elevated anion gap and low serum bicarbonate level. Hypokalemia may be observed in severe overdoses. Serum calcium levels are usually normal. Ionized serum calcium levels may be followed during treatment with intravenous calcium preparations, but the optimum serum calcium level for patients with severe CCB poisoning is unknown. CCB serum concentrations are not routinely available and are not used in management. Screen blood and urine for other potential toxins after suicidal overdose.

DIFFERENTIAL DIAGNOSIS

A few conditions and other drug toxicities can produce bradycardia, atrioventricular block, and hypotension (**Table 195-3**). Hypothermia should be detected during vital sign assessment. Myocardial infarction may be evident on the initial or subsequent ECG. Suspect hyperkalemia in patients with renal failure.

It may be difficult to distinguish CCB toxicity from cardiac glycoside toxicity; patients may be taking these drugs for the same indications and at the same time (see chapter 193, "Digitalis Glycosides"). In general, patients with chronic digoxin poisoning have greater ventricular excitation, including rate and ectopy, than patients with CCB toxicity. In acute overdose, digoxin toxicity may be distinguished by hyperkalemia. However, because the main manifestation of acute cardiac glycoside poisoning is heart block and bradycardia, bedside differentiation may be difficult.

Toxicity from β-adrenergic antagonists may be clinically indistinguishable from CCB toxicity (see chapter 194, "Beta-Blockers"). In general, β-blocker toxicity is not as severe, and patients tend to have low to normal glucose and normal to elevated serum potassium levels. However, these findings are not consistent enough to have diagnostic value. Fortunately, the treatment for these two poisonings is similar, with calcium, adrenergic agonists, glucagon, insulin, and pacing considered useful therapy for both.[19]

TREATMENT

Institute cardiopulmonary monitoring and obtain an ECG (**Table 195-4**). Evaluate patients with altered mental status for hypoglycemia and opioid toxicity. Decreased level of consciousness following CCB ingestion is a result of cerebral hypoperfusion or co-ingestion. Administer oral activated charcoal if within 1 hour of ingestion or in cases of extended-release preparations, as long as there are no contraindications such as altered mental status or vomiting. Provide early airway management in patients with mental status change or hemodynamic instability. Endotracheal intubation may minimize the risk of aspiration associated with GI decontamination. Vomiting is not only associated with decontamination, but glucagon administration also often precipitates vomiting. Finally, early airway management allows the physician to concentrate on treating the often-precipitous cardiovascular collapse without having to perform a "crash airway" procedure.

Following airway management, provide cardiovascular stabilization. The goal of treating bradycardia is to increase end-organ perfusion rather than restoring a specific heart rate; some patients with heart rates in the 30 to 40 beats/min range can maintain adequate blood pressure and perfusion, and therefore require only monitoring rather than a specific intervention. Conversely, patients may respond to cardiac pacing with an increase in heart rate to 90 to 100 beats/min without improvement in blood pressure or perfusion and require additional therapy to improve inotropy.

Therapies to increase heart rate include medications and cardiac pacing. Atropine alone is rarely effective for CCB-induced bradycardia, but administration is commonly recommended.[10] Calcium salts may improve both heart rate and blood pressure, but the response is variable. Transcutaneous and transvenous pacing may be attempted and are often successful in restoring an acceptable rate but may have little to no effect in correcting hypotension. However, pacing is indicated for hypotensive patients with severe bradycardia (heart rate <30 beats/min).

Administer IV crystalloid for hypotension, but overaggressive fluid administration may produce or worsen pulmonary edema. Persistent hypotension after treatment of bradycardia, administration of calcium salts, and infusion of crystalloid should be treated with adrenergic vasopressors. Recommendations for additional therapies are based on animal data and human case reports or series, with the caution that case reports often document the use of multiple therapies simultaneously.[19-21]

GI DECONTAMINATION

CCBs bind well to charcoal, and activated charcoal should be given to adults following any potentially significant ingestion if within an hour of ingestion.[22] Give activated charcoal after accidental ingestion of verapamil in children, because life-threatening toxicity has been reported following ingestion of a single tablet. Multiple-dose activated charcoal may be considered in the setting of ingestion of an extended-release preparation.

Ipecac syrup to induce emesis is not recommended.[22] Routine gastric lavage has no proven benefit in CCB ingestions. However, because large CCB overdoses are often life-threatening and may not respond to therapy, some toxicologists recommend gastric lavage for a patient who presents within 60 minutes of ingesting an amount significantly in excess of toxicity (Table 195-2) or for any patient who requires intubation after CCB ingestion. However, evidence for improvement in outcomes after gastric lavage is lacking.

Whole-bowel irrigation is frequently advocated for ingestion of extended-release CCBs.[23] Case reports note that a large amount of medication may be recovered. Given the potential for severe toxicity, consider whole-bowel irrigation for patients with large ingestions of extended-release products, although complications from whole-bowel irrigation may contribute to hemodynamic instability.[24]

CALCIUM SALTS

Exogenous calcium increases the extracellular calcium concentration and increases the transcellular gradient, driving calcium intracellularly through unblocked calcium channels. Administration of calcium salts has improved blood pressure in animal models and in human case reports of CCB toxicity.[23,25-28] However, the effect of calcium salts on the heart rate of patients with CCB toxicity is variable.

Calcium chloride is preferred to calcium gluconate because it provides triple the amount of calcium on a weight-to-weight basis. However, calcium chloride is best administered through a central venous line, because peripheral extravasation can result in severe soft tissue necrosis. Calcium chloride is usually given as a 1-gram (10 mL of 10% solution) IV bolus over 5 minutes in adults (pediatric dose is 15 milligrams/kg or 0.15 mL/kg of the 10% solution). Calcium gluconate can be given at three times this amount. **The effects of calcium administration may be transient, and repeat dosing up to every 10 to 20 minutes is commonly required. Alternatively, a continuous infusion of calcium chloride 2 to 6 grams/h may also be used in adults (pediatric dose is 10 to 40 milligrams/kg per hour).** Serum calcium levels should be measured every 1 to 2 hours, and a calcium concentration goal of approximately 1.5 to 2 times normal should be achieved. However, for patients who do not respond to other therapies, it is reasonable to continue calcium administration even when serum calcium levels are considerably elevated.

An acceptable level for hypercalcemia has not been defined. Published case reports of CCB poisoning describe survival following administration of 30 grams of calcium chloride over 12 hours resulting in a serum calcium level of 23 milligrams/dL (5.94 mmol/L)[23] and death from iatrogenic hypercalcemia with a serum calcium level of 32.3 milligrams/dL (8.07 mmol/L).[29] A safe but effective dose of calcium salts to use in the treatment of CCB toxicity is unclear. If repeat dosing or continuous infusions are used, hypercalcemia and/or hypophosphatemia can occur. Although monitoring of serum calcium and phosphorus concentrations during repeated or prolonged calcium therapy is recommended, it is unclear if such electrolyte abnormalities have clinical consequence or should be treated.

ADRENERGIC AGENTS

Patients who do not respond to calcium administration or who require repeated doses are usually given adrenergic agonists (Figure 195-1).[19-21] Although animal data suggest that other therapies may lead to better metabolic function and better survival in severe poisonings, adrenergic agonists have several advantages. Physicians and nurses are familiar with these agents, therapy can be initiated quickly, and most patients respond favorably. This prevents a period of nontreatment while the supplies for more esoteric therapies are gathered. Given the availability of adrenergic agonists and the familiarity of clinicians with their use, adrenergic agonists are the first line of treatment for persistent hypotension following CCB ingestion.

No single adrenergic vasopressor is consistently effective. A response may occur with dopamine, epinephrine, norepinephrine, vasopressin, dobutamine, and isoproterenol.[30-32] Patients with decreased contractility and peripheral vasodilatation, especially in the face of relative bradycardia, may benefit from an agent with both α- and β-agonist effects, such as epinephrine or norepinephrine (Figure 195-1). Phosphodiesterase inhibitors such as amrinone, milrinone, and enoximone have also been reported to improve blood pressure in animal studies and human case reports.[33-36]

When standard doses are inadequate, it is reasonable to use high doses or multiple agents titrated to achieve a systolic blood pressure >90 mm Hg (>12 kPa), although there is the risk of ischemic complications.[32]

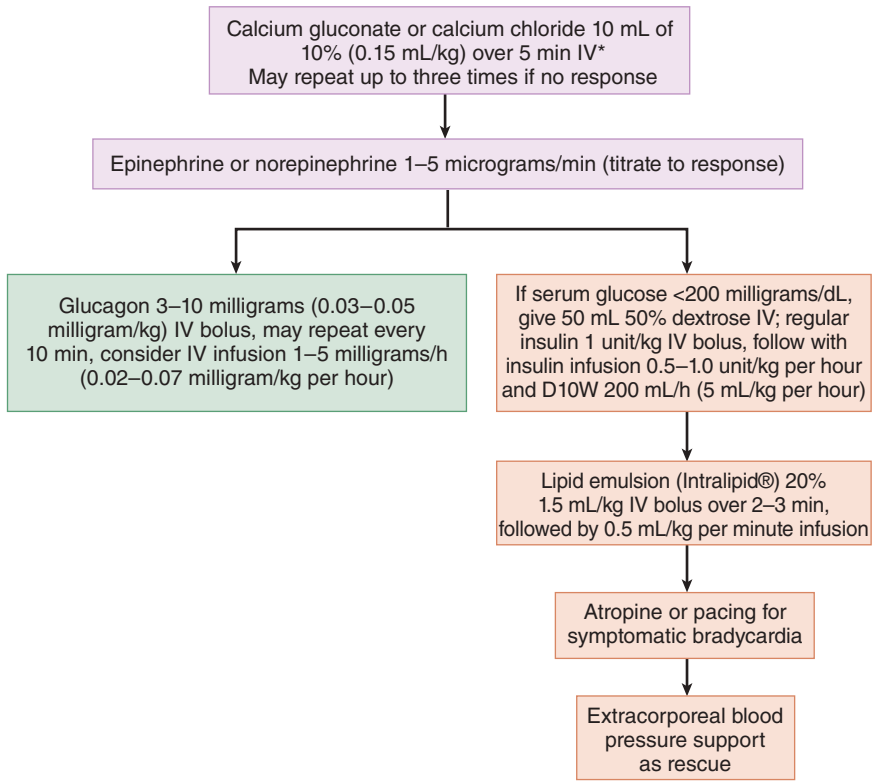

FIGURE 195-1. Treatment algorithm for severe calcium channel blocker toxicity, for stepwise or simultaneous therapy. *Calcium chloride provides three times as much elemental calcium as calcium gluconate; monitor for ventricular arrhythmias in concomitant digoxin toxicity. D10W = 10% dextrose in water.

Alternatively, another approach, such as high-dose insulin, glucagon, or lipid-emulsion, can be considered.

HIGH-DOSE INSULIN THERAPY

High-dose insulin therapy, also known as hyperinsulinemia-euglycemia therapy, is a promising treatment for the myocardial suppression associated with CCB poisoning.[37-46] Potential mechanisms of action include positive inotropic effects of insulin, increased calcium entry, and improved myocardial use of carbohydrates as an energy source.[18] Insulin increases intracellular transport of glucose into cardiac and skeletal muscle and has inotropic properties.[39] There are no clinical trials comparing high-dose insulin therapy directly to other treatments, but multiple human case reports show that high-dose insulin therapy improves perfusion in CCB poisoning unresponsive to other therapies, with a therapeutic response noted with 15 to 30 minutes.[39-45] The main adverse effect is potential hypoglycemia, which is easily detected with point-of-care glucose testing and treated with dextrose. When to institute therapy is unclear; some toxicologists recommend high-dose insulin therapy if the patient is refractory to standard doses of vasopressors, and others advocate it as first-line therapy. **Given benefit seen in animal models and clinical reports, high-dose insulin therapy should be considered if the patient does not respond to vasopressor therapy** (Figure 195-1).

Doses of insulin used for high-dose insulin therapy are greater than that for diabetic treatment (**Table 195-5**).[46] An initial insulin bolus is followed by a continuous infusion along with a dextrose infusion to prevent hypoglycemia (Table 195-5). The hemodynamic response to high-dose insulin therapy is usually seen in 15 to 45 minutes, so the infusion rate may be increased if no clinical improvement is seen within that time. Monitor the serum glucose concentrations and adjust the dextrose infusion to maintain an acceptable glucose range. Monitor serum potassium and replace as needed. Maintain the high-dose insulin therapy infusion until toxicity has resolved; durations of 9 to 49 hours may be necessary. The insulin infusion may either be weaned gradually or stopped abruptly and reinstituted if toxicity recurs. Dextrose supplementation may be required for up to 24 hours after the infusion is discontinued due to persistent elevated insulin concentrations.

GLUCAGON

Glucagon, a hormone synthesized by the pancreas, is the therapy of choice for β-adrenergic blocker poisoning because of its ability to bypass the β-adrenergic receptor and stimulate cardiac activity (see chapter 194). In CCB poisoning, the inhibition is downstream from glucagon's binding site, and therefore, glucagon theoretically offers no advantage over other agents. Nevertheless, glucagon administration improves blood pressure in animal models, and several case reports have also noted improvement in hemodynamics after glucagon therapy.[47-50] However, failure to respond has also been reported.[40]

The recommended glucagon dose is an IV bolus of 3 to 10 milligrams in adults and 0.03 to 0.05 milligram/kg in children (Figure 195-1). A response is usually seen within 15 minutes. If there is no response, the bolus dose may be repeated. If there is hemodynamic improvement, a maintenance infusion should be initiated at 1 to 5 milligrams/kg per hour in adults and 0.02 to 0.07 milligram/kg per hour in children.

The main adverse effects of glucagon are vomiting and hyperglycemia. Therefore, endotracheal intubation should be strongly considered prior to initiation of glucagon therapy in a patient with altered mental status. Also, an antiemetic such as ondansetron may be empirically administered. Because of the large amounts of glucagon required, hospital supplies of the drug are often rapidly depleted, and it may be necessary to contact other institutions for additional drug.

TABLE 195-5 Protocol for High-Dose Insulin Therapy in Severe Calcium Channel Blocker Overdose

Check serum glucose, and if <200 milligrams/dL (<11 mmol/L), administer 50 mL of 50% dextrose (0.5 gram/mL) in water IV (children, 1 mL/kg of 25% dextrose).
Administer regular insulin 1 unit/kg IV bolus.
Begin regular insulin infusion at 0.5–1.0 unit/kg per hour along with dextrose 10% (0.1 gram/mL) in water at 200 mL/h (adult) or 5 mL/kg per hour (pediatric).
Titrate insulin infusion rate up to 10 units/kg per hour according the hemodynamic goal of HR >50 beats/min and SBP >100 mm Hg (>13.3 kPa).
Monitor serum glucose every 15–20 min.
Titrate dextrose infusion rate to maintain serum glucose level between 100 and 200 milligrams/dL (5.3 and 10.7 mmol/L).
Once dextrose infusion rates have been stable for 60 min, glucose monitoring may be decreased to hourly.
Monitor serum potassium level and start IV potassium infusion if serum potassium level is <2.8 mEq/L (<2.8 mmol/L).
Maintain serum potassium between 2.8 and 3.2 mEq/L (2.8 and 3.2 mmol/L).

Abbreviations: HR = heart rate; SBP = systolic blood pressure.

INTRAVENOUS LIPID EMULSION THERAPY

Lipid emulsion therapy was first described in the management of local anesthetic toxicity. Lipid emulsions appear to create a pharmacologic sink for fat-soluble drugs.[51] Therapy may also provide fatty acid substrate for cardiac energy supply and improve myocyte function by increasing intracellular calcium levels. Lipid emulsion therapy prolongs survival in an animal model of verapamil poisoning,[52] and several case reports also describe benefit in CCB ingestions unresponsive to standard therapy.[53,54] There are many different commercial lipid emulsion preparations, with the major components typically being soybean oil, egg yolk phospholipids, and glycerin. Consult with the poison control center or pharmacist when considering lipid emulsion therapy.

The recommended dose is a 20% lipid emulsion given as a 1.5 mL/kg bolus over 2 to 3 minutes, followed by an 0.25 mL/kg per minute infusion. If the blood pressure remains low, an additional 1.5 mL/kg bolus may be repeated followed by an increase in the infusion rate to 0.5 mL/kg per minute. The recommended upper limit for lipid emulsion infusion is about 10 mL/kg over the initial 30 minutes. If the patient's hemodynamic stability is dependent on continued lipid infusion, the treatment may be continued.[55] Case reports suggest that if sudden cardiac arrest occurs in the setting of overdose, a bolus can be given in the hope of restoring spontaneous circulation. In addition to interference with laboratory parameters, there are rare adverse effects such as hypertriglyceridemia, hypoxemia (with high doses), and hyponatremia.[21]

EXTRACORPOREAL CIRCULATORY SUPPORT

Patients who do not respond to the aforementioned therapies may benefit from circulatory support measures, such as the placement of intra-aortic balloon pumps, the use of left ventricular assist devices, and even extracorporeal circulatory support, which may provide adequate blood pressure to allow clearance of the drug and resolution of symptoms.[21,56,57] Hemodialysis or hemoperfusion is not beneficial in the treatment of CCB overdoses.[58]

DISPOSITION AND FOLLOW-UP

In general, patients usually manifest toxicity within 6 hours of ingestion of non–extended-release products. Therefore, those who are asymptomatic and who have normal vital signs after a 6-hour observation period can be discharged after appropriate psychiatric evaluation.[22] Toxicity may be delayed for up to 12 hours after ingestion of extended-release products.[6,7] **As a rule, patients who ingest potentially toxic amounts of extended-release products should be monitored for 12 to 24 hours.** Contact the regional poison control center for assistance with management.

CHAPTER 196

Antihypertensives

Frank Lovecchio
Dan Quan

INTRODUCTION

An estimated 30% of adults in the United States have hypertension; thus, antihypertensives are medications commonly found in patient homes.[1] Several classes of drugs used to treat hypertension are discussed in this chapter: diuretics, sympatholytic agents, angiotensin-converting enzyme inhibitors (ACEIs), angiotensin II receptor blockers (ARBs), and vasodilators (**Table 196-1**). Calcium channel blockers and β-blockers, also used in the treatment of hypertension, are discussed elsewhere (see chapters 195, "Calcium Channel Blockers," and 194, "Beta-Blockers").

For most of these agents, life-threatening toxicity is not expected in acute overdose.[2] In nearly all cases, good supportive care is adequate. The initial approach to the patient with potential overdose of an antihypertensive drug is fairly uniform. Secure the airway as necessary, establish IV access, provide continuous cardiac monitoring, and obtain an ECG. A bolus of crystalloid solution is first-line treatment for hypotension. If a vasopressor is required, a direct-acting drug such as norepinephrine is preferred. If pulmonary aspiration is not a concern, activated charcoal can be given within the first hour. Although there is usually no specific therapy for initial management of these drugs in overdose, the different classes of antihypertensives are distinct in their potential for causing metabolic derangements and adverse effects.

DIURETICS

Acetazolamide, a carbonic anhydrase inhibitor diuretic, is not used for management of hypertension. Acetazolamide may be indicated for management of high-altitude disease or glaucoma (in oral or topical preparations). Carbonic anhydrase plays a role in the renal proximal tubule sodium-hydrogen exchange. In the proximal tubule, $[Na^+]$ is reabsorbed from the tubule in exchange for $[H^+]$. Carbonic anhydrase in the proximal tubule brush border catalyzes the conversion of H_2CO_3 (formed from $[H^+]$ and $[HCO_3^-]$ present within the tubular lumen) to H_2O and CO_2. The CO_2 is then reabsorbed. Inhibition of carbonic anhydrase reduces the amount of $[H^+]$ available for exchange, so that more $[Na^+]$ and $[HCO_3^-]$ stays within the tubular lumen and is eliminated. Because sodium can be reabsorbed distally, the most clinically significant effect of carbonic anhydrase inhibition is loss of urinary bicarbonate with the development of a non–anion gap metabolic acidosis. Overdose experience is limited, and treatment is supportive.

Diuretics initially control hypertension by increasing elimination of salts, but their mechanism of action in long-term blood pressure control is not clear. All diuretics cause increased sodium elimination, which results in the potential for hyponatremia, hypokalemia, hypomagnesaemia, and hypovolemia.

Thiazides, like hydrochlorothiazide, inhibit sodium chloride reabsorption in the renal distal convoluted tubule. Decreased sodium reabsorption leads to increased excretion of potassium and the possibility of hypokalemia. Calcium regulation is also affected by thiazide diuretics via two separate mechanisms: (1) inhibition of vitamin D synthesis and thus decreased calcium absorption from the GI tract, and (2) increased renal absorption of calcium. The net result, however, is calcium retention and potentially hypercalcemia.[3] Glucose intolerance is noted at higher doses.

Loop diuretics, such as furosemide and bumetanide, are used more frequently for control of edema and pulmonary congestion than for management of high blood pressure. Loop diuretics inhibit the activity of the sodium-potassium-chloride symporter (a type of cotransporter that facilitates transport across a plasma membrane) in the renal loop of Henle, where 25% of the filtered sodium load is typically reabsorbed. A secondary effect of the inhibition of this symporter is decreased calcium and magnesium reabsorption, which results in hypocalcemia, hypokalemia, and hypomagnesemia.

Triamterene, amiloride, spironolactone, and eplerenone are referred to as potassium-sparing diuretics for their ability to cause a sodium chloride diuresis without increased potassium secretion. Triamterene and amiloride inhibit sodium channels in the distal renal tubule and collecting duct, which play a role in both reabsorbing sodium and secreting potassium. These drugs may be used in conjunction with other stronger diuretics for management of hypertension. Triamterene has been associated with rare cases of crystalline nephropathy.[4]

Spironolactone and eplerenone are antagonists of mineralocorticoids, such as aldosterone. Mineralocorticoid antagonists increase elimination of sodium and retention of hydrogen and potassium. Spironolactone is typically used to treat heart failure and hepatic cirrhosis. In the acute overdose setting, hyperkalemia and hypotension are the most serious clinical manifestations of these drugs.

Clinical manifestations of excessive diuresis include tachycardia, hypotension (orthostatic or supine), electrolyte abnormalities, and generalized weakness. The ECG may show changes caused by these electrolyte abnormalities (see chapter 17, "Fluids and Electrolytes"). A widened QRS interval or peaked T waves may suggest hyperkalemia, such as from a potassium-sparing diuretic. A prolonged QT interval may indicate hypokalemia, hypomagnesemia, or hypocalcemia, which may be caused by a loop diuretic.

The first priority of therapy is restoration of plasma volume. Administer an isotonic crystalloid solution bolus, such as 0.9% saline. If life-threatening hyperkalemia is encountered, provide standard management and fluid resuscitation.

In addition to causing direct toxicity, diuretics may potentiate toxicity from other medications. Mechanisms include decreased renal clearance of drugs or creation of a metabolic state that changes a particular drug's effect. **Diuretics and ACEIs can increase the risk of lithium toxicity** by reducing lithium elimination (see chapter 181, "Lithium").[5] Because hypokalemia exacerbates digoxin toxicity, non–potassium-sparing diuretics may exacerbate arrhythmias seen in chronic digoxin poisoning or other antiarrhythmics (see chapter 193, "Digitalis Glycosides").

SYMPATHOLYTIC AGENTS

Catecholamines produced by the sympathetic nervous system play a key role in maintaining blood pressure. Drugs with action at α-adrenergic receptors are used to diminish peripheral sympathetic tone in order to decrease blood pressure. There are two subtypes of α-adrenergic receptors. Stimulation of the α_1-adrenergic receptors causes vasoconstriction of arterioles and veins, increasing peripheral vascular resistance and elevating blood pressure. Stimulation of the α_2-adrenergic receptors produces different effects in the peripheral and central nervous systems. In the peripheral nervous system, stimulation of the α_2-receptors produces vasoconstriction and increases blood pressure. In the CNS, stimulation of the α_2-receptors at presynaptic sympathetic terminals inhibits the release of catecholamines, thereby decreasing sympathetic tone, promoting peripheral vasodilation, and decreasing blood pressure.

Doxazosin, prazosin, and terazosin antagonize α_1-adrenergic receptors, reducing peripheral vascular resistance. Although the aforementioned drugs are used for the treatment of hypertension, other members of this class, such as **tamsulosin**, are used exclusively for management of benign prostatic hyperplasia and as an adjunct in nephrolithiasis management. Because an increase in peripheral vascular resistance is required to maintain blood pressure when changing from a supine to an upright position, it is not surprising that the most typical adverse effect observed with α_1-adrenergic antagonists is orthostatic hypotension, particularly within 30 to 90 minutes after ingestion, and is most prominent after taking the first dose.[6]

Although orthostatic hypotensive episodes may be associated with lightheadedness and adverse events such as falls resulting in hip fracture, patients rarely come to the ED with prolonged hemodynamic instability. Patients who do present with hypotension associated with α_1-adrenergic antagonist use should be placed supine and receive a crystalloid bolus. Based on the mechanism of action of these drugs, phenylephrine, an α_1-adrenergic agonist, is an ideal agent if blood pressure does not improve with IV fluids.

TABLE 196-1 Summary of Antihypertensive Drugs

Class	Drug	Mechanism of Action	Clinical Presentation with Toxicity	Comments
Diuretics	Acetazolamide	Inhibition of proximal tubule sodium-hydrogen exchange	Hypovolemia Non–anion gap metabolic acidosis	
	Chlorothiazide Chlorthalidone Hydrochlorothiazide Indapamide Metolazone	Inhibition of distal tubule sodium chloride absorption	Hypovolemia Hypokalemia Hypercalcemia	Metabolic complications, such as hypokalemia, glucose intolerance, and hyperuricemia seen with increased therapeutic thiazide doses.
	Bumetanide Furosemide	Inhibition of sodium-potassium-chloride symporter in renal loop of Henle	Hypovolemia Hypocalcemia Hypokalemia Hypomagnesemia	
	Amiloride Triamterene	Inhibition of sodium absorption and potassium elimination in renal distal collecting duct	Hypovolemia Hyperkalemia	
	Eplerenone Spironolactone	Mineralocorticoid antagonist	Hypovolemia Hyperkalemia	
Sympatholytics	Doxazosin Prazosin Tamsulosin Terazosin	α_1-Adrenergic receptor antagonist	Hypotension	Phenylephrine may be used for refractory hypotension.
	Clonidine Guanabenz Guanfacine	α_2-Adrenergic receptor agonist Imidazoline receptor agonist μ-Receptor opioid agonist	Hypotension Bradycardia Neurologic depression	Dopamine considered agent of choice for hypotension. Phenylephrine may be used for refractory hypotension.
	Oxymetazoline Tetrahydrozoline	Imidazoline receptor agonist	Hypotension, Bradycardia, and Neurologic depression	
	Guanadrel Methyldopa Reserpine	Decreased norepinephrine release	Hypotension Bradycardia Hemolytic anemia (idiosyncratic reaction to methyldopa)	
ACE inhibitors	Benazepril Captopril Enalapril Fosinopril Moexipril Perindopril Quinapril Trandolapril	Inhibition of ACE Inhibition of bradykininase	Hypotension Hyperkalemia Angioedema (idiosyncratic) Cough (idiosyncratic)	Epinephrine, corticosteroids, and antihistamines have no proven benefit in ACEI-induced angioedema. Icatibant 30 milligrams SC or C1 esterase inhibitor [human] 1000 U IV are effective in ACEI-induced angioedema.
Angiotensin receptor blockers	Candesartan Eprosartan Irbesartan Losartan Telmisartan Valsartan	Angiotensin II receptor antagonist	Hypotension Hyperkalemia Angioedema (less common than with ACE inhibitors)	Epinephrine, corticosteroids, or antihistamines have no proven benefit in ARB-induced angioedema.
Vasodilators	Hydralazine	Arteriolar vasodilation	Hypotension Lupus-like syndrome (idiosyncratic reaction to hydralazine)	
	Minoxidil	Arteriolar vasodilation	Tachycardia Increased myocardial oxygen demand	
	Sodium nitroprusside	Arteriolar and venous vasodilation (via nitric oxide release)	Hypotension Tachycardia Thiocyanate toxicity (after prolonged infusion) Cyanide toxicity (very rare)	Thiosulfate should be administered if cyanide toxicity is considered. Many pharmacies mix sodium nitroprusside and thiosulfate to avert cyanide toxicity.

Abbreviation: ACE = angiotensin-converting enzyme.

CLONIDINE

Clonidine is the most commonly used α_2-adrenergic agonist. Clonidine is available in an oral formulation and as a transdermal patch. This class of drugs, which also includes guanabenz and guanfacine, stimulates α_2-adrenergic receptors in the CNS, inhibiting release of catecholamines in the periphery, which results in decreased heart rate, contractility, and peripheral vascular resistance. Clonidine shares the imidazoline functional group with the nasal spray decongestant oxymetazoline and topical eye vasoconstrictor medication tetrahydrozoline. **Inappropriately ingesting oxymetazoline or tetrahydrozoline can result in toxicity similar to clonidine poisoning.**[7,8] In addition to hemodynamic effects, clonidine also possesses opioid agonist properties at the μ-receptor.[9] For this reason, clonidine is used in some opioid-dependent patients to ameliorate symptoms of withdrawal.

Clonidine poisoning typically results from either intentional overdose or exploratory pediatric poisoning.[10,11] **Even a single tablet may cause significant symptoms in a child.**[12,13] Toxicity can develop from ingesting clonidine patches.[14,15] Compounded ointments used for chronic pain may contain clonidine that when applied to small children or to adults in excessive quantity may produce toxicity.[16,17]

Shortly after an ingested overdose of clonidine, the peripheral α_2-adrenergic stimulation may cause hypertension.[11,18] By the time of presentation, however, the clinical manifestations of central α_2-adrenergic stimulation and imidazoline toxicity are present with bradycardia and hypotension.[10] Clonidine may produce miotic pupils in a manner similar to opioids.[19] Hypothermia may occur as a result of opioid or adrenergically mediated pathways. Somnolence is typical and may progress to apnea in severe cases.[7,10,20] Although clonidine is intended to be dosed twice daily, symptoms may last days with an overdose.

Focus on ventilatory and hemodynamic support in clonidine toxicity. Clonidine-induced respiratory and neurologic depression has variable response to naloxone, and its use is unlikely to be helpful.[21-25] Bradycardia may be treated with atropine. When encountered, hypertension should be treated only if it is severe and prolonged. Because hypertension may unpredictably give way to hypotension, a drug that can be immediately discontinued, such as nitroprusside, should be used. Hypotension associated with clonidine typically responds well to crystalloid fluid resuscitation. Theoretically, a direct α_1-adrenergic agonist such as phenylephrine may be appropriate in cases of refractory hypotension, but dopamine is a better choice.

METHYLDOPA

Methyldopa is also a centrally acting antihypertensive, although it has a unique mechanism. Methyldopa is a dopamine analog that, in the CNS, is converted in two steps to α-methylnorepinephrine, which in turn substitutes for norepinephrine in adrenergic neuron secretory vesicles. In the CNS, α-methylnorepinephrine stimulates presynaptic α_2-adrenergic receptors, reducing peripheral sympathetic tone. In therapeutic dosing, the peak effect of methyldopa is delayed for 6 to 8 hours, because time is required for methyldopa to pass into the brain and be converted to its active form. Methyldopa use is also associated with hemolytic anemia, of autoimmune etiology, which occurs during long-term therapeutic use.[26,27] If symptomatic hypotension is encountered in association with methyldopa, IV crystalloid solution should be administered. In cases of refractory, severe hypotension, a direct-acting vasopressor such as norepinephrine should be administered.

GUANADREL AND RESERPINE

Guanadrel and reserpine are antihypertensives that interfere with the release of catecholamines from synaptic terminals. Guanadrel, which has no intrinsic sympathetic activity, substitutes for norepinephrine in presynaptic storage vesicles. Reserpine inhibits formation of biogenic amine storage vesicles in central and peripheral neurons. In each case, there is a decreased capacity to release catecholamines in response to a sympathetic stimulus. Sympathetic tone is diminished, and peripheral vascular resistance decreases. There is little experience with these drugs in overdose. However, because the common mechanism of both drugs is a decrease in circulating catecholamines, it would seem reasonable to administer boluses of crystalloid as first-line therapy and to use a direct-acting vasopressor, such as norepinephrine or phenylephrine, to treat refractory hypotension.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS AND ANGIOTENSIN RECEPTOR BLOCKERS

Angiotensin II raises blood pressure by several mechanisms, including triggering aldosterone release, increasing response to catecholamines, and acting as a direct vasoconstrictor. Angiotensin II is created in a two-step process. In the first step, renin, released by the kidneys, cleaves angiotensinogen, forming angiotensin I. The second step uses angiotensin-converting enzyme, which separates the carboxy terminus off angiotensin I, forming angiotensin II. Inhibition of this conversion at either step results in decreased blood pressure.

ACEIs are thought to slow the progression of diabetic glomerulopathy and have been shown to improve mortality and left ventricular function when administered after myocardial infarction. Members of this large class of drugs can be identified by their shared "-pril" suffix: benazepril, captopril, enalapril, fosinopril, moexipril, perindopril, quinapril, and trandolapril. Inhibition of angiotensin-converting enzyme results in decreased production of angiotensin II, which causes vasodilation. Despite their widespread use, these medications have not been associated with significant morbidity in overdose. ACEIs can cause hyperkalemia in therapeutic dosing. If hypotension is encountered, initial therapy focuses on basic management, including administration of boluses of crystalloid and vasopressors for refractory cases.

Captopril, and possibly other ACEIs, are thought to inhibit the metabolism of the enkephalins, a group of endogenous opioids. Naloxone, a μ-opioid antagonist, may reverse captopril-associated hypotension[28] but is not universally effective.[29]

ARBs produce vasodilatation and increase renal salt elimination. Members of this class end with the suffix "-artan" and include losartan, candesartan, irbesartan, valsartan, telmisartan, and eprosartan. When they are taken therapeutically, the peak antihypotensive effect of agents in this class is not observed for 4 weeks. Typically these drugs are not associated with significant morbidity in overdose. There are no reported cases of ARBs causing life-threatening hypotension. Like ACEIs, ARBs can cause hyperkalemia, which results from decreased aldosterone production. This effect is typically seen in patients with renal insufficiency.[23]

Persistent dry cough occurs in 5% to 20% of patients treated with ACEIs.[30] Cough typically develops within a few weeks after ACEI therapy is started and is more common in women, and the rate of occurrence or severity does not correlate with dose. Cough will usually resolve in 1 to 4 weeks after the drug is stopped, although resolution may take up to 3 months for some patients. The only effective treatment is discontinuing the ACEI, substituting a different antihypertensive. ARBs are not associated with an increased incidence of chronic cough and may be used in patients with ACEI-induced cough.[31]

Angioedema is the most consequential adverse effect associated with ACEIs and ARBs (see chapter 14, "Anaphylaxis, Allergies, and Angioedema").[32,33] Angioedema is an idiopathic reaction that occurs in 0.1% to 0.7% of patients prescribed these drugs.[33,34] Because these agents are widely used, this small percentage represents a large number of events. Patients present with swelling of the lips, larynx, pharynx, tongue, or vocal cords, which can range in severity from mild to airway compromise. Symptoms develop over several hours and may not resolve for 24 hours or longer. **The absence of urticaria differentiates angioedema from allergic anaphylaxis**. The mechanism is thought to be related to inhibition of ACE-mediated degradation of bradykinin, a peptide associated with vasodilatation and tissue edema, and accumulation of substance P and other prostaglandins. ARBs do not inhibit bradykinin, so the exact pathophysiology of angioedema associated with drugs from this class is not clear. **The mean time from first use to development of angioedema has been reported as about 2 years,[35] but angioedema can occur at any time during therapy,** with 12% of patients developing this reaction in the first week of ACEI use.

Management of ACEI-induced angioedema begins with evaluation of the airway. If the patient has difficulty breathing, stridor, or severe oropharyngeal edema, secure the airway, usually by intubation. Edema of the oral cavity or oropharynx (especially the tongue) is the best predictor of the need for airway intervention.[36] Fiberoptic-guided laryngoscopy is recommended because it requires minimal sedation and provides direct visualization in an edematous airway. **Regardless of the method employed, a skilled operator should secure the airway early because angioedema can progress rapidly and anatomic landmarks may become obscured.**

Allergic reaction drugs, such as epinephrine, antihistamines, and corticosteroids, are often given but not likely beneficial because ACEI-induced angioedema is not mediated by immunoglobulin E.[33] Icatibant, a bradykinin-2 antagonist, is effective in reducing swelling; the dose is 30 milligrams SC.[37] C1 esterase inhibitor [human] 1000 U IV is also effective.[38] Plasma or fresh frozen plasma contains angiotensin-converting enzyme, so the administration of plasma is thought to degrade high levels of bradykinin with subsequent resolution of angioedema. Two units of fresh frozen plasma in adults are reported to resolve ACEI-induced angioedema in 2 to 4 hours.[39,40] Ecallantide is a recombinant protein that inhibits kallikrein and is approved for use in hereditary angioedema. However, ACEI-induced angioedema is caused by the persistence of bradykinin due to lack of metabolism rather than overproduction, so it is not likely that ecallantide would be effective.

Patients with milder symptoms should be observed and managed medically. There is no consensus regarding the disposition of patients with ACEI-associated angioedema who do not require ED airway intervention. Patients with milder swelling only around the lips or face should be observed for 12 to 24 hours and discharged when swelling is regressing. Patients should be instructed that angioedema can recur if they continue to take the same agent or switch to another agent of the same class.[41,42] **After an episode of angioedema, the safest and recommended course of action is to discontinue all ACEIs and ARBs.**

VASODILATORS

HYDRALAZINE AND MINOXIDIL

Hydralazine is an antihypertensive agent most commonly used during pregnancy. Hydralazine relaxes arteriolar smooth muscle but does not affect venous smooth muscle or epicardial coronary arteries. Hydralazine is metabolized to an inactive compound by hepatic acetylation. Roughly half of Americans are fast acetylators and therefore require a higher dose to achieve a given clinical effect. The peak effect of the drug is seen 30 to 120 minutes after ingestion, although effects may last as long as 12 hours. The most common adverse effects of hydralazine overdose result from vasodilatation, but serious events are rare. Hydralazine overdose with mild hypotension may develop ST-segment depressions on ECG.[43] This myocardial ischemia is thought to result from a steal syndrome in which peripheral vasodilatation is accompanied by reflex tachycardia without an increase in epicardial blood flow, so that myocardial demand increases while coronary perfusion does not. Because of this reflex tachycardia, hydralazine should not be used for treatment of acute coronary syndrome or cocaine-associated chest pain.

Patients on continuous treatment with hydralazine are at risk for development of a lupus-like syndrome. The mechanism is thought to be formation of autoantibodies, but it is not known how hydralazine contributes to this process. Risk factors include high dose, female gender, slow-acetylator phenotype, and white ethnic background. Symptoms of this syndrome include arthralgia, arthritis, fever, and pericardial effusion. Management includes administration of anti-inflammatories and discontinuation of the drug.

Minoxidil is a potent antihypertensive generally used only for resistant cases of hypertension. Minoxidil is better known for its topical formulation as a treatment for male pattern baldness. Minoxidil is metabolized to minoxidil sulfate, which in turn relaxes smooth muscle by opening potassium channels and causing hyperpolarization. Like hydralazine, minoxidil has little effect on venous smooth muscle. Peripheral vasodilatation results in reflex tachycardia and increased cardiac output. Reduced renal perfusion causes fluid retention. For this reason, minoxidil is usually prescribed with a β-blocker and diuretic. Overdose of minoxidil is associated with hypotension, common reflex tachycardia, and occasional myocardial ischemia in a manner similar to hydralazine.[44-46]

Hypotension from either hydralazine or minoxidil is treated with IV crystalloid fluids. Vasopressors should be avoided if possible, because severely poisoned patients may have coronary ischemia. If blood pressure is refractory to fluid resuscitation, an α_1-adrenergic agonist, such as phenylephrine or midodrine,[46] is preferable to a β-adrenergic agonist, such as dopamine, to minimize tachycardia and prevent increased myocardial oxygen demand.

SODIUM NITROPRUSSIDE

Sodium nitroprusside is administered IV for hypertensive emergencies.[47,48] Nitroprusside derives its activity from the release of nitric oxide, an endogenous mediator of vasodilation, which stimulates smooth muscle guanylyl cyclase to produce cyclic guanosine monophosphate. The onset of action is roughly 30 seconds, and the offset is 3 minutes. Nitroprusside dilates both arteriolar and venous smooth muscle. In the ED, hypotension is the adverse effect most likely to be observed. If hypotension occurs, the infusion should be stopped immediately. If signs of cerebral hypoperfusion are present, place the patient supine or possibly in the Trendelenburg position. Because of the very brief duration of action of the drug, little else is generally necessary after discontinuing the drug.

When nitric oxide is released from nitroprusside, cyanide is produced as well. As long as the nitroprusside infusion rate is not above 2 to 5 micrograms/kg per minute, the cyanide is usually of little consequence, because it is immediately metabolized by rhodanese to thiocyanate, a much less toxic metabolite. At higher infusion rates over several days, the ability of rhodanese to detoxify cyanide may become overwhelmed.[49] Administration of sodium thiosulfate, which serves as a substrate for rhodanese, can be protective for patients requiring a high rate of nitroprusside administration. Cyanide toxicity may manifests as confusion, lactic acidosis, and progression to cardiovascular collapse. If the clinician is concerned about cyanide toxicity, the infusion should be discontinued, and sodium thiosulfate should be administered.

Over time, the thiocyanate generated by detoxification of cyanide can itself cause toxicity. Thiocyanate toxicity, although much more common than cyanide toxicity during nitroprusside treatment, is unlikely to occur in the ED. Thiocyanate, which is eliminated by the kidney with a half-life of 3 to 7 days, usually does not accumulate until infusion has continued for several days. The most important predictors of toxicity are rate of production (nitroprusside infusion rate) and rate of elimination (renal function). Thiocyanate toxicity may manifest as nausea, fatigue, and CNS depression.

FENOLDOPAM

Fenoldopam is a selective dopamine-1 agonist used for hypertensive emergencies, although its clinical utilization in the United States has remained low.[50,51] Fenoldopam is administered parenterally and acts as a vasodilator and diuretic.[47,48] Fenoldopam has a half-life of approximately 5 minutes, and after infusion is instituted, steady-state serum levels are reached in about 30 to 60 minutes. If hypotension is encountered after fenoldopam administration, the infusion should be stopped immediately and a fluid bolus administered.

CHAPTER 197

Anticonvulsants

Frank LoVecchio

INTRODUCTION

Anticonvulsants, or antiepileptics, are used to treat acute seizures and prevent convulsions in patients with epilepsy. The first generation of antiepileptics was developed between 1939 and 1980 (**Table 197-1**). Since 1993, 15 additional agents have been introduced into clinical use, termed the "second and third generation" of antiepileptic drugs. In general, these new anticonvulsants have fewer serious adverse side effects and fewer drug interactions than the first-generation agents. The first-generation drugs have an established therapeutic range for serum levels that can guide therapy during long-term management and that correlate with acute toxicity from an overdose. Consistent therapeutic levels have not been established for the second- and third-generation anticonvulsants, and serum levels are not a useful guide to therapy.

This chapter reviews the pharmacology, clinical features, and treatment for commonly used anticonvulsants. Disposition recommendations depend on the resolution of clinical toxicity, but patients with intentional overdose need mental health evaluation in the ED before discharge.

PHENYTOIN AND FOSPHENYTOIN

Phenytoin is a primary anticonvulsant for partial and generalized tonic-clonic seizures. It is useful in the treatment of non–drug-induced status epilepticus in conjunction with rapidly acting anticonvulsants.[1] Phenytoin has been used to prevent seizures due to head trauma (in the immediate post-traumatic period) and in the management of some chronic pain syndromes. Serious complications are extremely rare after intentional phenytoin overdose if supportive care is provided. Most phenytoin-related deaths have been caused by rapid IV administration or hypersensitivity reactions.

Phenytoin is available in oral and injectable forms. Phenytoin has poor solubility in water, so the vehicle for the parenteral formulation is 40% propylene glycol and 10% ethanol, adjusted to a pH of 12 with sodium hydroxide. The acute cardiovascular toxicity seen with IV phenytoin infusion has frequently been ascribed to the propylene glycol diluent. Other limitations with parenteral phenytoin are the irritating nature of the vehicle and a tendency to precipitate in IV solutions. **Fosphenytoin** (a disodium phosphate ester of phenytoin) is a prodrug that is converted to phenytoin by phosphatases in the body with a conversion half-life of 10 to 15 minutes. **The advantage with parenteral fosphenytoin is that it is soluble in aqueous solutions, is buffered to a pH of 8.8, is nonirritating to the tissues, and can be given by IM injection.**[2]

TABLE 197-1 Anticonvulsant Drugs

First Generation	Second and Third Generation
Carbamazepine	Eslicarbazepine acetate
Ethosuximide	Ezogabine or retigabine
Phenobarbital	Felbamate
Phenytoin and fosphenytoin	Gabapentin
Primidone	Lacosamide
Valproate	Lamotrigine
	Levetiracetam
	Oxcarbazepine
	Pregabalin
	Rufinamide
	Stiripentol
	Topiramate
	Tiagabine
	Vigabatrin
	Zonisamide

PATHOPHYSIOLOGY

Mechanism of Action Phenytoin exerts its anticonvulsant effect by blocking voltage-sensitive and frequency-dependent sodium channels in the neurons, suppressing repetitive neuronal activity, and preventing the spread of a seizure focus.[3] At higher concentrations, phenytoin delays activation of outward potassium currents in nerves and prolongs the neuronal refractory period. It also may exert an anticonvulsant effect by influencing calcium channels and γ-aminobutyric acid receptors or by inhibiting adenosine reuptake.

Pharmacokinetics Phenytoin is a weak acid with a pK_a of 8.3. In the acid milieu of the stomach and even at physiologic pH, more of the drug is nonionized, and its aqueous solubility is limited. Absorption after oral ingestion is slow, variable, and often incomplete, especially after an overdose. Different phenytoin preparations can possess major differences in bioavailability. **Consequently, it may be necessary to obtain serial measurements of serum level in suspected overdose to determine peak levels.** Peak levels typically occur between 3 and 12 hours after a *single therapeutic* oral dose.

After absorption, phenytoin is distributed throughout the body, with a volume of distribution of 0.6 to 0.8 L/kg. Brain tissue concentrations equal those in plasma within about 10 minutes of IV infusion and are correlated with therapeutic effects, whereas cerebrospinal fluid and myocardium equilibrate within 30 to 60 minutes.

Protein Binding Phenytoin is extensively (about 90%) bound to plasma proteins, especially albumin. The free, unbound form is the biologically active moiety responsible for the drug's clinical effect and toxicity. The unbound fraction of the drug is greater in neonates, the elderly, pregnant women, renal failure, hypoalbuminemia (cirrhosis, nephrosis, malnutrition, burns, trauma, or cystic fibrosis), and hyperbilirubinemia. Drugs that displace phenytoin from binding sites (salicylate, valproate, phenylbutazone, tolbutamide, and sulfisoxazole) also result in an increased unbound fraction.

Patients with decreased protein binding have higher levels of free phenytoin and experience a greater biologic effect despite lower levels of total phenytoin. Free phenytoin concentrations are more useful in predicting toxicity. **Corrected serum phenytoin levels** (the concentration that would be present if a patient's serum albumin level were normal) can be calculated as follows: corrected phenytoin concentration = (measured phenytoin concentration × 4.4)/(albumin concentration), with phenytoin concentration measured in micrograms/mL and the albumin concentration measured in grams/dL.

Metabolism After absorption and distribution, only 4% to 5% of phenytoin is excreted unchanged in the urine. The remainder is metabolized by hepatic microsomal enzymes, primarily hydroxylated through a series of inactive compounds. The metabolism of phenytoin is capacity limited (dose dependent). At plasma concentrations of <10 micrograms/mL, elimination is **first-order kinetics** (a fixed *percentage* of drug metabolized per unit of time). At higher concentrations, including those in the therapeutic range of 10 to 20 micrograms/mL, the metabolic pathways may become saturated, and the elimination may change to **zero-order kinetics** (a fixed *amount* metabolized per unit of time). With zero-order kinetics, small increases in maintenance doses may saturate the enzyme systems, markedly prolonging the half-life of phenytoin, and result in a disproportionate increase in the plasma level. **Thus incremental dose increases should be limited to 30 to 50 milligrams at a time, and levels should be carefully monitored when it is necessary to raise phenytoin doses above 300 milligrams (or above 5 milligrams/kg) per day.**

Concomitant use of drugs that inhibit or enhance hepatic microsomal activity may result in an increase or decrease of phenytoin level, respectively. Phenytoin also affects the metabolism of various other agents (**Table 197-2**).

TABLE 197-2 Phenytoin Drug Interactions (Partial List)

Phenytoin increases serum levels of	Phenytoin levels are increased by
Acetaminophen	Amiodarone
Acetazolamide	Chloramphenicol
Amiodarone	Cimetidine
Oral contraceptives	Disulfiram
Primidone	Fluconazole
Zidovudine	Isoniazid
Phenytoin increases toxicity of	Oral anticoagulants
Carbamazepine	Phenylbutazone*
Oral anticoagulants	Salicylate (high dose)*
Phenytoin decreases serum levels of	Trimethoprim
Cyclosporine	Phenytoin levels are decreased by
Disopyramide	Antineoplastic drugs
Doxycycline	Calcium
Ethanol (chronic use)	Ethanol
Furosemide	Diazepam
Glucocorticoids	Diazoxide
Levodopa	Folic acid
Methadone	Phenobarbital
Mexiletine	Rifampin
Quinidine	Sucralfate
Theophylline	Sulfonamides*
Valproate	Theophylline
	Tolbutamide*
	Valproate*

*These drugs displace phenytoin from its protein-binding sites, thus increasing the free phenytoin fraction, although the total phenytoin level may decrease.

Propylene Glycol and Ethanol Diluents Propylene glycol is a potent myocardial depressant and vasodilator and also enhances vagal tone. This chemical can cause coma, seizures, circulatory collapse, ventricular dysrhythmias, atrioventricular node depression, and hypotension in experimental animals.[4] Other toxic effects from propylene glycol include hyperosmolality, hemolysis, and lactic acidosis.[5] The ethanol diluent fraction of parenteral phenytoin may precipitate a reaction in patients taking disulfiram.

CLINICAL FEATURES

Central Nervous System Toxicity As toxic phenytoin levels are reached, inhibitory cortical and excitatory cerebellar and vestibular effects begin to occur. The initial sign of toxicity is usually nystagmus, which is seen first on forced lateral gaze and later becomes spontaneous (**Table 197-3**).[6] Vertical, bidirectional, or alternating nystagmus may occur with severe intoxication. A decreased level of consciousness is common, with initial sedation, lethargy, ataxic gait, and dysarthria.[6] This may progress to confusion, coma, and even apnea in a large overdose. Nystagmus may disappear as the level of consciousness decreases, and complete ophthalmoplegia and loss of corneal reflexes may occur. Therefore, absence of nystagmus does not exclude severe phenytoin toxicity. Nystagmus returns as serum drug levels decrease and coma lightens.

Paradoxically, very high levels of phenytoin may be associated with seizures, although this is a rare occurrence, and such phenytoin-induced seizures are usually brief and generalized and almost always are preceded by other signs of toxicity, especially in acute overdose.[7]

Cerebellar stimulation and alterations in dopaminergic and serotonergic activities may cause acute dystonias and movement disorders, such as opisthotonos and choreoathetosis. Hyperactive deep tendon reflexes, clonus, and extensor toe responses also may be elicited. Chronic neurologic toxicity includes peripheral neuropathy and cerebellar degeneration with ataxia.

TABLE 197-3 Clinical Features of Phenytoin Toxicity

Central nervous system	Dizziness, tremor (intention), visual disturbance, horizontal and vertical nystagmus, diplopia, miosis or mydriasis, ophthalmoplegia, abnormal gait (bradykinesia, truncal ataxia), choreoathetoid movements, irritability, agitation, confusion, hallucinations, fatigue, coma, encephalopathy, dysarthria, meningeal irritation with pleocytosis, seizures (rare)
Peripheral nervous system	Peripheral neuropathy, urinary incontinence
Hypersensitivity (anticonvulsant hypersensitivity syndrome)	Eosinophilia, rash, pseudolymphoma (diffuse lymphadenopathy), systemic lupus erythematosus, pancytopenia, hepatitis, pneumonitis
Gastrointestinal	Nausea, vomiting, hepatotoxicity
Dermatologic	Hirsutism, acne, rashes (including Stevens-Johnson syndrome)
Other organs	Fetal hydantoin syndrome, gingival hyperplasia, coarsening of facial features, hemorrhagic disease of the newborn, hyperglycemia, hypocalcemia
Parenteral toxicity	May cause hypotension, bradycardia, conduction disturbances, myocardial depression, ventricular fibrillation, asystole, and tissue necrosis from infiltration

Cardiovascular Toxicity **Cardiovascular complications have been almost entirely limited to cases of IV administration, in large part due to the constituents of the parenteral vehicle, or in rare cases of chronic oral toxicity.**[8] Cardiac toxicity after oral phenytoin overdose in an otherwise healthy patient has not been reported and, if observed, is due to other causes (e.g., hypoxia and other drugs).[8]

Reported cardiovascular complications include hypotension with decreased peripheral vascular resistance, bradycardia, conduction delays progressing to complete AV nodal block, ventricular tachycardia, primary ventricular fibrillation, and asystole. ECG changes include increased PR interval, widened QRS interval, and altered ST segments and T waves. Cardiovascular toxicity is more common in the elderly, those with underlying cardiac disease, and the critically ill. Guidelines for parenteral phenytoin administration stress a slow rate of infusion and constant monitoring (**Table 197-4**).

TABLE 197-4 Guidelines for Phenytoin or Fosphenytoin Loading

IV	Loading dose is 18 milligrams/kg as phenytoin or fosphenytoin PE.* Mix total dose in 150–200 mL of normal saline. Keep phenytoin concentration <6 milligrams/mL or fosphenytoin PE concentration <25 milligrams/mL. Administer phenytoin through Millipore filter using an infusion pump. Rate of administration should not exceed 25–50 milligrams/min of phenytoin or 150 milligrams/min of fosphenytoin PE. Use a slower rate of infusion in patients with cardiovascular disease. Monitor the blood pressure and cardiac rhythm continually during the infusion. In the event of complications, immediately stop the infusion and administer isotonic crystalloid and other treatment as indicated.
IM	Administer 15 milligrams/kg fosphenytoin PE preparation in one or multiple IM sites.
PO†	Loading dose is 20 milligrams/kg. Phenytoin tablets or suspension may be used. Patient must be conscious with an intact gag reflex and not actively seizing or vomiting. Administer the total amount in one dose.

Abbreviation: PE = phenytoin equivalents.

*For simplicity, the pharmaceutical concentration and dose of fosphenytoin is expressed in PE, with 150 milligrams fosphenytoin = 100 milligrams PE.

†Unlike with IV loading, not all patients will reach a therapeutic level with oral loading.

Even though fosphenytoin does not contain the propylene glycol diluent, cardiovascular toxicity can occur with IV administration. Hypotension is seen in about 8%, and rare cases of bradycardia, AV nodal block, and asystole have been observed.[2,10,11]

Vascular and Soft Tissue Toxicity IM injection of *phenytoin* may result in localized crystallization of the drug with hematoma, sterile abscess, and myonecrosis at the injection site. IV extravasation may produce skin and soft tissue necrosis, compartment syndrome, and limb gangrene. Delayed bluish discoloration of the affected extremity ("purple glove syndrome") followed by erythema, edema, vesicles, bullae, and local tissue ischemia has been described.[12]

Hypersensitivity Reactions Hypersensitivity reactions usually occur within 1 to 6 weeks of beginning phenytoin therapy and can present as a febrile illness with skin changes (erythema multiforme, toxic epidermal necrolysis or Stevens-Johnson syndrome) and internal organ involvement (hepatitis, rhabdomyolysis, acute interstitial pneumonitis, renal failure, lymphadenopathy, leukopenia and/or disseminated intravascular coagulation). **Patients with a history of previous hypersensitivity reactions should not receive phenytoin, and because of similar reactions to phenobarbital, lamotrigine, felbamate, and carbamazepine, these anticonvulsants should also be avoided.**

Miscellaneous Effects Gingival hyperplasia is relatively common and is associated with poor dental hygiene (gingivitis and dental plaques). Because of the risk of fetal hydantoin syndrome, oral phenytoin therapy should never be initiated in a pregnant patient without consultation with and close follow-up by a neurologist and obstetrician.

DIAGNOSIS

The therapeutic phenytoin serum level is 10 to 20 micrograms/mL (40 to 80 micromoles/L), which generally corresponds to a free phenytoin level of 1 to 2 micrograms/mL.[13] Although 50% of patients achieve reduction in seizure frequency below these levels, some patients require levels as high as 20 micrograms/mL for adequate control. The ratio of toxic dose to therapeutic dose for phenytoin is rather low, and there is wide individual variability in the levels required to cause adverse effects. In general, toxicity is correlated with increasing plasma levels (**Table 197-5**).

TREATMENT

The initial treatment of severe oral phenytoin overdose is similar to that for ingestion of other drugs. Correct acidosis (respiratory or metabolic) to decrease the active free phenytoin fraction. Multidose activated charcoal may decrease drug half-life but does not decrease time to recovery and does not change outcome in overdose patients.[14] Seizures may be treated with IV benzodiazepines or phenobarbital, with the caution that seizures are uncommon in phenytoin overdose. **For patients with severe and persistent toxicity, hemodialysis and hemoperfusion can produce substantial improvement in neurologic toxicity.**[15-17]

Cardiac monitoring after isolated oral ingestion is unnecessary. Atropine and temporary cardiac pacing may be used for symptomatic bradyarrhythmias associated with IV phenytoin. Hypotension that occurs during IV administration of phenytoin or fosphenytoin usually responds to discontinuation of the infusion and administration of isotonic crystalloid.

TABLE 197-5 Correlation of Plasma Phenytoin Level and Toxic Effects

Total Plasma Level (micrograms/mL)	Toxic Effects
<10	Usually none
10–20	Occasional mild nystagmus
20–30	Nystagmus
30–40	Ataxia, slurred speech, nausea and vomiting
40–50	Lethargy, confusion
>50	Coma, seizures

DISPOSITION AND FOLLOW-UP

Phenytoin has a long and erratic absorption phase after oral overdose, so the decision to discharge or medically clear a patient for psychiatric evaluation cannot be based on one serum level. After acute ingestions, serum level should be measured every few hours. Patients with serious complications after an oral ingestion (seizures, coma, altered mental status, or significant ataxia) should be admitted for further evaluation and treatment. Those with mild symptoms should be observed in the ED and discharged once their levels of phenytoin are declining and they are clinically well. Mental health or psychiatric evaluation should be obtained, as indicated, in cases of intentional overdose.

Patients with symptomatic chronic intoxication should be admitted for observation unless signs are minimal, adequate care can be obtained at home, drug levels are decreasing, and 6 to 8 hours have elapsed since the patient's last therapeutic dose. Phenytoin therapy should be stopped in all cases, and if toxicity continues to resolve, serum level may be reassessed in 2 to 3 days to guide resumption of therapy. Surgical consultation should be obtained for patients with significant extravasation of IV phenytoin or with other signs of local vascular or tissue toxicity after infusion.

CARBAMAZEPINE

Carbamazepine is a primary anticonvulsant used in the treatment of partial and tonic-clonic seizures. Other uses include trigeminal neuralgia, chronic pain disorders, manic disorder, and bipolar disorder.

PATHOPHYSIOLOGY

Carbamazepine inhibits sodium channels and interferes with muscarinic acetylcholine receptors, nicotinic acetylcholine receptors, *N*-methyl-D-aspartate receptors, and central nervous system adenosine receptors.[3] Carbamazepine may relieve neuropathic pain through blockade of synaptic transmission in the trigeminal nucleus. Carbamazepine also possesses anticholinergic, antiarrhythmic, antidepressant, sedative, and neuromuscular-blocking properties. It has central antidiuretic effects, which may lead to the syndrome of inappropriate antidiuretic hormone secretion. Carbamazepine is a potent cytochrome P-450 enzyme inducer and enhances its own metabolism over time.

Carbamazepine is an iminostilbene derivative that is chemically and structurally similar to imipramine. Gastrointestinal absorption is slow, and peak serum concentrations usually occur within 8 hours but may be as late as 12 hours after ingestion. A therapeutic carbamazepine concentration is 4 to 12 micrograms/mL.[18]

Carbamazepine has a protein binding of about 80% and a volume of distribution of 0.8 to 1.2 L/kg. It is metabolized by liver cytochrome P-450 isoenzymes to an active metabolite (10,11-epoxide). The epoxide concentration comprises 15% of the parent compound in adults and slightly higher in children. The epoxide metabolite is responsible for much of the neurotoxicity seen in overdose. Autoinduction of the enzymes that metabolize carbamazepine occurs with about 1 month of continuous use. Because of this, the drug's half-life shortens over time: the half-life after an isolated carbamazepine dose is about 35 hours, much longer than the 10 to 20 hour half-life at steady state after 3 to 5 weeks of continuous therapy.[17]

CLINICAL FEATURES

After an overdose, the delayed and erratic absorption due to anticholinergic properties (which delay gastrointestinal motility) and low water solubility can cause delayed clinical deterioration or a crescendo-decrescendo clinical course.[19] Manifestations of acute toxicity include mental status depression, ataxia, nystagmus, ileus, hypertonicity with increased deep tendon reflexes, dystonic reactions, and an anticholinergic toxidrome.[19-21] Paradoxical seizures can occur in patients with high carbamazepine concentrations and an underlying seizure disorder. There are sporadic reports of left ventricular dysfunction with heart failure and transient heart block (without hemodynamic compromise). **Cardiac arrhythmias are rarely seen, but carbamazepine is one of the few drugs that can potentially cause both a wide QRS interval and seizures.** Laboratory

abnormalities seen with acute overdose include hyponatremia, hyperglycemia, and transient elevation of serum liver enzyme levels.

Adverse effects occur in 25% of patients receiving long-term carbamazepine therapy. Mild transient leukopenia may occur during the first month of treatment. This is unrelated to the more serious side effect of aplastic anemia, which has a reported incidence of 1 to 5 per million patient-years, approximately 11 times higher than in the normal population. Mild liver enzyme elevation occurs in up to 10% of patients on long-term therapy. Stevens-Johnson syndrome and toxic epidermal necrolysis are reported with about the same frequency as aplastic anemia.

DIAGNOSIS

Serum carbamazepine concentrations are not linearly correlated with poisoning severity. However, serum concentrations of >40 micrograms/mL are associated with an increased risk of serious complications such as seizures, respiratory failure, coma, and cardiac conduction defects.[22] Serum concentrations higher than 60 to 80 micrograms/mL may be fatal. The seriousness of toxicity should be judged by the clinical status of the patient, not by the serum concentration.[20-22]

Because the chemical structure of carbamazepine is related to imipramine, **carbamazepine can cause a false-positive tricyclic antidepressant result on a urine drug screen**.[23] Both carbamazepine and epoxide metabolite are measured by the standard enzyme-multiplied immunoassay to determine serum levels.

TREATMENT

Activated charcoal may be considered if the patient is not obtunded and presents within 1 hour of ingestion, because delayed absorption is possible.[14] Multidose activated charcoal may decrease drug half-life but does not decrease time to recovery or change outcome in overdose patients.[24] **In patients with severe toxicity and multiorgan dysfunction, hemodialysis, hemoperfusion, or hemodiafiltration is effective**.[25-31] Although cardiac conduction delays are rare, if conduction delay is noted on the electrocardiogram, sodium bicarbonate treatment seems reasonable.

DISPOSITION AND FOLLOW-UP

Patients can be medically cleared from the ED if at least two carbamazepine measurements obtained a few hours apart show decreasing levels (preferably below 15 micrograms/mL) and the patient is awake, ambulatory, and free of cardiac conduction abnormalities.

VALPROATE

Valproate (or valproic acid) is used to treat tonic-clonic seizures, absence seizures, partial complex seizures, and post-traumatic epilepsy. Valproate is also used in migraine headache prophylaxis, to control manic episodes in bipolar disorder, and to treat neuropathic pain.

PATHOPHYSIOLOGY

Valproate affects neurotransmitters and the function of electrically excitable cells.[3] Valproate increases γ-aminobutyric acid concentrations, reduces release of γ-hydroxybutyrate, and blocks *N*-methyl-D-aspartate receptors.[32] Valproate prolongs recovery of inactivated sodium channels, enhances potassium conductance, and reduces T-type calcium current firing.

With standard preparations at therapeutic doses, peak serum concentrations occur within 4 hours after ingestion. If the enteric-coated or controlled-release formulation has been ingested, peak serum concentration may be delayed for 12 to 17 hours.[33]

Valproate is metabolized by the liver by glucuronic acid conjugation and mitochondrial beta oxidation. Valproate enters mitochondria by using L-carnitine as a cofactor. Protein binding is extensive and influenced by serum concentration, with 90% of the drug protein bound at concentrations of 40 micrograms/mL. Valproate is an eight-carbon fatty acid and has a small volume of distribution of 0.13 to 0.23 L/kg. The half-life of valproate is 8 to 21 hours but may be two or three times longer after overdose.[33-36]

CLINICAL FEATURES

After an overdose with acute toxicity, the most frequent sign is CNS depression, ranging from drowsiness to coma.[35] Other findings include respiratory depression, hypotension, hypoglycemia, hypocalcemia, hypernatremia, hypophosphatemia, and anion gap metabolic acidosis that may persist for days. Toxicity to the liver produces elevated serum levels of aminotransferases, ammonia, and lactate. Pancreatitis may occur, and thrombocytopenia may be clinically significant and severe.[35]

Valproate increases renal ammonia production and blocks hepatic ammonia metabolism. Hyperammonemia in the absence of liver failure has been reported following valproate overdose and during long-term therapy.[37,38] Cerebral edema has been seen in acute overdose.[34,35] During long-term therapeutic use, increased serum liver enzyme levels occur in >50% of patients with therapeutic valproate serum concentrations. Liver enzyme levels typically normalize with dosage reduction or discontinuation of the drug. Hepatic failure, histologically evident as microvesicular steatosis, occurs in about 1 in 20,000 patients receiving long-term therapy.[39-41] Valproate-induced hepatotoxicity may be either intrinsic and benign (reversible, reproducible, and dose dependent) or idiosyncratic and fatal (unpredictable, not dose dependent, with a long latent period). Children <3 years of age who are receiving multiple antiepileptic agents and have additional medical problems are at highest risk for fatal hepatotoxicity, with an incidence of about 1 in 500. Serum levels of transaminases and ammonia should be checked in children on valproate therapy who demonstrate somnolence or lethargy.

DIAGNOSIS

Therapeutic valproate concentrations are 50 to 100 micrograms/mL. Although serum concentration does not correlate well with either seizure control or toxicity, adverse side effects increase as concentrations rise above 150 micrograms/mL, and coma may occur with levels above 800 micrograms/mL. When serum valproate concentrations are measured, the enzyme-multiplied immunoassay technique yields higher values than gas-liquid chromatography, so a consistent analytic methodology should be used when monitoring treatment. Serum ammonia and glucose concentrations should be measured with suspected valproate toxicity. **Valproate is eliminated partly as ketone bodies and may cause a positive test result for ketones in the urine or blood.**

TREATMENT

Single-dose activated charcoal alone is sufficient for the vast majority of patients with a valproate overdose. Consider multidose activated charcoal and/or whole-bowel irrigation after ingestion of enteric-coated, delayed-release preparations to prevent the ongoing absorption that may occur from delayed capsule or tablet dissolution.[14,42] Because of delayed peak serum levels after an overdose, serial concentrations should be measured.

Administration of high-dose naloxone has been reported to reverse valproate-induced neurologic depression, possibly by reversal of valproate-induced release of endogenous opioids or reversal of valproate-induced blockade of γ-aminobutyric acid uptake.[43,44] Because the serious toxic effects of valproate involve more than just these two mechanisms, naloxone is unlikely to be helpful in the management of a comatose patient after valproate overdose.

Overdose patients have been given **L-carnitine** in an attempt to increase valproate metabolism by beta oxidation, and this therapy appears to hasten the resolution of coma, prevent hepatic dysfunction, and reverse mitochondrial metabolic abnormalities in patients with acute valproate intoxication.[45-47] Administration of L-carnitine 100 milligrams/kg IV initially followed by infusions of 50 milligrams/kg every 8 hours is recommended in cases of valproate toxicity with lethargy, coma, hyperammonemia, and hepatic dysfunction.[46] For patients receiving long-term valproate therapy, oral carnitine administration reverses carnitine deficiency, decreases elevated ammonia levels, and reduces lethargy.

Hemoperfusion and hemodiafiltration have been used to treat severe valproate overdose.[48-52] Although valproate should not be amenable to dialysis due to significant protein binding, unbound (free) drug is markedly increased in overdose, and removal of valproate from this

pool appears beneficial. During hemoperfusion and hemodiafiltration treatment, elimination half-life ranges from 1.7 to 3 hours compared with 4.8 to 21 hours in patients before and after extracorporeal therapy. Clinical comparison of extracorporeal detoxification with supportive care reports a benefit to extracorporeal removal.[53]

DISPOSITION AND FOLLOW-UP

Assess valproate levels every few hours until a decline in the level is noted and the patient is asymptomatic.

SECOND- AND THIRD-GENERATION ANTICONVULSANTS

As a group, the second- and third-generation anticonvulsants are less toxic in acute overdose than the first-generation agents, and most of the serious complications reported occur in cases of mixed ingestion.[54] Some specific acute toxic effects are notable (**Table 197-6**).

ESLICARBAZEPINE ACETATE

Eslicarbazepine acetate is a prodrug drug for eslicarbazepine, an anticonvulsant that stabilizes sodium-dependent channels in their inactivated state.[55,56] Eslicarbazepine acetate has a half-life of 10 to 20 hours and possesses modest and possible clinically relevant drug interactions with phenytoin, carbamazepine, and oral contraceptives.[55-57] Symptoms of vertigo, ataxia, and hemiparesis have been observed after accidental overdose. Eslicarbazepine acetate is available in Europe but not in the United States as of March 2012.

EZOGABINE

Ezogabine (generic name in the United States) or **retigabine** (generic name in Europe) activates voltage-gated potassium channels in the brain, a unique mechanism among the anticonvulsants.[55,56,58] Ezogabine has a half-life of 6 to 10 hours and possesses drug interactions with phenytoin, carbamazepine, and lamotrigine.[55-57] Side effects seen with ezogabine therapy include dizziness, fatigue, confusion, tremor, and ataxia.[58] Increased rate of urinary retention and slight increase in QT interval have been reported. There is limited experience with overdose, but agitation, irritability, and aggressive behavior have been noted.

FELBAMATE

Felbamate was the first of the second-generation antiepileptics.[54] However, shortly after its introduction in 1993 it received a "black box warning" because of the association with aplastic anemia (with an incidence 100 times higher than in the general population) and hepatic failure. Hence it is only recommended when other treatment regimens have failed. The proposed mechanism of action of felbamate is inhibition at γ-aminobutyric acid receptors and excitation at *N*-methyl-d-aspartic acid receptors. Felbamate has a half-life of 20 to 23 hours and possesses drug intersections with the first-generation anticonvulsants and oral contraceptives. In overdose, the symptoms are usually mild, but in large ingestions, felbamate can crystallize in the kidney, producing crystalluria, hematuria, and possibly acute renal failure.[59-61] Treatment is supportive.

GABAPENTIN

Gabapentin, as its name suggests, increases γ-aminobutyric acid levels in the brain. It also has indirect effects on calcium channels located on the postsynaptic terminal. Gabapentin has a half-life of 5 to 9 hours and possesses drug interactions with cimetidine and antacids. With an overdose, gabapentin produces little toxicity, usually drowsiness, ataxia, nausea, and vomiting that resolve in about 10 hours.[62] Depressed level of consciousness has been described in a patient with end-stage renal disease who ingested multiple doses of gabapentin over 2 days without intervening hemodialysis; hemodialysis was associated with rapid recovery.[63] The only reported suicide from gabapentin overdose is controversial.[64]

LACOSAMIDE

Lacosamide affects voltage-gated sodium channels in the central nervous system.[65] Lacosamide has a half-life of 12 to 16 hours and has no significant drug interactions.[56,57] During therapeutic use, adverse reactions are usually mild to moderate and typically include dizziness, headache, nausea, and diplopia.[65] There is limited clinical experience with lacosamide overdose, but serious toxicity after an isolated overdose would not be expected to occur.

LAMOTRIGINE

Lamotrigine inhibits sodium channels in CNS neurons and likely has the same effect in the heart.[55] Lamotrigine has a half-life of 15 to 35 hours and interacts with the first-generation antiepileptics.[57] Autoimmune

TABLE 197-6 Unique Aspects of Overdose With Second- and Third-Generation Anticonvulsants

Drug (Generation)	Effects
Eslicarbazepine acetate (3rd)*	Vertigo, ataxia, hemiparesis
Ezogabine or retigabine (3rd)	Agitation, irritability, aggressive behavior
Felbamate (2nd)	Crystalluria, hematuria, aplastic anemia, liver failure
Gabapentin (2nd)	Drowsiness, ataxia, nausea, vomiting
Lacosamide (3rd)	Limited experience; serious toxicity unlikely
Lamotrigine (2nd)	Drowsiness, vomiting, ataxia, and dizziness; serious neurologic and cardiovascular toxicity with co-ingestants; "Stevens-Johnson syndrome"
Levetiracetam (2nd)	Lethargy, coma, respiratory depression
Oxcarbazepine (2nd)	Little toxicity from isolated oxcarbazepine overdose
Pregabalin (2nd)	Drowsiness and depressed level of consciousness
Rufinamide (2nd)	Limited experience; serious toxicity unlikely
Stiripentol (2nd)*	No information
Tiagabine (2nd)	Rapid onset of lethargy, coma, seizures, and status epilepticus; myoclonus, muscular rigidity, and delirium
Topiramate (2nd)	Somnolence, vertigo, agitation, and mydriasis; seizures and status epilepticus; metabolic acidosis
Vigabatrin (2nd)	Drowsiness, unconsciousness, coma
Zonisamide (2nd)	Little toxicity from isolated zonisamide overdose

*Not available in the United States as of March 2012.

reactions, such as Stevens-Johnson syndrome, have occurred during therapeutic use. With an overdose, the clinical course is usually benign, and the most common effects are drowsiness, vomiting, ataxia, and dizziness.[66,67] Serious neurologic and cardiovascular toxicity is rare, but has been reported after lamotrigine overdose, sometimes with coingestants.[68-72] Neurologic toxicity includes oculogyric crisis, provoking of seizures,[70,74-77] status epilepticus, and coma. Cardiac toxicity includes QRS complex widening,[78] AV nodal block,[79] and cardiovascular collapse.[72,77] Acute pancreatitis has been reported in association with a lamotrigine overdose.[80] Treatments used in lamotrigine overdose include **activated charcoal** to reduce absorption,[81] **sodium bicarbonate for QRS complex widening, magnesium sulfate for QT interval prolongation, and IV lipid emulsion** to remove active drug from binding sites and sequester it in a lipid sink.[82,83]

LEVETIRACETAM

The mechanism of action of **levetiracetam** is not known. Levetiracetam has a half-life of 6 to 8 hours and possesses drug interaction only with phenytoin. During therapeutic use, the major side effect is somnolence, usually seen during the initial 4 weeks of therapy.[84] There are few reports of levetiracetam overdose, and the most common symptom is lethargy that can progress to coma and respiratory depression.[85-88] Recovery is usually rapid with supportive care alone.

OXCARBAZEPINE

Oxcarbazepine inhibits voltage-sensitive sodium channels in the nervous system.[89] Oxcarbazepine has a half-life of 8 to 15 hours and interacts with phenytoin, lamotrigine, and oral contraceptives.[56,57] During therapeutic use, hyponatremia and drug rash can be seen. There appears to be little toxicity from isolated oxcarbazepine overdose; most of the serious neurologic depression has been seen with mixed ingestions.[90-93]

PREGABALIN

Pregabalin has a mechanism of action similar to that of gabapentin, increasing γ-aminobutyric acid levels in the brain in addition to having indirect effects on calcium channels located on the postsynaptic terminal. Pregabalin has a half-life of 5 to 7 hours and possesses drug interactions with ethanol, lorazepam, and oxycodone.[56,57] During long-term therapeutic use, the most commonly reported side effects are somnolence and dizziness; serious adverse effects are rare. There is little reported experience with pregabalin overdose; depressed level of consciousness appears to be the major symptom.[94,95] Similar to the experience with gabapentin, toxicity from pregabalin has been reported in patients with end-stage renal failure but resolves with dialysis.[96]

RUFINAMIDE

Rufinamide inhibits the activity of sodium channels, prolonging their inactive state.[97] Rufinamide has a half-life of 6 to 10 hours and has drug interactions with other anticonvulsants—phenytoin, carbamazepine, valproate, phenobarbital, and lamotrigine—as well as with oral contraceptives.[56,57] During long-term therapy, commonly reported adverse reactions include headache, dizziness, fatigue, and somnolence. There is limited clinical experience with rufinamide overdose, but given the lack of symptoms seen with doses of more than six times the recommended amount, toxicity would not be expected after an isolated overdose.

STIRIPENTOL

Stiripentol inhibits the reuptake of γ-aminobutyric acid into the presynpatic neuron, thereby increasing γ-aminobutyric acid concentrations in the synaptic cleft and promoting γ-aminobutyric acid activity. Stiripentol has a half-life of 5 to 13 hours and possesses modest drug interactions with valproate and clobazam.[56,57] Side effects during therapeutic use include drowsiness, ataxia, tremor, anorexia, nausea, and vomiting. Transient aplastic anemia and leukopenia have occurred. There is no information on clinical overdose with this medication. Stiripentol is available in Europe and Canada, but not in the United States as of March 2012.

TIAGABINE

Tiagabine inhibits the reuptake of γ-aminobutyric acid into the presynpatic neuron, thereby increasing γ-aminobutyric acid concentrations in the synaptic cleft and promoting γ-aminobutyric acid activity. Tiagabine has a half-life of 5 to 8 hours and interacts with most of the first-generation antiepileptics, including phenytoin, valproate, carbamazepine, phenobarbital, and primidone.[56,57] In overdose, tiagabine can cause the rapid onset of neurologic toxicity, including lethargy, coma, and seizures.[98-101] Tiagabine overdose can provoke status epilepticus, even in patients without an underlying seizure disorder.[102-105] Other signs seen in tiagabine overdose include myoclonus, muscular rigidity, and delirium.[98] Recovery usually occurs in about 24 hours.

TOPIRAMATE

Topiramate inhibits γ-aminobutyric acid receptors in addition to affecting sodium channels in the brain. Topiramate has a half-life of 20 to 30 hours and possesses drug interactions with other anticonvulsants—phenytoin, valproate, carbamazepine, phenobarbital, and primidone—as well as with oral contraceptives.[56,57] Adverse effects observed during therapeutic use include promotion of renal stone formation and glaucoma. In overdose, topiramate can produce somnolence, vertigo, agitation, and mydriasis.[106-108] Seizures and status epilepticus have been reported.[109,110] **A unique aspect of topiramate overdose is the production of a non-anion gap metabolic acidosis.**[111-113] The cause is inhibition of renal carbonic anhydrase, and because of the long half-life of topiramate, metabolic acidosis can last up to 7 days. However, this effect is completely reversible, and no permanent sequelae have been seen.

VIGABATRIN

Vigabatrin is a structural analog of γ-aminobutyric acid that increases brain concentrations of this neurotransmitter. Vigabatrin has a half-life of 5 to 7 hours and has a modest drug interaction with phenytoin.[56,57,114] During chronic therapy, vigabatrin may worsen mood and exacerbate psychosis. Sedation, headache, and weight gain are common side effects. After acute overdose, drowsiness, unconsciousness, and coma are described in the majority of cases.[115]

ZONISAMIDE

Zonisamide inhibits voltage-sensitive sodium channels in CNS neurons.[116] Zonisamide has a long half-life, 50 to 70 hours, and possesses drug interactions with most of the first-generation antiepileptics, including phenytoin, valproate, carbamazepine, phenobarbital, and primidone.[56,57] Serious adverse effects during therapeutic use include the promotion of renal stone formation and a drug-induced rash. Isolated zonisamide overdose is associated with lethargy.[117,118] A death ascribed to zonisamide overdose was actually a mixed ingestion that included mirtazapine, diphenhydramine, and caffeine.[119]

CHAPTER 198

Iron

Stephanie H. Hernandez
Lewis S. Nelson

INTRODUCTION

Iron supplements are widely available, particularly in homes with small children and young women. The attractiveness of the bright color and sugar coating of the tablets and their initial distribution in non–child-resistant vials made children susceptible to ingestion. The 1997 Federal requirement that all iron-containing pharmaceuticals containing more than 30 milligrams of elemental iron be distributed only in blister packs reduced the reported incidence of iron ingestion and deaths in young children.[1,2] This requirement was removed in 2003, but blister packs remain in common use along with child-resistant bottles, and serious iron poisonings in young children have remained low.[2] Women of childbearing age are at risk for intentional iron overdose due to the availability of iron and increased stress during pregnancy and the postnatal period.[3] Children with inadvertent overdoses[4,5] and adults with intentional overdose[6] are at risk of serious toxicity or death.

PHARMACOLOGY

Total-body iron store averages about 4 grams in adults; the range is between 2 and 6 grams, with less iron in women than in men. About two thirds of the body's iron is incorporated into hemoglobin, and the remainder is found in other iron-containing proteins such as myoglobin, cytochromes, and other enzymes and cofactors, or is stored as ferritin. The recommended daily intake of iron is about 8 milligrams for boys, adult men, and nonmenstruating women; 18 milligrams for menstruating women; and 27 milligrams for pregnant females.[7] Because excess iron is toxic, the body uses several mechanisms to maintain iron homeostasis: serum protein binding, intracellular storage, and, most importantly, regulation of GI tract absorption.[8]

The oral bioavailability of iron depends on the formulation ingested. Inorganic iron has <10% bioavailability, with ferrous iron (Fe^{2+}) better absorbed than ferric iron (Fe^{3+}). Common ionic formulations include ferrous chloride, ferrous fumarate, ferrous gluconate, ferrous lactate, and ferrous sulfate (**Table 198-1**). Nonionic formulations include carbonyl iron and iron polysaccharide (iron dextran). Most dietary iron is in the ferric form and chelated to the heme moiety. Following ingestion, the ferric ion is separated from heme and reduced to ferrous iron by a brush border ferrireductase. Chelated iron, such as that found in meat, is more readily absorbed than the iron in ionic preparations. Commercially available formulations of iron chelated with amino acids (e.g., glycinate) mimic the benefits of dietary meat for iron absorption (Table 198-1).

Ferrous iron is transported into enterocytes by a membrane proton-coupled metal transporter.[7] Within the enterocyte, ferrous iron is oxidized to ferric iron. Transferrin, a serum protein, serves as a carrier and moves ferric iron from the enterocytes into the circulation and transports iron through the body. The serum total iron-binding capacity assay primarily measures the amount of serum transferrin and is generally two to three times the normal serum iron concentration (50 to 170 micrograms/dL or 9 to 30 micromol/L). Iron is stored within the body in the form of ferritin, a large intracellular storage protein that can reversibly bind as many as 4500 molecules of iron. Ferritin can also be incorporated by phagolysosomes to form hemosiderin granules. In adults, about 0.5 to 1 gram of elemental iron is stored as ferritin and hemosiderin, primarily in the bone marrow, spleen, and liver. In iron deficiency, iron is mobilized from ferritin and transported via transferrin to the hematopoietic cells in the spleen and bone marrow, where it is incorporated into appropriate molecules.[8] Under normal conditions, unbound iron, or free iron, does not exist within the body, and essentially all circulating plasma iron is normally bound to transferrin.

There is no physiologic mechanism for removal of iron once it has entered the body.[7] Regulation of GI iron uptake and limitation of absorption by sloughing of mucosal cell containing surplus iron are the principal mechanisms for maintaining physiologic iron concentrations.[7]

TABLE 198-1 Iron Formulations and Elemental Iron Composition

	Iron Formulation	Elemental Iron Composition
Ionic	Ferrous fumarate (PO)	33%
	Ferrous chloride (PO)	28%
	Ferrous sulfate (PO)	20%
	Ferrous lactate (PO)	19%
	Ferrous gluconate (PO)	12%
	Ferrous gluconate (IV)	1.25%
Nonionic	Carbonyl iron (PO)	98%
	Iron polysaccharide (PO)	46%
	Ferric hydroxide dextran (IV)	10% or 20%
	Iron sucrose (IV)	2%
Chelated	Ferrous bisglycinate (PO)	20%
	Iron glycinate (PO)	27%

Example: A 325-milligram ferrous sulfate tablet is 20% elemental iron and contains 65 milligrams of elemental iron per tablet. Iron sucrose is a 2% elemental iron solution and contains 20 milligrams of elemental iron per 1 mL.

PATHOPHYSIOLOGY

Iron is a potent catalyst for the production of oxidants such as free radicals.[9] Through this mechanism, iron is a direct GI tract irritant and causes vomiting, diarrhea, abdominal pain, mucosal ulceration, and bleeding soon after a significant ingestion. As the mucosal surface is injured, the regulatory enterocyte barrier is compromised, and free iron passes unimpeded into the blood, becoming systemically available.

Free iron disrupts critical cellular processes and induces acidosis and widespread organ toxicity. It enters the mitochondria, where it inhibits oxidative phosphorylation by disrupting the electron transport chain, which results in metabolic acidosis with an elevated lactate. Production of toxic hydroxyl radicals, induction of membrane lipid peroxidation, liberation of hydrogen ions from reduction of ferrous iron, and hypotension all contribute to the metabolic acidosis seen with acute iron toxicity. Hepatotoxicity occurs as the portal blood supply delivers a large amount of iron to the liver. In addition, coagulopathy unrelated to hepatotoxicity may occur through inhibition of thrombin formation and the effect of thrombin on fibrinogen. Myocardial and vascular dysfunction result from vasodilation, negative ionotropic effect, and direct myocardial iron deposition.

TOXICITY

The amount of ingested elemental iron correlates with the potential for toxicity (**Table 198-2**). Toxic effects are reported after oral doses as low as 10 or 20 milligrams/kg of elemental iron. **In general, moderate toxicity occurs at doses of 20 to 60 milligrams/kg of elemental iron, and**

TABLE 198-2 Predicted Toxicity of Iron Ingestion

Predicted Clinical Effects	Elemental Iron Dose*	Serum Iron Concentration†
Nontoxic or mild GI symptoms	<20 milligrams/kg	<300 micrograms/dL (<54 micromol/L)
Expected significant GI symptoms and potential for systemic toxicity	20–60 milligrams/kg	300–500 micrograms/dL (54–90 micromol/L)
Moderate to severe systemic toxicity	>60 milligrams/kg	>500 micrograms/dL (>90 micromol/L)
Severe systemic toxicity and increased morbidity		>1000 micrograms/dL (>180 micromol/L)

*Elemental iron dose by history.

†Serum iron concentration obtained within 4–6 h of ingestion.

severe toxicity can be expected following ingestion of >60 milligrams/kg of elemental iron.[6] The most commonly prescribed formulation, a ferrous sulfate 325-milligram tablet, contains 65 milligrams of elemental iron, and approximately 20 to 35 tablets would be expected to produce moderate toxicity after an acute ingestion in an adult. Pediatric multivitamins typically contain 10 to 18 milligrams of elemental iron per tablet, and this reduced amount is associated with a near absence of fatalities after ingestion of iron-containing pediatric multivitamins in children compared with adult iron supplements.[10] Ferric chloride poisoning can occur with occupational inhalation, accidental ingestion through mislabeling, and suicidal ingestion.[11] Ingestion of commercially available chemical hand warmers, containing 95 to 120 grams of reduced elemental iron (not an iron salt), may cause corrosive injury of the esophagus and stomach[12] and result in significant iron absorption with potential toxicity.[13]

Exceptions to the correlation of ingested dose and toxicity include chelated iron and carbonyl iron. Despite their increased iron content, chelated sources of supplemental iron are less toxic than nonchelated iron in overdose, because the ligand sterically limits the iron from participating in redox reactions.[14] Similarly, carbonyl iron is a nonionic iron molecule that does not participate in redox reactions, and the limited experience with overdose of carbonyl iron suggests a lower incidence of toxicity compared with ingestion of an equivalent amount of ionic iron.[15]

CLINICAL FEATURES

Five stages of clinical toxicity are traditionally described, although in more practical terms, acute iron toxicity can be considered to manifest in two clinical stages: local GI tract toxicity and systemic toxicity.

Stage 1 of iron poisoning is characterized by abdominal pain, vomiting, and diarrhea.[16] Iron is directly irritating and corrosive to the GI tract and typically induces vomiting within the first few hours following ingestion. Vomiting is the clinical sign most consistently associated with acute iron toxicity. Patients with symptoms of gastric irritation may either recover over several hours or progress to systemic toxicity. **The absence of GI symptoms within 6 hours of ingestion essentially excludes a significant iron ingestion.**

Stage 2, or the "latent" stage, does not always occur. If present, this stage is a 6- to 24-hour interval following ingestion during which GI symptoms may resolve and falsely reassure the patient and physician. However, this is not a truly quiescent phase. Patients with significant toxicity have ongoing clinical illness and progressive systemic deterioration because of volume loss and worsening metabolic acidosis, despite the absence of GI symptoms. Alternatively, the resolution of GI findings may signal the end of mild poisoning, and in such a circumstance, the results of the patient's laboratory studies should be normal.

Stage 3 is characterized by systemic toxicity from iron-induced disruption of cellular metabolism with resultant shock and lactic acidosis. Iron-induced coagulopathy may worsen bleeding and hypovolemia. The coagulopathy may be biphasic, with prolonged prothrombin time and partial thromboplastin time within the first 24 hours. This initial coagulopathy appears to be reversible with chelation therapy, because it is free iron that initially interferes with the activity of factors in the coagulation cascade. Subsequent coagulopathy is from iron-induced hepatic injury that reduced coagulation factor production. During stage 3, renal failure, cardiomyopathy, and failure of other critical organ systems may also occur.

Stage 4, the hepatic stage, develops 2 to 5 days following ingestion.[6,17] It results from iron uptake by the reticuloendothelial system with local lipid peroxidation; it manifests as elevation of aminotransferase levels and may progress to hepatic failure.

Stage 5 refers to delayed sequelae, including gastric outlet obstruction secondary to the corrosive effects of iron on the pyloric mucosa. Delayed sequelae are rare and occur 4 to 6 weeks after ingestion.[16]

DIAGNOSIS

LABORATORY TESTING

Laboratory tests should include CBC, determination of serum electrolyte levels, renal and liver function studies, coagulation function tests, serum glucose, and serum iron levels, with the understanding that these results are to assess the overall condition of the patient, because **iron toxicity is largely a clinical diagnosis.**

Arterial blood gas analysis and serum lactate determination are usually unnecessary in mild cases, because determination of serum electrolyte levels (anion gap evaluation) usually yields all the important information. However, in patients with moderate to severe toxicity or in those with respiratory compromise, arterial blood gas results yield useful information regarding the patient's acid-base status. With moderate to severe ingestions, the blood bank should perform blood typing and screening in anticipation of potential need.

Interpret serum iron levels to assess toxicity and direct management with caution. **In general, serum iron levels measured within 4 to 6 hours after an acute ingestion correlate with the severity of toxicity** (Table 198-2), **but low serum iron levels do not necessarily mean absence of toxicity**. Serum iron levels may be low because of variable times to peak level following ingestions of different iron preparations, and treatment with deferoxamine can artificially lower serum iron levels. **Serum total iron-binding capacity has little value in the assessment of iron-poisoned patients.** It becomes falsely elevated in the presence of elevated serum iron levels or deferoxamine, and significant organ damage occurs despite exceeding the serum iron level.

IMAGING

Standard ferrous sulfate tablets and reduced iron are radiopaque and frequently visible on routine radiographs,[12,13] and this may help guide GI decontamination when present. However, many iron preparations are not routinely detected, including pediatric chewable and liquid preparations, and absence of radiopaque material on radiographs does not exclude iron ingestion.[2]

TREATMENT

Iron poisoning is a clinical diagnosis. Signs and symptoms consistent with iron poisoning should guide treatment, rather than serum iron concentrations alone (**Figure 198-1**). Patients who are asymptomatic on ED arrival, have not ingested a potentially toxic amount, and have normal findings on physical examination can be observed and do not require specific medical treatment. Patients who vomit once or twice from the gastric irritant effects of iron but who are otherwise asymptomatic can also be observed and may require no specific treatment.

Patients with clinical toxicity should first be stabilized with attention to airway, breathing, and circulation, after which GI decontamination and chelation therapy with deferoxamine may proceed.[2,18] Antiemetics such as metoclopramide or ondansetron should be used for repetitive vomiting. Patients with persistent vomiting and abnormal vital sign values or other signs of poor perfusion or shock should undergo aggressive fluid resuscitation and treatment with deferoxamine. Coagulopathy should be treated with parenteral vitamin K_1 and/or fresh frozen plasma, as indicated. Significant blood loss may require transfusion.

GI DECONTAMINATION

Do not use ipecac syrup because it may obscure the initial signs of clinical toxicity and is not proven to be more effective at gastric emptying than is iron-induced vomiting.[19] **Do not give activated charcoal, cathartics, oral sodium bicarbonate, or phosphosoda.** Activated charcoal does not adsorb significant amounts of iron in an overdose to prevent toxicity, and its use may complicate endoscopy if that becomes necessary.[19] Cathartics should not be given. Orogastric lavage may not be effective if the ingested tablets are large or if several hours have elapsed since ingestion, but it may be useful in rare cases if performed shortly after large ingestion, prior to significant vomiting, or if a modified-release formulation was ingested.[2,20] There are no data to support the efficacy of oral sodium bicarbonate or phosphosoda in forming insoluble iron salts and preventing absorption.[2,19]

Radiopaque tablets visible on radiography indicate potential for progressive toxicity and can guide decontamination measures

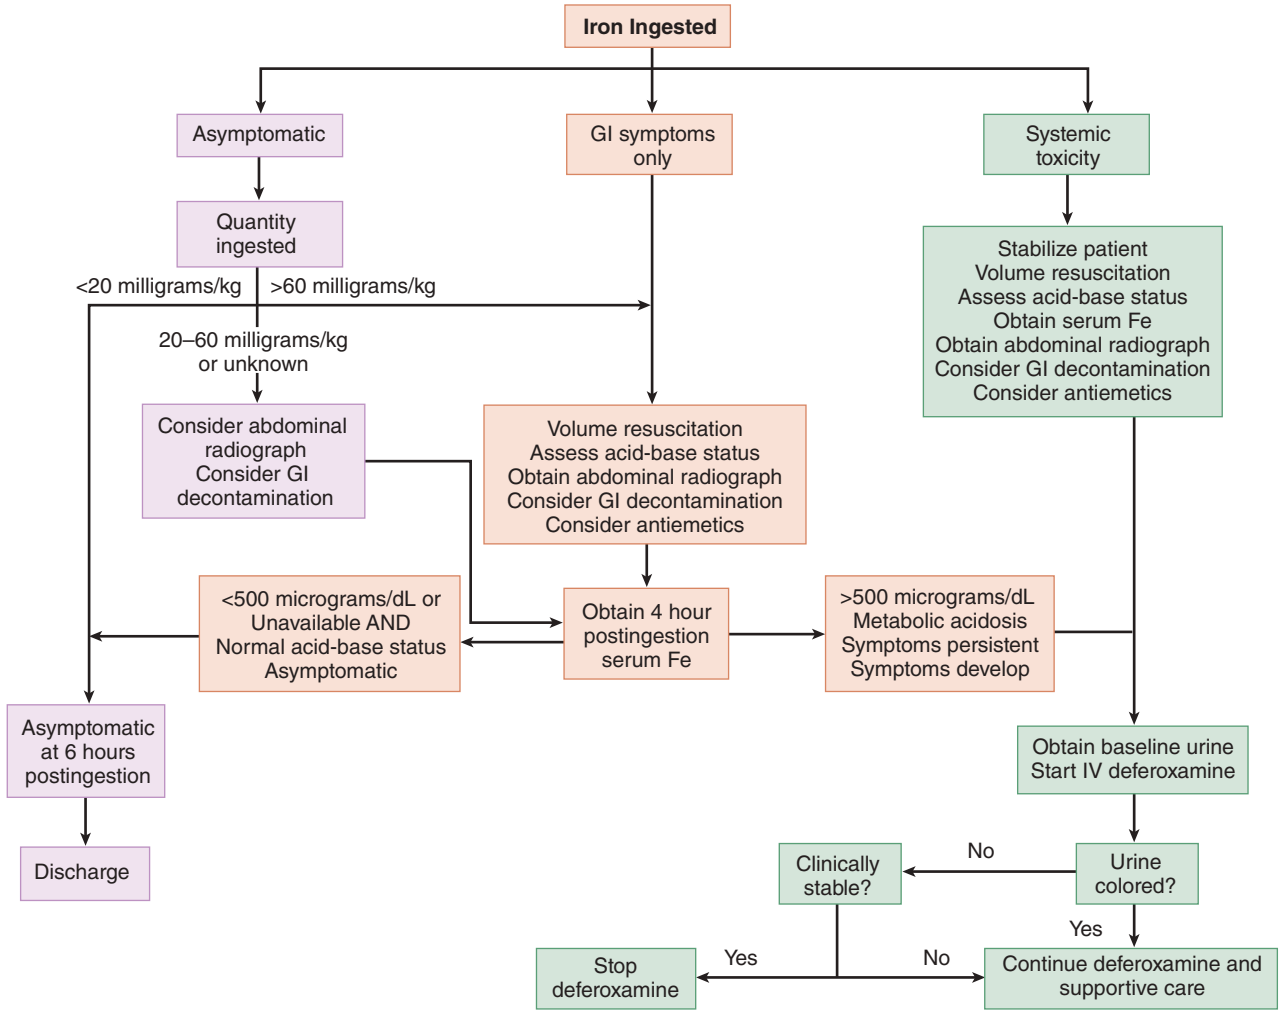

FIGURE 198-1. Algorithm for clinical management of iron ingestion.

(**Figure 198-2**). Whole-bowel irrigation with a polyethylene glycol solution is effective in children with large iron ingestions.[2,21] Administration of 250 to 500 mL/h in children or 2 L/h in adults by nasogastric tube may clear the GI tract of iron pills before absorption can occur.[21] Endoscopy can remove large iron loads or an iron-containing gastric bezoar.[22,23] Laparoscopic gastrotomy may be a rare option for removal of an iron-containing gastric bezoar in profoundly ill patients when other measures are unsuccessful or impractical.[24]

DEFEROXAMINE

Deferoxamine is chelating agent derived from *Streptomyces pilosus* used to treat iron toxicity. Deferoxamine binds free iron, iron from plasma, and iron from inside cells and mitochondria, but not iron bound to organic molecules. Upon binding, it forms the complex ferrioxamine, which is renally excreted. Deferoxamine can be safely administered to children and pregnant women.[3] Although deferoxamine binds a small amount of iron (9 milligrams of elemental iron for each 100 milligrams of deferoxamine) and thus chelates only a small fraction of the total amount of iron ingested, removing this small but critical amount of iron often proves clinically effective in restoring cellular function. Deferoxamine may work by other mechanisms in addition to binding excess iron, and complete binding of ingested iron is not the goal of therapy.

Administration of deferoxamine is indicated in the iron-poisoned patient with systemic toxicity, persistent emesis, metabolic acidosis, progressive symptoms, or a serum iron level predictive of moderate to severe toxicity (Figure 198-1).[2,18] The manufacturer recommends IM administration for all patients not in shock,[25] but most toxicologists advise IV administration rather than IM administration because of the unreliability of IM absorption and enhanced iron excretion following IV administration.[2,18]

The initial deferoxamine adult dose is 1000 milligrams (children 50 milligrams/kg) IV. Begin the infusion slowly, starting at 5 milligrams/kg per hour to avoid producing a rate-related drop in blood pressure. Aggressive volume resuscitation may be required in the volume-depleted, hypotensive, iron-toxic patient who is in need of deferoxamine. **Hypotension is not a contraindication to IV deferoxamine administration.**

The infusion rate of deferoxamine IV can be increased up to 15 milligrams/kg per hour as tolerated. The recommended amount of deferoxamine for an acute iron overdose is a total of 360 milligrams/kg or 6 grams in an adult during the first 24 hours, typically ordered as 500-milligram infusions over 4 to 8 hours after the initial 1000-milligram dose.[18,25] Amounts larger than this are associated with complications, including mucormycosis, renal insufficiency or failure,[26] pulmonary toxicity,[27] and sepsis from *Yersinia enterocolitica*, which may be related to duration of therapy.

As ferrioxamine is excreted, the urine color changes to what is classically called "vin rosé" but is more typically a brown or rusty hue.[28] Theoretically, the disappearance of the "vin rosé" color means that the patient no longer has significant toxicity because there is no more free iron available to be complexed with deferoxamine and excreted. False-negative results, color-change latency, and difficulty in visualizing a color change can limit the utility of this test.[18]

There is uncertainty regarding the duration of deferoxamine therapy.[2,18,25] Recommended endpoints include clinical recovery and normal iron levels, measurement of normal iron-to-creatinine ratios, and clinical recovery with normal iron level in conjunction with normal urine color. **Clinical**

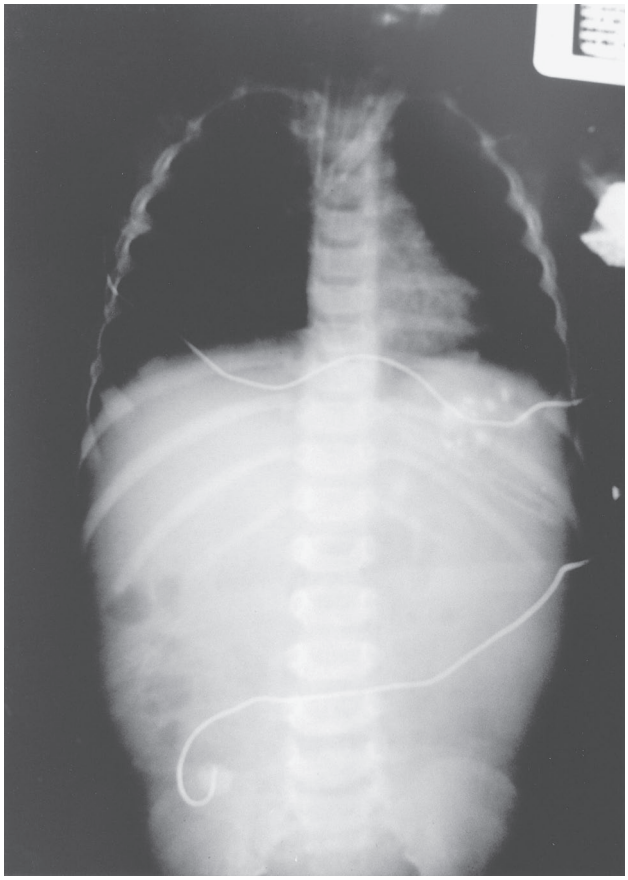

FIGURE 198-2. A 17-month-old boy came to the hospital with lethargy and hematemesis following a large ingestion of iron supplement pills. [Reproduced with permission from Nelson LS, Lewin NA, Howland MA, Hoffman RS, Goldfrank LR, Flomenbaum NE: *Goldfrank's Toxicologic Emergencies*, 9th ed. © 2011 by McGraw-Hill, Inc., New York.]

recovery of the patient is probably the most important factor guiding the decision to terminate therapy because measured iron levels are artificially depressed by the presence of deferoxamine and urine color change can be unreliable. Continue deferoxamine therapy in patients who continue to exhibit severe iron toxicity after 24 hours of treatment, using a decreased rate to avoid the associated risks mentioned earlier.

OTHER THERAPIES

Oral iron chelators—**deferiprone** and **deferasirox**—reduce iron absorption when administered simultaneously or within 1 hour of iron ingestion.[29] However, there is no evidence of benefit in human overdoses, and oral chelation therapy would theoretically be of use only when taken promptly after the iron ingestion; thus their use is limited by the time to presentation for treatment and the significant vomiting expected with clinical iron toxicity. **Oral iron chelating agents should NOT replace intravenous deferoxamine when chelation is indicated in clinical iron toxicity.**

Although hemodialysis and hemofiltration do not remove iron, such treatment may be necessary to remove the deferoxamine–iron complex in patients with renal failure who are unable to excrete the complex in their urine.[18,30,31] Severe iron poisoning can be treated with exchange transfusion in addition to deferoxamine therapy.[32]

DISPOSITION AND FOLLOW-UP

Patients who have not ingested a potentially toxic amount of iron, who remain asymptomatic (other than vomiting once or twice from the gastric irritant effects of iron), and who have normal findings on physical examination for a period of 6 hours can be safely discharged or transferred for appropriate mental health evaluation. Patients who receive deferoxamine therapy should be admitted to the intensive care unit. The regional poison control center should be contacted for both data collection purposes and assistance with management.

CHAPTER 199

Hydrocarbons and Volatile Substances

C. William Heise
Frank LoVecchio

INTRODUCTION

Hydrocarbons are a diverse group of organic compounds consisting primarily of carbon and hydrogen atoms. The two basic forms of hydrocarbons are aliphatic (straight- or branched-chain carbon arrangement) or aromatic (carbon arranged in a ring). Hydrocarbons are in many household and occupational products (**Table 199-1**). While all hydrocarbons can be toxic, aromatic and halogenated hydrocarbons are

TABLE 199-1 Common Products That Contain Hydrocarbons

Hydrocarbon (state at room temperature)	Commercial Use
Aliphatic – linear structure, toxicity varies depending on volatility	
Gasoline (petrol) – liquid	Motor fuel
Kerosene (paraffin) – liquid	Stove and lamp fuel
Mineral seal oil – liquid	Furniture polish
Petroleum ether – liquid	Industrial solvent
Diesel fuel – liquid	Motor fuel
n-Hexane – liquid	Plastic cement, rubber cement
Methane, butane, propane, and ethane – gas	Fuel
Mineral spirits (white spirits) – liquid	Solvent, paint thinner
Turpentine – liquid	Solvent, paint thinner
Mineral oil (liquid paraffin) – liquid	Lubricant, laxative
Paraffin wax – solid	Industrial uses, candles
Petroleum jelly (petrolatum or soft paraffin) – solid	Skin lotion
Aromatic – ring structure, high toxicity	
Benzene – liquid	Chemical intermediate, gasoline (small amount, 0.8% on average)
Toluene – liquid	Airplane glue, plastic cement, acrylic paint
Xylene – liquid	Solvent, cleaning agent, degreaser
Halogenated – high toxicity	
Carbon tetrachloride – liquid	Solvent, refrigerant, aerosol propellant
Chloroform – liquid	Solvent, chemical intermediate
Methylene chloride – liquid	Paint stripper, varnish remover, aerosol paint, degreaser
Trichloroethylene – liquid	Spot remover, degreaser, typewriter correction fluid
Trichloroethane – liquid	Spot remover, degreaser, typewriter correction fluid
Tetrachloroethylene (perchloroethylene) – liquid	Dry cleaning agent, degreaser

TABLE 199-2 Commonly Abused Volatile Substances

Product	Volatile Agent
Acrylic spray paint	Toluene
Adhesives, glue	Toluene, trichloroethylene
Aerosol propellants	Propellants and butane
Cigarette lighter refills	Butane
Degreasing agents	Trichloroethylene
Dry cleaning agents	Tetrachloroethylene
Fire extinguishers	Bromochlorodifluoromethane
Inhalational anesthetics	Nitrous oxide, halothane
Lighter fluid	Naphtha
Motor fuel	Gasoline (petrol)
Nitrites ("poppers")	Isobutyl nitrite, amyl nitrite
Paint stripper	Methylene chloride
Plastic modeling cement	Methyl ethyl ketone, toluene
Spot removers	Trichloroethylene, trichloroethane
Typewriter correction fluid	Trichloroethane, trichloroethylene

associated with the most severe systemic toxicity. Volatile agents are associated with the highest aspiration risk. Identification of the specific hydrocarbon or class can help anticipate specific potential toxicity and guide management.

Chain length and branching determine the phase of the hydrocarbon at room temperature. Short-chain aliphatic compounds (up to 4 carbons), such as methane, ethane, propane, and butane, are gases; intermediate-chain aliphatic compounds (5 to 19 carbons), such as solvents, lamp oil, lighter fluid, and gasoline, are liquid; and long-chain aliphatic compounds (>19 carbons), such as waxes, are solids. Liquid hydrocarbons account for most exposures seen in the ED.[1]

Most hydrocarbon exposures occur as liquid ingestions or inhalations and usually have a benign clinical course.[1,2] Serious toxicity and deaths associated with hydrocarbon exposure are usually due to ingestions rather than inhalation. Symptoms and signs of pulmonary injury develop in up to 50% of the children who ingest hydrocarbons,[3,4] and hydrocarbon aspiration can produce acute respiratory distress syndrome.[5] Suicidal injection of gasoline or kerosene with severe multiorgan toxicity has been reported.[6,7]

Volatile substances, usually hydrocarbon solvents contained in household or commercial products, can be inhaled for their euphoric effects (**Table 199-2**).[8] Abusers are typically teenagers and younger adults, especially those in lower socioeconomic groups.[9] Inhalation occurs by three different methods: (1) in "huffing," the individual soaks a rag with the inhalant and then places it over the mouth and nose; (2) in "bagging," the individual puts the hydrocarbon in a bag (usually a plastic bag) and repeatedly inhales deeply from the bag; and (3) in "sniffing," the hydrocarbon is directly inhaled via the nostrils.[10] In addition to causing deaths, abuse of volatile agents is associated with crimes such as homicide, sexual assault, and child abuse.[11] The most commonly abused volatile hydrocarbons are paints, solvents, and gasoline.

PATHOPHYSIOLOGY

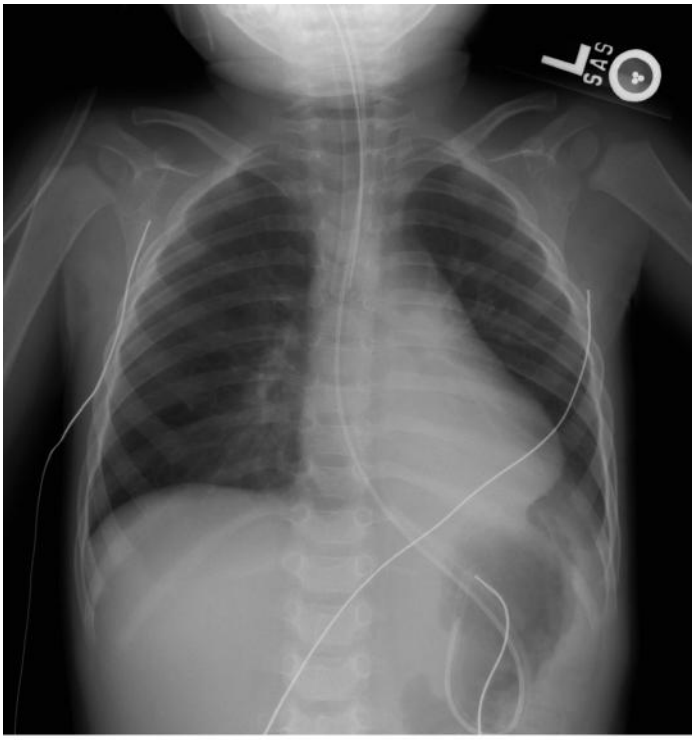
The toxic potential of hydrocarbons depends on their physical characteristics (viscosity, surface tension, and volatility), chemical characteristics (aliphatic, aromatic, or halogenated), presence of toxic additives (pesticides or heavy metals), routes of exposure, concentration, and dose. The physical characteristics contribute the most to aspiration risk.

Viscosity refers to the general "thickness" of a liquid; fluids with a lower viscosity flow more easily than ones with high viscosity. Viscosity is measured in Saybolt universal seconds (SUS); fluids such as gasoline, kerosene, mineral seal oil, and turpentine have low viscosity (<60 SUS), whereas diesel fuel, grease, mineral oil, paraffin wax, and petroleum jelly have high viscosity (>100 SUS).[12] Surface tension refers to the property where liquid molecules tend to cohere to each other. Liquids with high surface tension in contact with a solid surface tend to ball up, creating the smallest surface area rather than spreading out. Volatility refers to the ability of the liquid or solid to vaporize and is inversely related to the boiling point; highly volatile liquids have a low boiling point. **Ingestion of liquids with low viscosity and surface tension and high volatility increases the risk for aspiration because these substance can flow easily, spreading out widely on the oral mucosa, and vaporize at body temperature. Inhalation of aromatic hydrocarbons or halogenated hydrocarbons can result in systemic absorption and the potential for significant toxicity.**

CLINICAL FEATURES

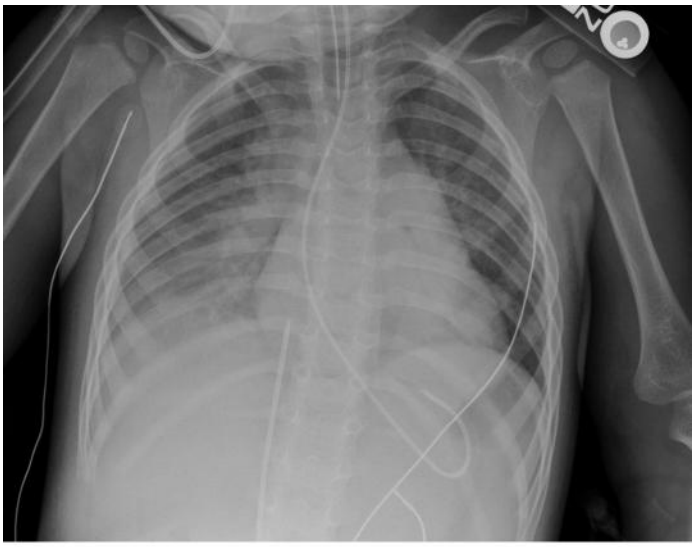
Ingestion or aspiration of hydrocarbons mainly impairs the pulmonary system, but depending on the specific compound, the central nervous, peripheral nervous, GI, cardiovascular, renal, hepatic, dermal, and/or hematologic systems may be affected (**Table 199-3**).[13]

PULMONARY TOXICITY



Hydrocarbon aspiration causes chemical pneumonitis by direct toxicity to the pulmonary parenchyma and alteration of surfactant function. Destruction of alveolar and capillary membranes results in increased vascular permeability and edema. The clinical manifestations of pulmonary aspiration are usually apparent soon after exposure from irritation of the oral mucosa and tracheobronchial tree. Symptoms include coughing, choking, gasping, dyspnea, and burning of the mouth. Patients with these symptoms should be assumed to have aspirated.

Signs include tachypnea, grunting respirations, wheezing, or retractions depending on the severity of aspiration. An odor of the hydrocarbon may be noted on the patient's breath. Hyperthermia of ≥39°C (≥102.2°F) is likely and may occur initially or 6 to 8 hours after exposure. The fever is usually an inflammatory response due to pneumonitis. Necrotizing pneumonitis and hemorrhagic pulmonary edema may develop within minutes to hours in patients with severe aspiration. In most fatalities, these complications occur rapidly. With less severe damage, symptoms usually subside within 2 to 5 days, except in the case of pneumatoceles and lipoid pneumonias, the symptoms of which may persist for weeks to months.



Although in most patients with clinically significant aspiration chest radiographic results eventually are abnormal, the time course of radiographic changes varies, and correlation with physical examination findings may be poor. Changes may be seen as early as 30 minutes after aspiration, but **the initial radiograph in a symptomatic patient may be deceptively clear. Conversely, an asymptomatic patient can still have abnormal chest radiographic findings later during the clinical course.**

TABLE 199-3 Clinical Manifestations of Hydrocarbon Exposure

System	Clinical Manifestations
Pulmonary	Tachypnea, grunting respirations, wheezing, retractions
Cardiac	Ventricular dysrhythmias (may occur after exposure to halogenated hydrocarbons and aromatic hydrocarbons)
Central nervous	Slurred speech, ataxia, lethargy, coma
Peripheral nervous	Numbness and paresthesias in the extremities
GI and hepatic	Nausea, vomiting, abdominal pain, loss of appetite (mostly with halogenated hydrocarbons)
Renal and metabolic	Muscle weakness or paralysis secondary to hypokalemia in patients who abuse toluene
Hematologic	Lethargy (anemia), shortness of breath (anemia), neurologic depression/syncope (carbon monoxide from methylene chloride), cyanosis (methemoglobinemia from amine-containing hydrocarbons)
Dermal	Local erythema, papules, vesicles, generalized scarlatiniform eruption, exfoliative dermatitis, "huffer's rash," cellulitis

A

B

FIGURE 199-1. Two chest radiographs of a child who aspirated lamp oil and developed aspiration pneumonitis. **A.** Day 1: intubated, left lower lobe infiltrates. **B.** Day 3: intubated, worsening perihilar and bibasilar patchy infiltrates and new right small pleural effusion.

Radiographic changes usually appear by 2 to 6 hours and are almost always present by 24 hours, if they are to occur (**Figure 199-1**). The most common radiologic finding is bilateral infiltrates at the bases with multilobar involvement more common than single-lobe involvement and right-sided involvement more common than left-sided involvement.[14-16] Hydrocarbon-induced aspiration pneumonitis can lead to lung necrosis and the creation of a pneumatocele.[17]

CARDIAC TOXICITY

Life-threatening dysrhythmias, such as ventricular tachycardia and ventricular fibrillation, may occur with systemic absorption. Dysrhythmias occur most commonly after exposure to halogenated hydrocarbons and aromatic hydrocarbons. Exposure to short-chain aliphatic hydrocarbons occasionally causes dysrhythmias (ventricular fibrillation).[10] The most worrisome acute complication found in solvent abusers is "**sudden sniffing death syndrome**" and occurs within minutes of exposure.[8] The mechanism of toxicity is believed to be catecholamine sensitization of the heart by hydrocarbons (especially halogenated hydrocarbons), resulting in ventricular dysrhythmias.[8,10,18] Other mechanisms for sudden death include simple asphyxia, respiratory depression, and vagal inhibition. Ventricular akinesia and polymorphic ventricular dysrhythmias have also been described after overdose of chloral hydrate (a halogenated aliphatic hydrocarbon).[18]

CNS TOXICITY

CNS effects, primarily depression of consciousness, result from: (1) a direct toxic response to the systemic absorption of the hydrocarbon, (2) an indirect result of severe hypoxia secondary to aspiration, (3) simple asphyxiation due to the displacement of oxygen by the volatile hydrocarbon, and/or (4) volatile substance abuse with a plastic bag that prevents adequate oxygenation. Systemic effects occur through GI absorption, the inhalation of highly volatile petroleum distillates, or direct dermal penetration.

Signs of neurologic toxicity include slurred speech, ataxia, lethargy, and coma.[13] Although hydrocarbons are central neurologic depressants, they often have an initial excitatory effect manifested as hallucinations, tremor, agitation, and convulsions. Individuals who abuse volatile solvents or workers who experience long-term hydrocarbon exposure may present to the ED complaining of recurrent headaches, ataxia, emotional lability, cognitive impairment, or psychomotor impairment.

PERIPHERAL NERVOUS SYSTEM TOXICITY

Exposure to *n*-hexane, methyl *n*-butyl ketone, and other six-carbon aliphatic hydrocarbons is associated with the development of a characteristic peripheral polyneuropathy caused by demyelinization and retrograde axonal degeneration.[19] Onset of symptoms may be delayed for weeks, and toxicity is attributed to a metabolite, 2,5-hexanedione, produced by the cytochrome P-450–mediated biotransformation of the parent compounds. This neurotoxic metabolite is thought to inhibit glutaraldehyde-3-phosphate dehydrogenase, which supplies energy for axonal transport.

Clinically, the patient may complain of chronic numbness and paresthesias in the extremities. The key component in making the diagnosis is a history of exposure to solvents, usually through occupations and hobbies. The compound *n*-hexane is found in solvents used in the printing, shoemaking, textile, and furniture industries, as well as in gasoline, quick-drying glues, and rubber cement.[20]

GI AND HEPATIC TOXICITIES

Most hydrocarbons are GI irritants. Vomiting, which occurs in many patients with aliphatic hydrocarbon ingestions, increases the risk of pulmonary aspiration. Gastric perforation has been reported after accidental ingestion of chlorofluorocarbons.[21]

Hepatic damage resulting from ingestion of halogenated hydrocarbons is well described.[22,23] **Chlorinated hydrocarbons, such as carbon tetrachloride, methylene chloride, trichloroethylene, and tetrachloroethylene, are especially hepatotoxic.** For example, carbon tetrachloride causes centrilobular liver necrosis similar to acetaminophen toxicity. Free radical metabolites of these agents that cause lipid peroxidation are apparently responsible for hepatocellular destruction. The time course of hepatic dysfunction with acute exposures appears similar to that of acetaminophen hepatotoxicity—within 24 to 48 hours after ingestion.

Clinically, patients may come to the ED complaining of nausea, vomiting, abdominal pain, or loss of appetite. Depending on the severity, the physical examination may reveal a patient with jaundice, lethargy, and/or abdominal tenderness, especially in the right upper quadrant. Results of serum transaminase tests and other hepatic synthetic function tests may be abnormal within 24 hours after ingestion.

RENAL AND METABOLIC TOXICITIES

Solvent abuse and occupational exposure to hydrocarbons may result in renal dysfunction. **Chlorinated hydrocarbons, such as chloroform,**

carbon tetrachloride, and trichloroethylene, are also nephrotoxic. Toluene, an aromatic hydrocarbon that is commonly abused, may cause renal tubular acidosis in patients who inhale toluene-containing substances.[8,24] The mechanism of toluene-induced renal tubular acidosis is not clear. The typical metabolic profile of renal tubular acidosis is a normal anion gap hyperchloremic acidosis with hypokalemia and a urine pH of >5.5. The metabolites of toluene (hippuric acid and benzoic acid) can be the cause of an elevated anion gap metabolic acidosis.[25]

Clinically, habitual toluene abusers may complain of muscle weakness caused by hypokalemia.[26] The serum potassium level may be so low (<2 mEq/L) that severe weakness develops, occasionally resulting in muscle paralysis. Significant rhabdomyolysis may also result.[27] **Toluene abuse should be considered in individuals (especially young patients) who come to the ED with symptoms similar to hypokalemic periodic paralysis.**[24,26]

HEMATOLOGIC TOXICITY

Hydrocarbon-induced hemolysis rarely occurs after the acute ingestion of gasoline, kerosene, and tetrachloroethylene, and after inhalation of mineral spirits. Exposure to benzene (an aromatic hydrocarbon) is associated with an increased incidence of hematologic disorders, including aplastic anemia, acute myelogenous leukemia, and multiple myeloma.[28] Naphthalene exposure is associated with hemolytic anemia. Delayed methemoglobinemia is associated with occupational exposure to hydrocarbons containing amine functional groups such as aniline (see chapter 207, "Dyshemoglobinemias").[29] Delayed carboxyhemoglobinemia is associated with **methylene chloride** exposure due to its metabolism to carbon monoxide, which takes a few hours.[30] This is unlike ordinary carbon monoxide exposure from exogenous sources in which the maximum carboxyhemoglobin level occurs at the time of the exposure. **Clinically, patients may come to the ED with malaise, headache, dyspnea, or cyanosis depending on the exposure and the severity of the toxicity.**

DERMAL TOXICITY

Dermal toxicity from exposure to hydrocarbons is most often associated with the short-chain aliphatic, aromatic, and halogenated hydrocarbons. These agents act as primary irritants and as sensitizers. Occasionally, highly permeable hydrocarbons can penetrate the skin, resulting in systemic toxicity. Skin findings can range from local erythema, papules, and vesicles to a generalized scarlatiniform eruption and an exfoliative dermatitis (Table 199-3). A "huffer's rash" may be noted over the face of patients who habitually abuse the volatile hydrocarbons.[8] Frostbite of the face may develop during the inhalational abuse of fluorinated agents. A defatting dermatitis, similar to chronic eczematoid dermatitis, may occur.

Cellulitis and sterile abscesses have been associated with the injection of hydrocarbons, and even a small amount of injected hydrocarbon can cause significant injury.[31] Hydrocarbon-induced soft tissue necrosis has recently been seen in patients using "**krokodil**," desomorphine synthesized from codeine with the use of hydrocarbon solvents.[32] Dermal exposure to heated high-viscosity, long-chain aliphatics, such as tar, asphalt, or bitumen, presents a particularly challenging problem because of their association with thermal burns, hyperthermia, and difficulty with decontamination.[33] Tar burns are discussed in the chapter 217, "Chemical Burns."

DIAGNOSIS

Diagnosis of hydrocarbon toxicity incorporates the findings of the history, physical examination, bedside cardiac and pulmonary monitoring, laboratory tests, and chest radiography. Determine the specific hydrocarbon-containing product, because identification can help anticipate specific potential toxicity and guide management. Pulse oximetry is useful to evaluate oxygenation status, and arterial blood gas analysis can be used to assess ventilation and acid-base status. Cardiac rhythm monitoring and an ECG are indicated in symptomatic patients and patients who ingest halogenated hydrocarbons. A chest radiograph is indicated in a symptomatic patient after hydrocarbon aspiration.

There are no specific quantitative hydrocarbon tests in standard use when evaluating suspected hydrocarbon intoxication. A basic metabolic panel is indicated in patients with a history of toluene abuse or in whom electrolyte abnormalities and renal insufficiency are suspected. Obtain hepatic function studies, serum ammonia, and prothrombin time in patients who ingest or inhale halogenated hydrocarbons. A CBC is indicated if anemia, bleeding disorder, hemolysis, or leukemia is considered. Measure carboxyhemoglobin level in patients with exposure to methylene chloride; repeat measurements may be necessary. Determination of methemoglobin level is indicated in patients with exposure to hydrocarbons containing amine functional groups. Abdominal radiographs may show evidence of ingestion of chlorinated hydrocarbons such as carbon tetrachloride or chloroform because of the radiopaque nature of polyhalogenated substances.[22]

An outpatient nerve conduction study and electromyography can be considered in patients who present with chronic numbness and paresthesias in the extremities and who have a history of *n*-hexane exposure.

TREATMENT

Securing the airway and maintaining ventilation are the critical maneuvers in patients who present with respiratory depression and/or significant neurologic depression (**Table 199-4**). Swelling of the lips and tongue due to irritant effect or freeze injuries can complicate airway management. Administer oxygen to correct hypoxia. Inhaled β_2-agonists may also be useful, especially in the setting of bronchospasm, but their role in the treatment of hydrocarbon pneumonitis has not been studied. Positive end-expiratory pressure or continuous positive-pressure airway ventilation may sometimes be required to maintain oxygenation, but may increase the potential for further injury from barotrauma, such as the development of pneumatoceles or pneumothorax. In cases of severe pulmonary aspiration resulting in refractory hypoxemia, treatment

TABLE 199-4 Management of Hydrocarbon Exposures

Airway and breathing	Secure airway. Antidotes: Administer oxygen for carboxyhemoglobinemia and methylene blue for methemoglobinemia. Provide supplemental oxygen. Administer inhaled β_2-agonists. Ventilatory support: Provide positive end-expiratory pressure or continuous positive airway pressure as needed to achieve adequate oxygenation.
Cardiac	Circulation: Administer IV crystalloid fluid for initial volume resuscitation of hypotensive patients. Do not use catecholamines in cases of halogenated hydrocarbon exposure. Consider propranolol, esmolol, or lidocaine for ventricular dysrhythmias induced by halogenated hydrocarbon exposure. Consult the poison control center, toxicologist, and other appropriate specialists as needed.
Decontamination	Dermal: Remove hydrocarbon-soaked clothes, decontaminate skin with soap and water, and decontaminate eyes with saline irrigation. GI: Not indicated. See discussion below.
Other	Laboratory tests: Order CBC, basic metabolic panel, liver function tests (serum transaminase, bilirubin, albumin levels), prothrombin time, partial thromboplastin time, carboxyhemoglobin level, methemoglobin level, and/or radiologic studies as indicated (see text). Correct electrolyte abnormalities. Do not give steroids Administer blood products as needed.

with high-frequency jet ventilation or extracorporeal membrane oxygenation has proved successful according to case reports.[34,35] Surfactant therapy has been used to treat acute lung injury from hydrocarbon aspiration.[36-38]

Treat hypotension with aggressive fluid resuscitation. **Avoid administration of catecholamines such as dopamine, norepinephrine, and epinephrine. Catecholamines may cause dysrhythmias, especially after exposure to halogenated hydrocarbons and aromatic hydrocarbons.** Hydrocarbon-induced dysrhythmias are generally seen shortly after the exposure, especially with inhalational use. Continuous cardiac monitoring should be initiated, and an ECG should be obtained. For hydrocarbon-induced ventricular dysrhythmias, class IA (procainamide) or class III (amiodarone, bretylium, and sotalol) antiarrhythmics should be avoided because of the risk of QT-interval prolongation.[18] Propranolol, esmolol, and lidocaine have been reported to treat these ventricular dysrhythmias successfully.[10,18,39]

There is no benefit to gastric lavage because risks of aspiration far outweigh any theoretical benefits.[40] Activated charcoal does not adsorb hydrocarbons well and poses a risk for vomiting and aspiration, so charcoal is not recommended either. In the rare case where the hydrocarbon was combined with a highly toxic substance, such as a pesticide, or is highly toxic itself, such as an aromatic or halogenated chemical, and ingestion has occurred in the last hour or less, consult with the poison center first, as even in that situation, benefit from gastric lavage is unproven.

There is no clear evidence that corticosteroids are helpful in hydrocarbon-induced pneumonitis.[13] One meta-analysis advocating low-dose steroids for acute lung injury and respiratory distress[41] has been criticized because the patients were not generally treated with current lung-protective ventilation strategies.[42] Antibiotics are not indicated unless there is clinical suspicion of superimposed bacterial pneumonitis.

In dermal exposures, decontamination is preferably done at the scene or before entering the ED to avoid spreading fumes to patient treatment areas. The patient needs to be fully undressed to prevent ongoing contamination from hydrocarbon-soaked clothes. Make sure staff wear protective gloves and aprons to prevent secondary exposure, especially to organophosphate-containing mixtures. Dermal decontamination with soap and cold water, and eye decontamination with saline irrigation should be performed.

DISPOSITION AND FOLLOW-UP

Consult a medical toxicologist or regional poison control center for all symptomatic or asymptomatic exposures to aromatic hydrocarbons or hydrocarbons with toxic additives. In cases of inhalation or aspiration of **nonhalogenated aliphatic hydrocarbons**, asymptomatic patients may be discharged home after about 6 to 8 hours of observation with instructions to return if delayed symptoms develop.

Further observation or hospitalization is required for patients who are symptomatic after hydrocarbon exposure. For pediatric hydrocarbon ingestions, the presence of wheezing, altered consciousness, or tachypnea within 2 hours predicts the need for further treatment.[43] Hospitalization is also recommended for those who ingest hydrocarbons capable of producing delayed complications (e.g., halogenated hydrocarbons causing hepatic toxicity) or hydrocarbons with toxic additives (organophosphates and organic metal compounds). Patients with suicidal intent or with complications of solvent abuse need behavioral health evaluation.

CHAPTER 200

Caustic Ingestions

Nicole C. Bouchard
Wallace A. Carter

INTRODUCTION AND EPIDEMIOLOGY

Caustics are substances that cause both functional and histologic damage on contact with body surfaces. Many household and industrial chemicals have caustic potential. Caustics are broadly classified as alkalis (pH >7) or acids (pH <7). In developed nations, increased education and product regulation (especially of acids) have decreased morbidity and mortality from caustic exposures in both adults and children. However, in underdeveloped parts of the world, exposure to caustics remains a significant problem.[1-4] The challenges to exposure prevention and patient care include relative lack of childproof containers, easy and unregulated access to highly corrosive substances, cultural-specific propensities to ingest caustics in suicide attempts, sheer high volume of cases, delays to care in rural settings, malnutrition, financial resources of hospitals and families to provide the services needed, and poor follow-up.[4] Alkaline ingestions predominate in the developed world,[5] whereas acid ingestions are more common in developing countries.[6]
